Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Anton Pozniak
- 44** Infections of the upper respiratory tract 567
Nicholas A. Francis and Christopher C. Butler

Preface

The first edition of this book was published almost half a century ago. Subsequent editions have generally been published in response to the steady flow of novel antibacterial compounds or the marketing of derivatives of existing classes of agents exhibiting advantages, sometimes questionable, over their parent compound. In producing the ninth edition of this book the rationale has been not so much in response to the availability of new antibacterial compounds, but to capture advances in antiviral and, to a lesser extent, antifungal chemotherapy and also to highlight a number of changing therapeutic approaches to selected infections. For example, the recognition that combination therapy has an expanded role in preventing the emergence of drug resistance; traditionally applied to the treatment of tuberculosis, it is now being used in the management of HIV, hepatitis B and C virus infections and, most notably, malaria among the protozoal infections.

The impact of antibiotic resistance has reached critical levels. Multidrug-resistant pathogens are now commonplace in hospitals and not only affect therapeutic choice, but also, in the seriously ill, can be life threatening. While methicillin-resistant *Staphylococcus aureus* (MRSA) has been taxing healthcare systems and achieved prominence in the media, resistance among Gram-negative bacillary pathogens is probably of considerably greater importance. More specifically, resistance based on extended spectrum β-lactamase production has reached epidemic proportions in some hospitals and has also been recognized, somewhat belatedly, as a cause of much community infection. There are also emerging links with overseas travel and possibly with the food chain. The dearth of novel compounds to treat resistant Gram-negative bacillary infections is particularly worrying. What is clear is that the appropriate use of antimicrobial drugs in the management of human and animal disease has never been more important.

As in the past, the aim of this book is to provide an international repository of information on the properties of antimicrobial drugs and authoritative advice on their clinical application. The structure of the book remains unchanged, being divided into three parts. Section 1 addresses the general aspects of antimicrobial chemotherapy while Section 2 provides a detailed description of the agents, either by group and their respective compounds, or by target microorganisms as in the case of non-antibacterial agents. Section 3 deals with the treatment of all major infections by site, disease or target pathogens as appropriate. Some new chapters have been introduced and others deleted. The *recommended International Non-proprietary Names (rINN)* with minor exceptions has once again been adopted to reflect the international relevance of the guidance provided.

Our thanks go to our international panel of authors who have been selected for their expertise and who have shown patience with our deadlines and accommodated our revisions. We also thank those who have contributed to earlier editions and whose legacy lives on in some areas of the text. Here we wish to specifically thank both Francis O'Grady and Harold Lambert who edited this book for many years and did much to establish its international reputation. Their continued support and encouragement is gratefully acknowledged. We also welcome and thank Tim Hill for his pharmacy expertise in ensuring the accuracy of the information contained in the *Preparation and Dosages* boxes and elsewhere in the text. Finally, we thank the Editorial Team at Elsevier Science for their efficiency and professionalism in the production of this new edition.

Historical introduction

David Greenwood

The first part of this chapter was written by Professor Lawrence Paul Garrod (1895–1979), co-author of the first five editions of *Antibiotic and Chemotherapy*. Garrod, after serving as a surgeon probationer in the Navy during the 1914–18 war, then qualified and practiced clinical medicine before specializing in bacteriology, later achieving world recognition as the foremost authority on antimicrobial chemotherapy. He witnessed, and studied profoundly, the whole development of modern chemotherapy. A selection of over 300 leading articles written by him (but published anonymously) for the *British Medical Journal* between 1933 and 1979, was reprinted in a supplement to the *Journal of Antimicrobial Chemotherapy* in 1985.* These articles themselves provide a remarkable insight into the history of antimicrobial chemotherapy as it happened.

Garrod's original historical introduction was written in 1968 for the second edition of *Antibiotic and Chemotherapy* and updated for the fifth edition just before his death in 1979. It is reproduced here as a tribute to his memory. The development of antimicrobial chemotherapy is summarized so well, and with such characteristic lucidity, that to add anything seems superfluous, but a brief summary of events that have occurred since about 1975 has been added to complete the historical perspective.

THE EVOLUTION OF ANTIMICROBIC DRUGS

No one recently qualified, even with the liveliest imagination, can picture the ravages of bacterial infection which continued until rather less than 40 years ago. To take only two examples, lobar pneumonia was a common cause of death even in young and vigorous patients, and puerperal septicaemia and other forms of acute streptococcal sepsis had a high mortality, little affected by any treatment then available. One purpose of this introduction is therefore to place the subject of this book in historical perspective.

*Waterworth PM (ed.) L.P. Garrod on antibiotics. *Journal of Antimicrobial Chemotherapy* 1985; 15 (Suppl. B)

This subject is chemotherapy, which may be defined as the administration of a substance with a systemic antimicrobial action. Some would confine the term to synthetic drugs, and the distinction is recognized in the title of this book, but since some all-embracing term is needed, this one might with advantage be understood also to include substances of natural origin. Several antibiotics can now be synthesized, and it would be ludicrous if their use should qualify for description as chemotherapy only because they happened to be prepared in this way. The essence of the term is that the effect must be systemic, the substance being absorbed, whether from the alimentary tract or a site of injection, and reaching the infected area by way of the blood stream. 'Local chemotherapy' is in this sense a contradiction in terms: any application to a surface, even of something capable of exerting a systemic effect, is better described as antisepsis.

THE THREE ERAS OF CHEMOTHERAPY

There are three distinct periods in the history of this subject. In the first, which is of great antiquity, the only substances capable of curing an infection by systemic action were natural plant products. The second was the era of synthesis, and in the third we return to natural plant products, although from plants of a much lower order; the moulds and bacteria forming antibiotics.

1. *Alkaloids*. This era may be dated from 1619, since it is from this year that the first record is derived of the successful treatment of malaria with an extract of cinchona bark, the patient being the wife of the Spanish governor of Peru.[†] Another South American discovery was the efficacy of ipecacuanha root in amoebic dysentery. Until the early years of this century these extracts, and in more recent times the alkaloids, quinine and emetine, derived from them, provided the only curative chemotherapy known.

[†]Garrod was mistaken in perpetuating this legend, which is now discounted by medical historians.

2. Synthetic compounds. Therapeutic progress in this field, which initially and for many years after was due almost entirely to research in Germany, dates from the discovery of salvarsan by Ehrlich in 1909. His successors produced germanin for trypanosomiasis and other drugs effective in protozoal infections. A common view at that time was that protozoa were susceptible to chemotherapeutic attack, but that bacteria were not: the treponemata, which had been shown to be susceptible to organic arsenicals, are no ordinary bacteria, and were regarded as a class apart.

The belief that bacteria are by nature insusceptible to any drug which is not also prohibitively toxic to the human body was finally destroyed by the discovery of Prontosil. This, the forerunner of the sulphonamides, was again a product of German research, and its discovery was publicly announced in 1935. All the work with which this book is concerned is subsequent to this year: it saw the beginning of the effective treatment of bacterial infections.

Progress in the synthesis of antimicrobial drugs has continued to the present day. Apart from many new sulphonamides, perhaps the most notable additions have been the synthetic compounds used in the treatment of tuberculosis.

3. Antibiotics. The therapeutic revolution produced by the sulphonamides, which included the conquest of haemolytic streptococcal and pneumococcal infections and of gonorrhoea and cerebrospinal fever, was still in progress and even causing some bewilderment when the first report appeared of a study which was to have even wider consequences. This was not the discovery of penicillin – that had been made by Fleming in 1929 – but the demonstration by Florey and his colleagues that it was a chemotherapeutic agent of unexampled potency. The first announcement of this, made in 1940, was the beginning of the antibiotic era, and the unimaginable developments from it are still in progress. We little knew at the time that penicillin, besides providing a remedy for infections insusceptible to sulphonamide treatment, was also a necessary second line of defence against those fully susceptible to it. During the early 1940s, resistance to sulphonamides appeared successively in gonococci, haemolytic streptococci and pneumococci: nearly 20 years later it has appeared also in meningococci. But for the advent of the antibiotics, all the benefits stemming from Domagk's discovery might by now have been lost, and bacterial infections have regained their pre-1935 prevalence and mortality.

The earlier history of two of these discoveries calls for further description.

SULPHONAMIDES

Prontosil, or sulphonamido-chrysoidin, was first synthesized by Klarer and Mietzsch in 1932, and was one of a series of azo dyes examined by Domagk for possible effects on haemolytic streptococcal infection. When a curative effect in mice had been demonstrated, cautious trials in erysipelas and

other human infections were undertaken, and not until the evidence afforded by these was conclusive did the discoverers make their announcement. Domagk (1935) published the original claims, and the same information was communicated by Hörlein (1935) to a notable meeting in London.[‡]

These claims, which initially concerned only the treatment of haemolytic streptococcal infections, were soon confirmed in other countries, and one of the most notable early studies was that of Colebrook and Kenny (1936) in England, who demonstrated the efficacy of the drug in puerperal fever. This infection had until then been taking a steady toll of about 1000 young lives per annum in England and Wales, despite every effort to prevent it by hygiene measures and futile efforts to overcome it by serotherapy. The immediate effect of the adoption of this treatment can be seen in Figure 1.1: a steep fall in mortality began in 1935, and continued as the treatment became universal and better understood, and as more potent sulphonamides were introduced, until the present-day low level had almost been reached *before penicillin became generally available*. The effect of penicillin between 1945 and 1950 is perhaps more evident on incidence: its widespread use tends completely to banish haemolytic streptococci from the environment. The apparent rise in incidence after 1950 is due to the redefinition of puerperal pyrexia as any rise of temperature to 38°C, whereas previously the term was only applied when the temperature was maintained for 24 h or recurred. Needless to say, fever so defined is frequently not of uterine origin.

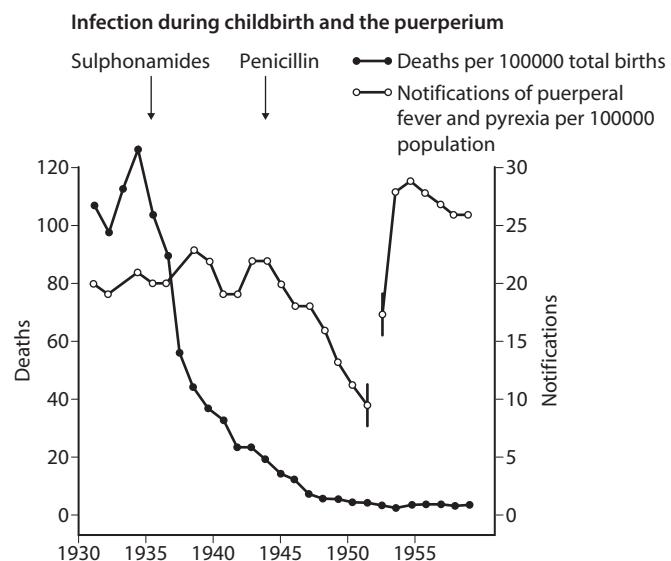

Fig. 1.1 Puerperal pyrexia. Deaths per 100 000 total births and incidence per 100 000 population in England and Wales, 1930–1957. N.B. The apparent rise in incidence in 1950 is due to the fact that the definition of puerperal pyrexia was changed in this year (see text). (Reproduced with permission from Barber 1960 *Journal of Obstetrics and Gynaecology* 67:727 by kind permission of the editor.)

[‡]A meeting at which Garrod was present.

Prontosil had no antibacterial action in vitro, and it was soon suggested by workers in Paris (Tréfouël et al 1935) that it owed its activity to the liberation from it in the body of *p*-aminobenzene sulphonamide (sulphanilamide); that this compound is so formed was subsequently proved by Fuller (1937). Sulphanilamide had a demonstrable inhibitory action on streptococci in vitro, much dependent on the medium and particularly on the size of the inoculum, facts which are readily understandable in the light of modern knowledge. This explanation of the therapeutic action of Prontosil was hotly contested by Domagk. It must be remembered that it relegated the chrysoidin component to an inert role, whereas the affinity of dyes for bacteria had been a basis of German research since the time of Ehrlich, and was the doctrine underlying the choice of this series of compounds for examination. German workers also took the attitude that there must be something mysterious about the action of a true chemotherapeutic agent: an effect easily demonstrable in a test tube by any tyro was too banal altogether to explain it. Finally, they felt justifiable resentment that sulphanilamide, as a compound which had been described many years earlier, could be freely manufactured by anyone.

Every enterprising pharmaceutical house in the world was soon making this drug, and at one time it was on the market under at least 70 different proprietary names. What was more important, chemists were soon busy modifying the molecule to improve its performance. Early advances so secured were of two kinds, the first being higher activity against a wider range of bacteria: sulphapyridine (M and B 693), discovered in 1938, was the greatest single advance, since it was the first drug to be effective in pneumococcal pneumonia. The next stage, the introduction of sulphathiazole and sulphadiazine, while retaining and enhancing antibacterial activity, eliminated the frequent nausea and cyanosis caused by earlier drugs. Further developments, mainly in the direction of altered pharmacokinetic properties, have continued to the present day and are described in Chapter 1 (now Ch. 29).

ANTIBIOTICS

'Out of the earth shall come thy salvation.' – S.A.
Waksman

DEFINITION

Of many definitions of the term antibiotic which have been proposed, the narrower seem preferable. It is true that the word 'antibiosis' was coined by Vuillemin in 1889 to denote antagonism between living creatures in general, but the noun 'antibiotic' was first used by Waksman in 1942 (Waksman & Lechevalier 1962), which gives him a right to re-define it, and definition confines it to substances produced by

micro-organisms antagonistic to the growth or life of others in high dilution (the last clause being necessary to exclude such metabolic products as organic acids, hydrogen peroxide and alcohol). To define an antibiotic simply as an antibacterial substance from a living source would embrace gastric juice, antibodies and lysozyme from man, essential oils and alkaloids from plants, and such oddities as the substance in the faeces of blowfly larvae which exerts an antiseptic effect in wounds. All substances known as antibiotics which are in clinical use and capable of exerting systemic effect are in fact products of micro-organisms.

EARLY HISTORY

The study of intermicrobic antagonism is almost as old as microbiology itself: several instances of it were described, one by Pasteur himself, in the seventies of the last century.[§] Therapeutic applications followed, some employing actual living cultures, others extracts of bacteria or moulds which had been found active. One of the best known products was an extract of *Pseudomonas aeruginosa*, first used as a local application by Czech workers, Honl and Bukovsky, in 1899: this was commercially available as 'pyocyanase' on the continent for many years. Other investigators used extracts of species of *Penicillium* and *Aspergillus* which probably or certainly contained antibiotics, but in too low a concentration to exert more than a local and transient effect. Florey (1945) gave a revealing account of these early developments in a lecture with the intriguing title 'The Use of Micro-organisms as Therapeutic Agents': this was amplified in a later publication (Florey 1949).

The systemic search, by an ingenious method, for an organism which could attack pyogenic cocci, conducted by Dubos (1939) in New York, led to the discovery of tyrothricin (gramicidin + tyrocidine), formed by *Bacillus brevis*, a substance which, although too toxic for systemic use in man, had in fact a systemic curative effect in mice. This work exerted a strong influence in inducing Florey and his colleagues to embark on a study of naturally formed antibacterial substances, and penicillin was the second on their list.

PENICILLIN

The present antibiotic era may be said to date from 1940, when the first account of the properties of an extract of cultures of *Penicillium notatum* appeared from Oxford (Chain et al 1940): a fuller account followed, with impressive clinical evidence (Abraham et al 1941). It had been necessary to find means of extracting a very labile substance from culture fluids, to examine its action on a wide range of bacteria, to examine its toxicity by a variety of methods, to establish a unit of its activity, to study its distribution and excretion when

[§]i.e. the nineteenth century.

administered to animals, and finally to prove its systemic efficacy in mouse infections. There then remained the gigantic task, seemingly impossible except on a factory scale, of producing in the School of Pathology at Oxford enough of a substance, which was known to be excreted with unexampled rapidity, for the treatment of human disease. One means of maintaining supplies was extraction from the patients' urine and re-administration.

It was several years before penicillin was fully purified, its structure ascertained, and its large-scale commercial production achieved. That this was of necessity first entrusted to manufacturers in the USA gave them a lead in a highly profitable industry which was not to be overtaken for many years.

LATER ANTIBIOTICS

The dates of discovery and sources of the principal antibiotics are given chronologically in Table 1.1. This is far from being a complete list, but subsequently discovered antibiotics have been closely related to others already known, such as aminoglycosides and macrolides. A few, including penicillin, were chance discoveries, but 'stretching out suppliant Petri dishes' (Florey 1945) in the hope of catching a new antibiotic-producing organism was not to lead anywhere. Most further discoveries resulted from soil surveys, a process from which a large annual outlay might or might not be repaid a hundred-fold, a gamble against much longer odds than most oil prospecting. Soil contains a profuse and very mixed flora varying with climate, vegetation, mineral content and other factors, and is a medium in which antibiotic formation may well play a part in the competition for nutrient. A soil survey consists of obtaining samples from as many and as varied sources as possible, cultivating them on plates, subcultivating all colonies of promising organisms such as actinomycetes and examining each for antibacterial activity. Alternatively, the primary plate culture may be inoculated by spraying or by agar layering with suitable bacteria, the growth of which may then be seen to be inhibited in a zone surrounding some of the original colonies. This is only a beginning: many thousands of successive colonies so examined are found to form an antibiotic already known or useless by reason of toxicity.

Antibiotics have been derived from some odd sources other than soil. Although the original strain of *P. notatum* apparently floated into Fleming's laboratory at St. Mary's from one on another floor of the building in which moulds were being studied, that of *Penicillium chrysogenum* now used for penicillin production was derived from a mouldy Canteloupe melon in the market at Peoria, Illinois. Perhaps the strangest derivation was that of helenine, an antibiotic with some antiviral activity, isolated by Shope (1953) from *Penicillium funiculosum* growing on 'the isinglass cover of a photograph of my wife, Helen, on Guam, near the end of the war in 1945'.

Table 1.1 Date of discovery and source of natural antibiotics

Name	Date of discovery	Microbe
Penicillin	1929–40	<i>Penicillium notatum</i>
Tyrothricin {Gramicidin} Tyrocidine}	1939	<i>Bacillus brevis</i>
Griseofulvin	1939	<i>Penicillium griseofulvum</i>
	1945	<i>Dierckx</i> <i>Penicillium janczewski</i>
Streptomycin	1944	<i>Streptomyces griseus</i>
Bacitracin	1945	<i>Bacillus licheniformis</i>
Chloramphenicol	1947	<i>Streptomyces venezuelae</i>
Polymyxin	1947	<i>Bacillus polymyxa</i>
Framycetin	1947–53	<i>Streptomyces lavendulae</i>
Chlortetracycline	1948	<i>Streptomyces aureofaciens</i>
Cephalosporin C, N and P	1948	<i>Cephalosporium</i> sp.
Neomycin	1949	<i>Streptomyces fradiae</i>
Oxytetracycline	1950	<i>Streptomyces rimosus</i>
Nystatin	1950	<i>Streptomyces noursei</i>
Erythromycin	1952	<i>Streptomyces erythreus</i>
Oleandomycin	1954	<i>Streptomyces antibioticus</i>
Spiramycin	1954	<i>Streptomyces ambofaciens</i>
Novobiocin	1955	<i>Streptomyces sphaeroides</i> <i>Streptomyces niveus</i>
Cycloserine	1955	<i>Streptomyces orchidaceus</i> <i>Streptomyces gaeryphalus</i>
Vancomycin	1956	<i>Streptomyces orientalis</i>
Rifamycin	1957	<i>Streptomyces mediterranei</i>
Kanamycin	1957	<i>Streptomyces kanamyceticus</i>
Nebramycins	1958	<i>Streptomyces tenebraeus</i>
Paromomycin	1959	<i>Streptomyces rimosus</i>
Fusidic acid	1960	<i>Fusidium coccineum</i>
Spectinomycin	1961–62	<i>Streptomyces flavopersicus</i>
Lincomycin	1962	<i>Streptomyces lincolnensis</i>
Gentamicin	1963	<i>Micromonospora purpurea</i>
Josamycin	1964	<i>Streptomyces narvonensis</i> var. <i>josamyceticus</i>
Tobramycin	1968	<i>Streptomyces tenebraeus</i>
Ribostamycin	1970	<i>Streptomyces ribosidificus</i>
Butirosin	1970	<i>Bacillus circulans</i>
Sissomicin	1970	<i>Micromonospora myosensis</i>
Rosaramycin	1972	<i>Micromonospora rosaria</i>

He proceeds to explain that he chose the name because it was non-descriptive, non-committal and not pre-empted, 'but largely out of recognition of the good taste shown by the mould ... in locating on the picture of my wife'.

Those antibiotics out of thousands now discovered which have qualified for therapeutic use are described in chapters which follow.

FUTURE PROSPECTS

All successful chemotherapeutic agents have certain properties in common. They must exert an antimicrobial action, whether inhibitory or lethal, in high dilution, and in the complex chemical environment which they encounter in the body. Secondly, since they are brought into contact with every tissue in the body, they must so far as possible be without harmful effect on the function of any organ. To these two essential qualities may be added others which are highly desirable, although sometimes lacking in useful drugs: stability, free solubility, a slow rate of excretion, and diffusibility into remote areas.

If a drug is toxic to bacteria but not to mammalian cells the probability is that it interferes with some structure or function peculiar to bacteria. When the mode of action of sulphanilamide was elucidated by Woods and Fildes, and the theory was put forward of bacterial inhibition by metabolite analogues, the way seemed open for devising further antibacterial drugs on a rational basis. Immense subsequent advances in knowledge of the anatomy, chemical composition and metabolism of the bacterial cell should have encouraged such hopes still further. This new knowledge has been helpful in explaining what drugs do to bacteria, but not in devising new ones. Discoveries have continued to result only from random trials, purely empirical in the antibiotic field, although sometimes based on reasonable theoretical expectation in the synthetic.

Not only is the action of any new drug on individual bacteria still unpredictable on a theoretical basis, but so are its effects on the body itself. Most of the toxic effects of antibiotics have come to light only after extensive use, and even now no one can explain their affinity for some of the organs attacked. Some new observations in this field have contributed something to the present climate of suspicion about new drugs generally, which is insisting on far more searching tests of toxicity, and delaying the release of drugs for therapeutic use, particularly in the USA.

THE PRESENT SCOPE OF CHEMOTHERAPY

Successive discoveries have added to the list of infections amenable to chemotherapy until nothing remains altogether untouched except the viruses. On the other hand, however, some of the drugs which it is necessary to use are far

from ideal, whether because of toxicity or of unsatisfactory pharmacokinetic properties, and some forms of treatment are consequently less often successful than others. Moreover, microbial resistance is a constant threat to the future usefulness of almost any drug. It seems unlikely that any totally new antibiotic remains to be discovered, since those of recent origin have similar properties to others already known. It therefore will be wise to husband our resources, and employ them in such a way as to preserve them. The problems of drug resistance and policies for preventing it are discussed in Chapters 13 and 14.

ADAPTATION OF EXISTING DRUGS

A line of advance other than the discovery of new drugs is the adaptation of old ones. An outstanding example of what can be achieved in this way is presented by the sulphonamides. Similar attention has naturally been directed to the antibiotics, with fruitful results of two different kinds. One is simply an alteration for the better in pharmacokinetic properties. Thus procaine penicillin, because less soluble, is longer acting than potassium penicillin; the esterification of macrolides improves absorption; chloramphenicol palmitate is palatable, and other variants so produced are more stable, more soluble and less irritant. Secondly, synthetic modification may also enhance antimicrobial properties. Sometimes both types of change can be achieved together; thus rifampicin is not only well absorbed after oral administration, whereas rifamycin, from which it is derived, is not, but antibacterially much more active. The most varied achievements of these kinds have been among the penicillins, overcoming to varying degrees three defects in benzylpenicillin: its susceptibility to destruction by gastric acid and by staphylococcal penicillinase, and the relative insusceptibility to it of many species of Gram-negative bacilli. Similar developments have provided many new derivatives of cephalosporin C, although the majority differ from their prototypes much less than the penicillins.

One effect of these developments, of which it may seem captious to complain, is that a quite bewildering variety of products is now available for the same purposes. There are still many sulphonamides, about 10 tetracyclines, more than 20 semisynthetic penicillins, and a rapidly extending list of cephalosporins, and a confident choice between them for any given purpose is one which few prescribers are qualified to make – indeed no one may be, since there is often no significant difference between the effects to be expected. Manufacturers whose costly research laboratories have produced some new derivative with a marginal advantage over others are entitled to make the most of their discovery. But if an antibiotic in a new form has a substantial advantage over that from which it was derived and no countervailing disadvantages, could not its predecessor sometimes simply be dropped? This rarely seems to happen, and there are doubtless good reasons for it,

but the only foreseeable opportunity for simplifying the prescriber's choice has thus been missed.

LATER DEVELOPMENTS IN ANTIMICROBIAL CHEMOTHERAPY

ANTIBACTERIAL AGENTS

At the time of Garrod's death, penicillins and cephalosporins were still in the ascendancy: apart from the aminoglycoside, amikacin, the latest advances in antimicrobial therapy to reach the formulary in the late 1970s were the antipseudomonal penicillins, azlocillin, mezlocillin and piperacillin, the amidopenicillin mecillinam (amdinocillin), and the β -lactamase-stable cephalosporins cefuroxime and cefoxitin. The latter compounds emerged in response to the growing importance of enterobacterial β -lactamases, which were the subject of intense scrutiny around this time. Discovery of other novel, enzyme-resistant, β -lactam molecules elaborated by micro-organisms, including clavams, carbapenems and monobactams (see Ch. 15) were to follow, reminding us that Mother Nature still has some antimicrobial surprises up her copious sleeves.

The appearance of cefuroxime (first described in 1976) was soon followed by the synthesis of cefotaxime, a methoximino-cephalosporin that was not only β -lactamase stable but also exhibited a vast improvement in intrinsic activity. This compound stimulated a wave of commercial interest in cephalosporins with similar properties, and the early 1980s were dominated by the appearance of several variations on the cefotaxime theme (ceftizoxime, ceftriaxone, cefmenoxime, ceftazidime and the oxa-cephem, latamoxef). Although they have not been equally successful, these compounds arguably represent the high point in a continuing development of cephalosporins from 1964, when cephaloridine and cephalothin were first introduced.

The dominance of the cephalosporins among β -lactam agents began to decline in the late 1980s as novel derivatives such as the monobactam aztreonam and the carbapenem imipenem came on stream. The contrasting properties of these

two compounds reflected a still unresolved debate about the relative merits of narrow-spectrum targeted therapy and ultra-broad spectrum cover. Meanwhile, research emphasis among β -lactam antibiotics turned to the development of orally absorbed cephalosporins that exhibited the favorable properties of the expanded-spectrum parenteral compounds; formulations that sought to emulate the successful combination of amoxicillin with the β -lactamase inhibitor, clavulanic acid; and variations on the carbapenem theme pioneered by imipenem.

Interest in most other antimicrobial drug families languished during the 1970s. Among the aminoglycosides the search for new derivatives petered out in most countries after the development of netilmicin in 1976. However, in Japan, where amikacin was first synthesized in 1972 in response to concerns about aminoglycoside resistance, several novel aminoglycosides that are not exploited elsewhere appeared on the market. A number of macrolides with rather undistinguished properties also appeared during the 1980s in Japan and some other countries, but not in the UK or the USA. Wider interest in new macrolides had to await the emergence of compounds that claimed pharmacological advantages over erythromycin (see Ch. 22); two, azithromycin and clarithromycin, reached the UK market in 1991 and others became available elsewhere.

Quinolone antibacterial agents enjoyed a renaissance when it was realized that fluorinated, piperazine-substituted derivatives exhibited much enhanced potency and a broader spectrum of activity than earlier congeners (see Ch. 26). Norfloxacin, first described in 1980, was the forerunner of this revival and other fluoroquinolones quickly followed. Soon manufacturers of the new fluoroquinolones such as ciprofloxacin, enoxacin and ofloxacin began to struggle for market dominance in Europe, the USA and elsewhere, and competing claims of activity and toxicity began to circulate. The commercial appeal of the respiratory tract infection market also ensured a sustained interest in derivatives that reliably included the pneumococcus in their spectrum of activity. Several quinolones of this type subsequently appeared on the market, though enthusiasm has been muted to some extent by unexpected problems of serious toxicity: several were withdrawn soon after they were launched because of unacceptable adverse reactions.

As the 20th century drew to a close, investment in new antibacterial agents in the pharmaceutical houses underwent a spectacular decline. Ironically, the period coincided with a dawning awareness of the fragility of conventional resources in light of the spread of antimicrobial drug resistance. Indeed, such new drugs that have appeared on the market have arisen from concerns about the development and spread of resistance to traditional agents, particularly, but not exclusively, methicillin-resistant *Staphylococcus aureus*. Most have been developed by small biotech companies, often on licence from the multinational firms.

Further progress on antibacterial compounds in the 21st century has been spasmodic at best, though some compounds

in trial at the time of writing, notably the glycopeptide oritavancin and ceftobiprole, a cephalosporin with activity against methicillin-resistant *Staph. aureus*, have aroused considerable interest.

OTHER ANTIMICROBIAL AGENTS

ANTIVIRAL AGENTS

The massive intellectual and financial investment that was brought to bear in the wake of the HIV pandemic began to pay off in the last decade of the 20th century. In the late 1980s only a handful of antiviral agents were available to the prescriber, whereas about 40 are available today (see Chs 36 and 37). Discovery of new approaches to the attack on HIV opened the way to effective combination therapy (see Chs 36 and 43). In addition, new compounds for the prevention and treatment of influenza and cytomegalovirus infection emerged (see Ch. 37).

ANTIFUNGAL AGENTS

Many of the new antifungal drugs that appeared in the late 20th century (see Chs 32, 59 and 60) were variations on older themes: antifungal azoles and safer formulations of amphotericin B. They included useful new triazoles (fluconazole and itraconazole) that are effective when given systemically and a novel allylamine compound, terbinafine, which offers a welcome alternative to griseofulvin in recalcitrant dermatophyte infections. Investigation of antibiotics of the echinocandin class bore fruit in the development of caspofungin and micafungin. The emergence of *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*; long a taxonomic orphan, but now accepted as a fungus) as an important pathogen in HIV-infected persons stimulated the investigation of new therapies, leading to the introduction of trimetrexate and atovaquone for cases unresponsive to older drugs.

ANTIPARASITIC AGENTS

The most serious effects of parasitic infections are borne by the economically poor countries of the world, and research into agents for the treatment of human parasitic disease has always received low priority. Nevertheless, some useful new antimalarial compounds have found their way into therapeutic use. These include mefloquine and halofantrine, which originally emerged in the early 1980s from the extensive antimalarial research program undertaken by the Walter Reed Army Institute of Research in Washington, and the hydroxynaphthoquinone, atovaquone, which is used in

antimalarial prophylaxis in combination with proguanil. Derivatives of artemisinin, the active principle of the Chinese herbal remedy qinghaosu, also became accepted as valuable additions to the antimalarial armamentarium. These developments have been slow, but very welcome in view of the inexorable spread of resistance to standard antimalarial drugs in *Plasmodium falciparum*, which continues unabated (see Ch. 62).

There have been few noteworthy developments in the treatment of other protozoan diseases, but one, eflofornithine (difluoromethylornithine), provides a long-awaited alternative to arsenicals in the West African form of trypanosomiasis. Unfortunately, long-term availability of the drug remains insecure. Although a commercial use for a topical formulation has emerged (for removal of unwanted facial hair), manufacture of an injectable preparation is uneconomic. For the present it remains available through a humanitarian arrangement between the manufacturer and the World Health Organization.

On the helminth front, the late 20th century witnessed a revolution in the reliability of treatment. Three agents – albendazole, praziquantel and ivermectin – emerged, which between them cover most of the important causes of human intestinal and systemic worm infections (see Chs 34 and 64). Most anthelmintic compounds enter the human anti-infective formulary by the veterinary route, underlying the melancholy fact that animal husbandry is of relatively greater economic importance than the well-being of the approximately 1.5 billion people who harbor parasitic worms.

THE PRESENT SCOPE OF ANTIMICROBIAL CHEMOTHERAPY

Science, with a little help from Lady Luck, has provided formidable resources for the treatment of infectious disease during the last 75 years. Given the enormous cost of development of new drugs, and the already crowded market for antimicrobial compounds, it is not surprising that anti-infective research in the pharmaceutical houses has turned to more lucrative fields. Meanwhile, antimicrobial drug resistance continues to increase inexorably. Although most bacterial infection remains amenable to therapy with common, well-established drugs, the prospect of untreatable infection is already becoming an occasional reality, especially among seriously ill patients in high-dependency units where there is intense selective pressure created by widespread use of potent, broad-spectrum agents. On a global scale, multiple drug resistance in a number of different organisms, including those that cause typhoid fever, tuberculosis and malaria, is an unsolved problem. These are life-threatening infections for which treatment options are limited, even when fully sensitive organisms are involved.

Garrod, surveying the scope of chemotherapy in 1968 (in the second edition of this book), warned of the threat of microbial resistance and the need to husband our

resources. That threat and that need have not diminished. The challenge for the future is to preserve the precious assets that we have acquired by sensible regulation of the availability of antimicrobial drugs in countries in which controls are presently inadequate; by strict adherence to control of infection procedures in hospitals and other healthcare institutions; and by informed and cautious prescribing everywhere.

2 Modes of action

Ian Chopra

Selective toxicity is the central concept of antimicrobial chemotherapy, i.e. the infecting organism is killed, or its growth prevented, without damage to the host. The necessary selectivity can be achieved in several ways: targets within the pathogen may be absent from the cells of the host or, alternatively, the analogous targets within the host cells may be sufficiently different, or at least sufficiently inaccessible, for selective attack to be possible. With agents like the polymyxins, the organic arsenicals used in trypanosomiasis, the antifungal polyenes and some antiviral compounds, the gap between toxicity to the pathogen and to the host is small, but in most cases antimicrobial drugs are able to exploit fundamental differences in structure and function within the infecting organism, and host toxicity generally results from unexpected secondary effects.

ANTIBACTERIAL AGENTS

Bacteria are structurally and metabolically very different from mammalian cells and, in theory, there are numerous ways in which bacteria can be selectively killed or disabled. In the event, it turns out that only the bacterial cell wall is structurally unique; other subcellular structures, including the cytoplasmic membrane, ribosomes and DNA, are built on the same pattern as those of mammalian cells, although sufficient differences in construction and organization do exist at these sites to make exploitation of the selective toxicity principle feasible.

The most successful antibacterial agents are those that interfere with the construction of the bacterial cell wall, the synthesis of protein, or the replication and transcription of DNA. Indeed, relatively few clinically useful agents act at the level of the cell membrane, or by interfering with specific metabolic processes within the bacterial cell (Table 2.1).

Unless the target is located on the outside of the bacterial cell, antimicrobial agents must be able to penetrate to the site of action. Access through the cytoplasmic membrane is usually achieved by passive diffusion, or occasionally by active transport processes. In the case of Gram-negative organisms,

Table 2.1 Sites of action of antibacterial agents

Site	Agent	Principal target
Cell wall	Penicillins	Transpeptidase
	Cephalosporins	Transpeptidase
	Bacitracin, ramoplanin	Isoprenylphosphate
	Vancomycin, teicoplanin	Acyl-D-alanyl-D-alanine
	Telavancin	Acyl-D-alanyl-D-alanine (and the cell membrane)
	Cycloserine	Alanine racemase/ligase
	Fosfomycin	Pyruvyl transferase
	Isoniazid	Mycolic acid synthesis
Ribosome	Ethambutol	Arabinosyl transferases
	Chloramphenicol	Peptidyl transferase
	Tetracyclines	Ribosomal A site
	Aminoglycosides	Initiation complex/translation
	Macrolides	Ribosomal 50S subunit
	Lincosamides	Ribosomal A and P sites
	Fusidic acid	Elongation factor G
	Linezolid	Ribosomal A site
tRNA charging	Pleuromutilins	Ribosomal A site
	Mupirocin	Isoleucyl-tRNA synthetase
Nucleic acid	Quinolones	DNA gyrase (α subunit)/topoisomerase IV
	Novobiocin	DNA gyrase (β subunit)
	Rifampicin	RNA polymerase
	5-Nitroimidazoles	DNA strands
	Nitrofurans	DNA strands
Cell membrane	Polymyxins	Phospholipids
	Daptomycin	Phospholipids
Folate synthesis	Sulfonamides	Pteroyl synthetase
	Diaminopyrimidines	Dihydrofolate reductase

the antibacterial drug must also cross the outer membrane (Figure 2.1). This contains a lipopolysaccharide-rich outer bilayer, which may prevent a drug from reaching an otherwise sensitive intracellular target. However, the outer membrane contains aqueous transmembrane channels (porins), which does allow passage of hydrophilic molecules, including drugs, depending on their molecular size and ionic charge. Many antibacterial agents use porins to gain access to Gram-negative organisms, although other pathways are also exploited.¹

London: Academic Press; p.62, with permission of Elsevier.)

INHIBITORS OF BACTERIAL CELL WALL SYNTHESIS

Peptidoglycan forms the rigid, shape-maintaining layer of most medically important bacteria. Its structure is similar in Gram-positive and Gram-negative organisms, although there are important differences. In both types of organism the basic macromolecular chain is *N*-acetylglucosamine alternating with its lactyl ether, *N*-acetylmuramic acid. Each muramic acid unit carries a pentapeptide, the third amino acid of which is L-lysine in most Gram-positive cocci and *meso*-diaminopimelic acid in Gram-negative bacilli. The cell wall is given its rigidity by cross-links between this amino acid and the penultimate amino acid (which is always D-alanine)

of adjacent chains, with loss of the terminal amino acid (also D-alanine) (Figure 2.2). Gram-negative bacilli have a very thin peptidoglycan layer, which is loosely cross-linked; Gram-positive cocci, in contrast, possess a very thick peptidoglycan coat, which is tightly cross-linked through interpeptide bridges. The walls of Gram-positive bacteria also differ in containing considerable amounts of polymeric sugar alcohol phosphates (teichoic and teichuronic acids), while Gram-negative bacteria possess an outer membrane as described above.

A number of antibacterial agents selectively inhibit different stages in the construction of the peptidoglycan (Figure 2.3). In addition, the unusual structure of the mycobacterial cell wall is exploited by several antituberculosis agents.

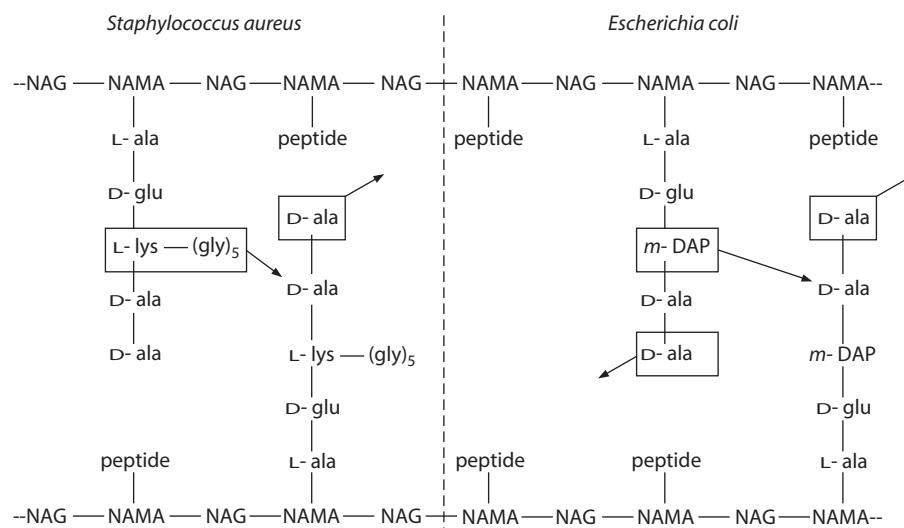

Fig. 2.2 Schematic representations of the terminal stages of cell wall synthesis in Gram-positive (*Staphylococcus aureus*) and Gram-negative (*Escherichia coli*) bacteria. See text for explanation. Arrows indicate formation of cross-links, with loss of terminal D-alanine; in Gram-negative bacilli many D-alanine residues are not involved in cross-linking and are removed by D-alanine carboxypeptidase. NAG, *N*-acetylglucosamine; NAMA, *N*-acetylmuramic acid; ala, alanine; glu, glutamic acid; lys, lysine; gly, glycine; m-DAP, *meso*-diaminopimelic acid.

FOSFOMYCIN

The *N*-acetylmuramic acid component of the bacterial cell wall is derived from *N*-acetylglucosamine by the addition of a lactic acid substituent derived from phosphoenolpyruvate. Fosfomycin blocks this reaction by inhibiting the pyruvyl transferase enzyme involved. The antibiotic enters bacteria by utilizing active transport mechanisms for α -glycerophosphate and glucose-6-phosphate. Glucose-6-phosphate induces the hexose phosphate transport pathway in some organisms (notably *Escherichia coli*) and potentiates the activity of fosfomycin against these bacteria.²

CYCLOSERINE

The first three amino acids of the pentapeptide chain of muramic acid are added sequentially, but the terminal D-alanyl-D-alanine is added as a dipeptide unit (see Figure 2.3). To form this unit the natural form of the amino acid, L-alanine, is first racemized to D-alanine and two molecules are then joined by D-alanyl-D-alanine ligase. Both of these reactions are blocked by the antibiotic cycloserine, which is a structural analog of D-alanine.

VANCOMYCIN, TEICOPLANIN AND TELAVANCIN

Once the muramylpentapeptide is formed in the cell cytoplasm, an *N*-acetylglucosamine unit is added, together with any amino acids needed for the interpeptide bridge of Gram-positive organisms. It is then passed to a lipid carrier molecule, which transfers the whole unit across the cell membrane to be added to the growing end of the peptidoglycan macromolecule (see Figure 2.3). Addition of the new building block (transglycosylation) is prevented by vancomycin (a glycopeptide

antibiotic) and teicoplanin (a lipoglycopeptide antibiotic) which bind to the acyl-D-alanyl-D-alanine tail of the muramylpentapeptide. Telavancin (a lipoglycopeptide derivative of vancomycin) also prevents transglycosylation by binding to the acyl-D-alanyl-D-alanine tail of the muramylpentapeptide. However, telavancin appears to have an additional mechanism of action since it also increases the permeability of the cytoplasmic membrane, leading to loss of adenosine triphosphate (ATP) and potassium from the cell and membrane depolarization.³ Because these antibiotics are large polar molecules, they cannot penetrate the outer membrane of Gram-negative organisms, which explains their restricted spectrum of activity.

BACITRACIN AND RAMOPLANIN

The lipid carrier involved in transporting the cell wall building block across the membrane is a C₅₅ isoprenyl phosphate. The lipid acquires an additional phosphate group in the transport process and must be dephosphorylated in order to regenerate the native compound for another round of transfer. The cyclic peptide antibiotics bacitracin and ramoplanin both bind to the C₅₅ lipid carrier. Bacitracin inhibits its dephosphorylation and ramoplanin prevents it from participating in transglycosylation. Consequently both antibiotics disrupt the lipid carrier cycle (see Figure 2.3).

β -LACTAM ANTIBIOTICS

The final cross-linking reaction that gives the bacterial cell wall its characteristic rigidity was pinpointed many years ago as the primary target of penicillin and other β -lactam agents. These compounds were postulated to inhibit formation of the transpeptidase bond by virtue of their structural resemblance to the terminal D-alanyl-D-alanine unit that participates in the transpeptidation reaction. This knowledge had to be

reconciled with various concentration-dependent morphological responses that Gram-negative bacilli undergo on exposure to penicillin and other β -lactam compounds: filamentation (caused by inhibition of division rather than growth of the bacteria) at low concentrations, and the formation of osmotically fragile spheroplasts (peptidoglycan-deficient forms that have lost their bacillary shape) at high concentrations.

Three observations suggested that these morphological events could be dissociated:

- The oral cephalosporin cefalexin (and some other β -lactam agents, including cefradine, temocillin and the monobactam, aztreonam) causes the filamentation response alone over an extremely wide range of concentrations.
- Mecillinam (amdinocillin) does not inhibit division (and hence does not cause filamentation in Gram-negative bacilli), but has a generalized effect on the bacterial cell wall.
- Combining cefalexin and mecillinam evokes the ‘typical’ spheroplast response in *Esch. coli* that neither agent induces when acting alone.⁴

It was subsequently shown that isolated membranes of bacteria contain a number of proteins that bind penicillin and other β -lactam antibiotics. These penicillin-binding proteins (PBPs) are numbered in descending order of their molecular weight.⁵ The number found in bacterial cells varies from species to species: *Esch. coli* has at least seven and *Staphylococcus aureus* four. β -Lactam agents that induce filamentation in Gram-negative bacilli bind to PBP 3; similarly, mecillinam binds exclusively to PBP 2. Most β -lactam antibiotics, when present in sufficient concentration, bind to both these sites and to others (PBP 1a and PBP 1b) that participate in the rapidly lytic response of Gram-negative bacilli to many penicillins and cephalosporins.

The low-molecular-weight PBPs (4, 5 and 6) of *Esch. coli* are carboxypeptidases, which may operate to control the extent of cross-linking in the cell wall. Mutants lacking these enzymes grow normally and have thus been ruled out as targets for the inhibitory or lethal actions of β -lactam antibiotics. The PBPs with higher molecular weights (PBPs 1a, 1b, 2 and 3) possess transpeptidase activity, and it seems that these PBPs represent different forms of the transpeptidase enzyme necessary to arrange the complicated architecture of the cylindrical or spherical bacterial cell during growth, septation and division.

The nature of the lethal event

The mechanism by which inhibition of penicillin-binding proteins by β -lactam agents causes bacterial lysis and death has been investigated for decades. Normal cell growth and division require the coordinated participation of both peptidoglycan synthetic enzymes and those with autolytic activity (murein, or peptidoglycan hydrolases; autolysins). To prevent widespread hydrolysis of the peptidoglycan it appears that the autolysins are normally restricted in their access to peptidoglycan. Possibly, as a secondary consequence of β -lactam action, there are changes in cell envelope structure (e.g. the

formation of protein channels in the cytoplasmic membrane) that allow autolysins to more readily reach their peptidoglycan substrate and thereby promote destruction of the cell wall.⁶

ANTIMYCOBACTERIAL AGENTS

Agents acting specifically against *Mycobacterium tuberculosis* and other mycobacteria have been less well characterized than other antimicrobial drugs. Nevertheless, it is believed that several of them owe their activity to selective effects on the biosynthesis of unique components in the mycobacterial cell envelope.⁷ Thus isoniazid and ethionamide inhibit mycolic acid synthesis and ethambutol prevents arabinogalactan synthesis.⁸ The mode of action of pyrazinamide, a synthetic derivative of nicotinamide, is more controversial. Pyrazinamide is a pro-drug which is converted into pyrazinoic acid (the active form of pyrazinamide) by mycobacterial pyrazinamidase. Some evidence suggests that pyrazinoic acid inhibits mycobacterial fatty acid synthesis,⁸ whereas other data support a mode of action involving disruption of membrane energization.⁹

INHIBITORS OF BACTERIAL PROTEIN SYNTHESIS

The process by which the information encoded by DNA is translated into proteins is universal in living systems. In prokaryotic, as in eukaryotic cells, the workbench is the ribosome, composed of two distinct subunits, each a complex of ribosomal RNA (rRNA) and numerous proteins. However, bacterial ribosomes are open to selective attack by drugs because they differ from their mammalian counterparts in both protein and RNA structure. Indeed, the two types can be readily distinguished in the ultracentrifuge: bacterial ribosomes exhibit a sedimentation coefficient of 70S (composed of 30S and 50S subunits), whereas mammalian ribosomes display a coefficient of 80S (composed of 40S and 60S subunits). Nevertheless, bacterial and mitochondrial ribosomes are much more closely related and it is evident that some of the adverse side effects associated with the therapeutic use of protein synthesis inhibitors as antibacterial agents results from inhibition of mitochondrial protein synthesis.¹⁰

In the first stage of bacterial protein synthesis, messenger RNA (mRNA), transcribed from a structural gene, binds to the smaller ribosomal subunit and attracts *N*-formylmethionyl transfer RNA (fMet-tRNA) to the initiator codon AUG. The larger subunit is then added to form a complete initiation complex. fMet-tRNA occupies the P (peptidyl donor) site; adjacent to it is the A (aminoacyl acceptor) site aligned with the next trinucleotide codon of the mRNA. Transfer RNA (tRNA) bearing the appropriate anticodon, and its specific amino acid, enters the A site assisted by elongation factor Tu. Peptidyl transferase activity joins *N*-formylmethionine to the new amino acid with loss of the tRNA in the P site, via the exit

(E) site. The first peptide bond of the protein has therefore been formed. A translocation event, assisted by elongation factor G, then moves the remaining tRNA with its dipeptide to the P site and concomitantly aligns the next triplet codon of mRNA with the now vacant A site. The appropriate aminoacyl-tRNA enters the A site and the transfer process and subsequent translocation are repeated. In this way, the peptide chain is synthesized in precise fashion, faithful to the original DNA blueprint, until a termination codon is encountered on the mRNA that signals completion of the peptide chain and release of the protein product. The mRNA disengages from the ribosome, which dissociates into its component subunits, ready to form a new initiation complex. Within bacterial cells, many ribosomes are engaged in protein synthesis during active growth, and a single strand of mRNA may interact with many ribosomes along its length to form a polysome.

Several antibacterial agents interfere with the process of protein synthesis by binding to the ribosome (Figure 2.4). In addition, the charging of isoleucyl tRNA, i.e. one of the steps in protein synthesis preceding ribosomal involvement, is subject to inhibition by the antibiotic mupirocin. Therapeutically useful inhibitors of protein synthesis acting on the ribosome include many of the naturally occurring antibiotics, such as chloramphenicol, tetracyclines, aminoglycosides, fusidic acid,

macrolides, lincosamides and streptogramins. Linezolid, a newer synthetic drug, also selectively inhibits bacterial protein synthesis by binding to the ribosome. In recent years considerable insight into the mode of action of agents that inhibit bacterial protein synthesis has been gained from structural studies on the nature of drug binding sites in the ribosome.^{11–14}

CHLORAMPHENICOL

The molecular target for chloramphenicol is the peptidyl transferase center of the ribosome located in the 50S subunit. Peptidyl transferase activity is required to link amino acids in the growing peptide chain. Consequently, chloramphenicol prevents the process of chain elongation, bringing bacterial growth to a halt. The process is reversible, and hence chloramphenicol is fundamentally a bacteriostatic agent. Structural studies reveal that chloramphenicol binds exclusively to specific nucleotides within the 23S rRNA of the 50S subunit and has no direct interaction with ribosomal proteins.¹¹ The structural data suggest that chloramphenicol could inhibit the formation of transition state intermediates that are required for the completion of peptide bond synthesis.

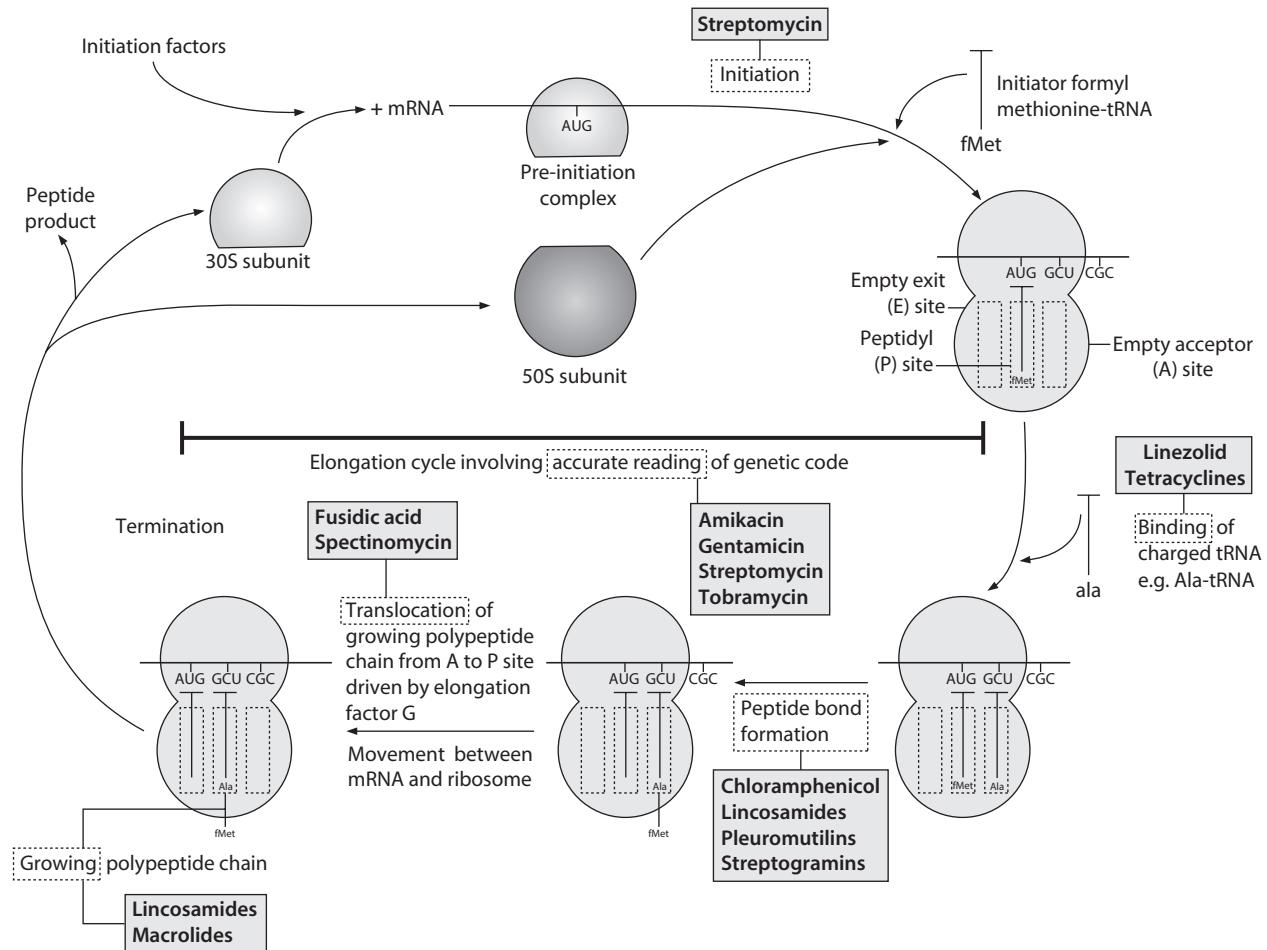

Fig. 2.4 The process of protein synthesis and the steps inhibited by various antibacterial agents.

TETRACYCLINES

Antibiotics of the tetracycline group interact with 30S ribosomal subunits and prevent the binding of incoming aminoacyl-tRNA to the A site.¹² However, this appears to occur after the initial binding of the elongation factor Tu–aminoacyl-tRNA complex to the ribosome, which is not directly affected by tetracyclines. Inhibition of A-site occupation prevents polypeptide chain elongation and, like chloramphenicol, these antibiotics are predominantly bacteriostatic. Structural analysis reveals several binding sites for tetracycline in the 30S subunit which account for the ability of the antibiotic to cause physical blockage of tRNA binding in the A site.¹²

Tetracyclines also penetrate into mammalian cells (indeed, the effect on Chlamydiae depends on this) and can interfere with protein synthesis on eukaryotic ribosomes. Fortunately, cytoplasmic ribosomes are not affected at the concentrations achieved during therapy, although mitochondrial ribosomes are. The selective toxicity of tetracyclines thus presents something of a puzzle, the solution to which is presumably that these antibiotics are not actively concentrated by mitochondria as they are by bacteria, and concentrations reached are insufficient to deplete respiratory chain enzymes.¹⁵

AMINOGLYCOSIDES

Much of the literature on the mode of action of aminoglycosides has concentrated on streptomycin. However, the action of gentamicin and other deoxystreptamine-containing aminoglycosides is clearly not identical, since single-step, high-level resistance to streptomycin, which is due to a change in a specific protein (S12) of the 30S ribosomal subunit, does not extend to other aminoglycosides.

Elucidation of the mode of action of aminoglycosides has been complicated by the need to reconcile a variety of enigmatic observations:

- Streptomycin and other aminoglycosides cause misreading of mRNA on the ribosome while paradoxically halting protein synthesis completely by interfering with the formation of functional initiation complexes.
- Inhibition of protein synthesis by aminoglycosides leads not just to bacteristasis as with, for example, tetracycline or chloramphenicol, but also to rapid cell death.
- Susceptible bacteria (but not those with resistant ribosomes) quickly become leaky to small molecules on exposure to the drug, apparently because of an effect on the cell membrane.

A complete understanding of these phenomena has not yet been achieved, but the situation is slowly becoming clearer. The two effects of aminoglycosides on initiation and misreading may be explained by a concentration-dependent effect on ribosomes engaged in the formation of the initiation complex and those in the process of chain elongation:¹⁶ in the presence of a sufficiently high concentration of drug, protein synthesis

is completely halted once the mRNA is run off because re-initiation is blocked; under these circumstances there is little or no opportunity for misreading to occur. However, at concentrations at which only a proportion of the ribosomes can be blocked at initiation, some protein synthesis will take place and the opportunity for misreading will be provided.

The mechanism of misreading has been clarified by recent structural information on the interaction of streptomycin with the ribosome.¹³ Streptomycin binds near to the A site through strong interactions with four nucleotides in 16S rRNA and one residue in protein S12. This tight binding promotes a conformational change which stabilizes the so-called *ram* state in the ribosome which reduces the fidelity of translation by allowing non-cognate aminoacyl-tRNAs to bind easily to the A site.

The effects of aminoglycosides on membrane permeability, and the potent bactericidal activity of these compounds, remain enigmatic. However, the two phenomena may be related.¹⁷ The synthesis and subsequent insertion of misread proteins into the cytoplasmic membrane may lead to membrane leakiness and cell death.¹⁸

Spectinomycin

The aminocyclitol antibiotic spectinomycin, often considered alongside the aminoglycosides, binds in reversible fashion (hence the bacteriostatic activity) to the 16S rRNA of the ribosomal 30S subunit. There it interrupts the translocation event that occurs as the next codon of mRNA is aligned with the A site in readiness for the incoming aminoacyl-tRNA. Structural studies reveal that the antibiotic binds to an area of the 30S subunit known as the head region which needs to move during translocation. Binding of the rigid spectinomycin molecule appears to prevent the movement required for translocation.¹³

MACROLIDES, KETOLIDES, LINCOSAMIDES, STREPTOGRAMINS

These antibiotic groups are structurally very different, but bind to closely related sites on the 50S ribosomal subunit of bacteria. One consequence of this is that a single mutation in adenine 2058 of the 23S rRNA can confer cross-resistance to macrolides, lincosamides and streptogramin B antibiotics (MLS_B resistance).

Crystallographic studies indicate that, although the binding sites for macrolides and lincosamides differ, both drug classes interact with some of the same nucleotides in 23S rRNA.¹¹ Neither of the drug classes binds directly to ribosomal proteins. Although streptogramin B antibiotics have not been co-crystallized with ribosomes, it is assumed that parts of their binding sites overlap with those of macrolides and lincosamides (see above). The structural studies support a model whereby macrolides block the entrance to a channel that directs nascent peptides away from the peptidyl transferase

center. Lincosamides also affect the exit path of the nascent polypeptide chain but in addition disrupt the binding of aminoacyl-tRNA and peptidyl-tRNA to the ribosomal A and P sites.

The streptogramins are composed of two interacting components designated A and B. The type A molecules bind to 50S ribosomal subunits and appear, like lincosamides, to affect both the A and P sites of the peptidyl transferase center, thereby preventing peptide bond formation. Type B streptogramins occupy an adjacent site on the ribosome and also prevent formation of the peptide bond; in addition, premature release of incomplete polypeptides also occurs.¹⁹ Type A molecules bind to free ribosomes, but not to polysomes engaged in protein synthesis, whereas type B can prevent further synthesis during active processing of the mRNA. The bactericidal synergy between the two components arises mainly from conformational changes induced by type A molecules that improve the binding affinity of type B compounds.²⁰

Ketolides, such as telithromycin, which are semisynthetic derivatives of the macrolide erythromycin, appear to block the entrance to the tunnel in the large ribosomal subunit through which the nascent polypeptide exits from the ribosome.²¹ However, the binding of ketolides must differ from those of the macrolides, lincosamides or streptogramin B antibiotics because the ketolides are not subject to the MLS_B-based resistance mechanism.²¹

PLEUROMUTILINS

Pleuromutilins such as tiamulin and valnemulin have been used for some time in veterinary medicine to treat swine infections.²² More recently a semisynthetic pleuromutilin, retapamulin, has been introduced as a topical treatment for Gram-positive infections in humans.²³ Pleuromutilins inhibit the peptidyl transferase activity of the bacterial 50S ribosomal subunit by binding to the A site.^{22,24}

FUSIDIC ACID

Fusidic acid forms a stable complex with an elongation factor (EF-G) involved in translocation and with guanosine triphosphate (GTP), which provides energy for the translocation process. One round of translocation occurs, with hydrolysis of GTP, but the fusidic acid-EF-G-GDP complex cannot dissociate from the ribosome, thereby blocking further chain elongation and leaving peptidyl-tRNA in the P site.²⁵

Although protein synthesis in Gram-negative bacilli – and, indeed, mammalian cells – is susceptible to fusidic acid, the antibiotic penetrates poorly into these cells and the spectrum of action is virtually restricted to Gram-positive bacteria, notably staphylococci.²⁵

LINEZOLID

Linezolid is a synthetic bacteriostatic agent that inhibits bacterial protein synthesis. It was previously believed that the drug prevented the formation of 70S initiation complexes. However, more recent analysis suggests that the drug interferes with the binding, or correct positioning, of aminoacyl-tRNA in the A site.¹⁴

MUPIROCIN

Mupirocin has a unique mode of action. The epoxide-containing monic acid tail of the molecule is an analog of isoleucine and, as such, is a competitive inhibitor of isoleucyl-tRNA synthetase in bacterial cells.²⁵⁻²⁷ The corresponding mammalian enzyme is unaffected.

INHIBITORS OF NUCLEIC ACID SYNTHESIS

Compounds that bind directly to the double helix are generally highly toxic to mammalian cells and only a few – those that interfere with DNA-associated enzymic processes – exhibit sufficient selectivity for systemic use as antibacterial agents. These compounds include antibacterial quinolones, novobiocin and rifampicin (rifampin). Diaminopyrimidines, sulfonamides, 5-nitroimidazoles and (probably) nitrofurans also affect DNA synthesis and will be considered under this heading.

QUINOLONES

The problem of packaging the enormous circular chromosome of bacteria (>1 mm long) into the cell requires it to be twisted into a condensed ‘supercoiled’ state – a process aided by the natural strain imposed on a covalently closed double helix. The twists are introduced in the opposite sense to those of the double helix itself and the molecule is said to be negatively supercoiled. During the process of DNA replication, the DNA helicase and DNA polymerase enzyme complexes introduce positive supercoils into the DNA to allow progression of the replication fork. Re-introduction of negative supercoils involves precisely regulated nicking and resealing of the DNA strands, accomplished by enzymes called topoisomerases. One topoisomerase, DNA gyrase, is a tetramer composed of two pairs of α and β subunits, and the primary target of the action of nalidixic acid and other quinolones is the α subunit of DNA gyrase, although another enzyme, topoisomerase IV, is also affected.²⁸ Indeed, in Gram-positive bacteria, topoisomerase IV seems to be the main target.²⁹ This enzyme does not have supercoiling activity; it appears to be involved in relaxation of the DNA chain and chromosomal segregation.

Although DNA gyrase and topoisomerase IV are the primary determinants of quinolone action, it is believed that the drugs bind to enzyme–DNA complexes and stabilize intermediates with double-stranded DNA cuts introduced by the enzymes. The bactericidal activity of the quinolones is believed to result from accumulation of these drug stabilized covalently cleaved intermediates which are not subject to rescue by DNA repair mechanisms in the cell.³⁰

The coumarin antibiotic novobiocin acts in a complementary fashion to quinolones by binding specifically to the β subunit of DNA gyrase.³¹

RIFAMPICIN (RIFAMPIN)

Rifampicin and other compounds of the ansamycin group specifically inhibit DNA-dependent RNA polymerase; that is, they prevent the transcription of RNA species from the DNA template. Rifampicin is an extremely efficient inhibitor of the bacterial enzyme, but fortunately eukaryotic RNA polymerase is not affected. RNA polymerase consists of a core enzyme made up of four polypeptide subunits, and rifampicin specifically binds to the β subunit where it blocks initiation of RNA synthesis, but is without effect on RNA polymerase elongation complexes. The structural mechanism for inhibition of bacterial RNA polymerase by rifampicin has recently been elucidated.³² The antibiotic binds to the β subunit in a pocket which directly blocks the path of the elongating RNA chain when it is two to three nucleotides in length. During initiation the transcription complex is particularly unstable and the binding of rifampicin promotes dissociation of short unstable RNA–DNA hybrids from the enzyme complex. The binding pocket for rifampicin, which is absent in mammalian RNA polymerases, is some 12 Å away from the active site.

SULFONAMIDES AND DIAMINOPYRIMIDINES

These agents act at separate stages in the pathway of folic acid synthesis and thus act indirectly on DNA synthesis, since the reduced form of folic acid, tetrahydrofolic acid, serves as an essential co-factor in the synthesis of thymidylic acid.³³

Sulfonamides are analogs of *p*-aminobenzoic acid. They competitively inhibit dihydropteroate synthetase, the enzyme that condenses *p*-aminobenzoic acid with dihydropteroic acid in the early stages of folic acid synthesis. Most bacteria need to synthesize folic acid and cannot use exogenous sources of the vitamin. Mammalian cells, in contrast, require preformed folate and this is the basis of the selective action of sulfonamides. The antileprotic sulfone dapsone, and the antituberculosis drug *p*-aminosalicylic acid, act in a similar way; the basis for their restricted spectrum may reside in differences of affinity for variant forms of dihydropteroate synthetase in the bacteria against which they act.

Diaminopyrimidines act later in the pathway of folate synthesis. These compounds inhibit dihydrofolate reductase, the enzyme that generates the active form of the co-factor tetrahydrofolic acid. In the biosynthesis of thymidylic acid, tetrahydrofolate acts as hydrogen donor as well as a methyl group carrier and is thus oxidized to dihydrofolic acid in the process. Dihydrofolate reductase is therefore crucial in recycling tetrahydrofolate, and diaminopyrimidines act relatively quickly to halt bacterial growth. Sulfonamides, in contrast, cut off the supply of folic acid at source and act slowly, since the existing folate pool can satisfy the needs of the cell for several generations.

The selective toxicity of diaminopyrimidines comes about because of differential affinity of these compounds for dihydrofolate reductase from various sources. Thus trimethoprim has a vastly greater affinity for the bacterial enzyme than for its mammalian counterpart, pyrimethamine exhibits a particularly high affinity for the plasmodial version of the enzyme and, in keeping with its anticancer activity, methotrexate has high affinity for the enzyme found in mammalian cells.

5-NITROIMIDAZOLES

The most intensively investigated compound in this group is metronidazole, but other 5-nitroimidazoles are thought to act in a similar manner. Metronidazole removes electrons from ferredoxin (or other electron transfer proteins with low redox potential) causing the nitro group of the drug to be reduced. It is this reduced and highly reactive intermediate that is responsible for the antimicrobial effect, probably by binding to DNA, which undergoes strand breakage.³⁴ The requirement for interaction with low redox systems restricts the activity largely to anaerobic bacteria and certain protozoa that exhibit anaerobic metabolism. The basis for activity against microaerophilic species such as *Helicobacter pylori* and *Gardnerella vaginalis* remains speculative, though a novel nitroreductase, which is altered in metronidazole-resistant strains, is implicated in *H. pylori*.³⁵

NITROFURANS

As with nitroimidazoles, the reduction of the nitro group of nitrofurantoin and other nitrofurans is a prerequisite for antibacterial activity. Micro-organisms with appropriate nitroreductases act on nitrofurans to produce a highly reactive electrophilic intermediate and this is postulated to affect DNA as the reduced intermediates of nitroimidazoles do. Other evidence suggests that the reduced nitrofurans bind to bacterial ribosomes and prevent protein synthesis.³⁶ An effect on DNA has the virtue of explaining the known mutagenicity of these compounds *in vitro* and any revised mechanism relating to inhibition of protein synthesis needs to be reconciled with this property.

AGENTS AFFECTING MEMBRANE PERMEABILITY

Agents acting on cell membranes do not normally discriminate between microbial and mammalian membranes, although the fungal cell membrane has proved more amenable to selective attack (*see below*). The only membrane-active antibacterial agents to be administered systemically in human medicine are polymyxin, the closely related compound colistin (polymyxin E) and the recently introduced cyclic lipopeptide daptomycin. The former have spectra of activity restricted to Gram-negative bacteria whereas daptomycin is active against Gram-positive bacteria, but inactive against Gram-negative species.

Polymyxin and colistin appear to act like cationic detergents, i.e. they disrupt the Gram-negative bacterial cytoplasmic membrane, probably by attacking the exposed phosphate groups of the membrane phospholipid. However, initial interaction with the cell appears to depend upon recognition by lipopolysaccharides in the outer membrane followed by translocation from the outer membrane to the cytoplasmic membrane.³⁷ The end result is leakage of cytoplasmic contents and death of the cell. Various factors, including growth phase and incubation temperature, alter the balance of fatty acids within the bacterial cell membrane, and this can concomitantly affect the response to polymyxins.³⁸

The cyclic lipopeptide daptomycin exhibits calcium-dependent insertion into the cytoplasmic membrane of Gram-positive bacteria, interacting preferentially with anionic phospholipids such as phosphatidyl glycerol.³⁹ It distorts membrane structure and causes leakage of potassium, magnesium and ATP from the cell together with membrane depolarization (Figure 2.5).^{40–42} Collectively these events lead to inhibition of macromolecular synthesis and bacterial cell death.^{41,42} Daptomycin is inactive against Gram-negative bacteria because it fails to penetrate the outer membrane. However, the basis of selective toxicity against the cytoplasmic membrane of Gram-positive bacteria as opposed to eukaryotic membranes is currently unclear.

ANTIFUNGAL AGENTS

The antifungal agents in current clinical use can be divided into the antifungal antibiotics (griseofulvin and polyenes) and a variety of synthetic agents including flucytosine, the azoles (e.g. miconazole, ketoconazole, fluconazole, itraconazole, voriconazole, posaconazole), the allylamines (terbinafine) and echinocandins (caspofungin, micafungin, anidulafungin).^{43–45}

In view of the scarcity of antibacterial agents acting on the cytoplasmic membrane, it is surprising to find that some of the most successful groups of antifungal agents – the polyenes, azoles and allylamines – all achieve their effects in this way.^{43–45} However, the echinocandins, the most recent antifungals introduced into clinical practice,⁴⁶ differ in affecting the synthesis of the fungal cell wall.^{45,47}

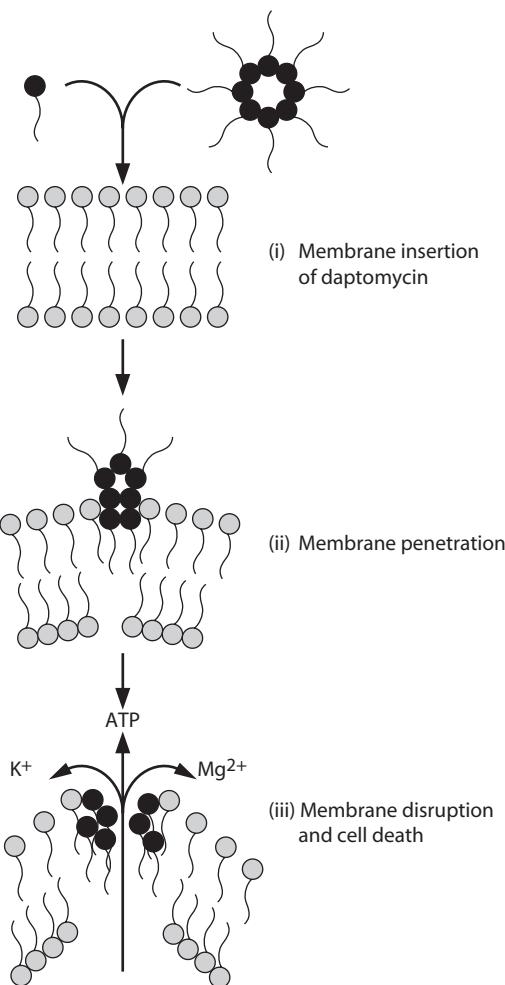

Fig. 2.5 A model for the mode of action of daptomycin in Gram-positive bacteria. (i) Daptomycin, in the presence of Ca²⁺, inserts into the cytoplasmic membrane either as an aggregate or as individual molecules that aggregate once within the membrane. (ii) Daptomycin penetrates the membrane and causes membrane curvature. (iii) Extensive membrane curvature and strain results in membrane disruption leading to leakage of intracellular components, membrane depolarization, loss of biosynthetic activity and cell death. Daptomycin (black-filled circles); phospholipids (gray-filled circles).

GRISEOFULVIN

The mechanism of action of the antidermatophyte antibiotic griseofulvin is not fully understood.⁴⁵ There are at least two possibilities:

- Inhibition of synthesis of the fungal cell wall component chitin
- Antimitotic activity exerted by the binding of drug to the microtubules of the mitotic spindle, interfering with their assembly and function.

POLYENES

The polyene antibiotics (nystatin and amphotericin B) bind only to membranes containing sterols; ergosterol, the predominant sterol of fungal membranes, appears to be particularly susceptible.^{45,47} The drugs form pores in the fungal membrane which makes the membrane leaky, leading to loss of normal membrane function. Unfortunately, mammalian cell membranes also contain sterols, and polyenes consequently exhibit a relatively low therapeutic index.

AZOLES

In contrast to the polyenes, whose action depends upon the presence of ergosterol in the fungal membrane, the antifungal azoles prevent the synthesis of this membrane sterol. These compounds block ergosterol synthesis by interfering with the demethylation of its precursor, lanosterol.^{45,48} Lanosterol demethylase is a cytochrome P₄₅₀ enzyme and, although azole antifungals have much less influence on analogous mammalian systems, some of the side effects of these drugs are attributable to such action.

Antifungal azole derivatives are predominantly fungistatic but some compounds at higher concentrations, notably miconazole and clotrimazole, kill fungi apparently by causing direct membrane damage. Other, less well characterized, effects of azoles on fungal respiration have also been described.⁴⁹

ALLYLAMINES

The antifungal allylamine derivatives terbinafine and naftifine inhibit squalene epoxidase, another enzyme involved in the biosynthesis of ergosterol.⁵⁰ Fungicidal effects may be due to the accumulation of squalene in the membrane leading to its rupture, rather than a deficiency of ergosterol. In *Candida albicans* the drugs are primarily fungistatic and the yeast form is less susceptible than is mycelial growth. In this species there is less accumulation of squalene than in dermatophytes, and ergosterol deficiency may be the limiting factor.⁵¹

ECHINOCANDINS

Caspofungin and related compounds inhibit the formation of glucan, an essential polysaccharide of the cell wall of many fungi, including *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*). The vulnerable enzyme is β-1,3-glucan synthase, which is located in the cell membrane.^{47,52}

FLUCYTOSINE (5-FLUOROCYTOSINE)

The spectrum of activity of flucytosine (5-fluorocytosine) is virtually restricted to yeasts. In these fungi flucytosine is transported into the cell by a cytosine permease; a cytosine

deaminase then converts flucytosine to 5-fluorouracil, which is incorporated into RNA in place of uracil, leading to the formation of abnormal proteins.⁴⁵ There is also an effect on DNA synthesis through inhibition of thymidylate synthetase.⁵³ The absence of major side effects in humans can be attributed to the lack of cytosine deaminase in mammalian cells.⁴⁵

ANTIPROTOZOAL AGENTS

The actions of some antiprotozoal drugs overlap with, or are analogous to, those seen with the antibacterial and antifungal agents already discussed. Thus, the activity of 5-nitroimidazoles such as metronidazole extends to those protozoa that exhibit an essentially anaerobic metabolism; the antimalarial agents pyrimethamine and cycloguanil (the metabolic product of proguanil), like trimethoprim, inhibit dihydrofolate reductase.

A number of antibacterial agents also have antiprotozoal activity. For instance the sulfonamides, tetracyclines, lincosamides and macrolides all display antimalarial activity, although they are most frequently used in combination with specific antimalarial agents. Some antifungal polyenes and antifungal azoles also display sufficient activity against *Leishmania* and certain other protozoa for them to have received attention as potential therapeutic agents.

There is considerable uncertainty about the mechanism of action of other antiprotozoal agents. Various sites of action have been ascribed to many of them and, with a few notable exceptions, the literature reveals only partial attempts to define the primary target.

ANTIMALARIAL AGENTS

QUINOLINE ANTIMALARIALS

Quinine and the various quinoline antimalarials were once thought to achieve their effect by intercalation with plasmoidal DNA after concentration in parasitized erythrocytes. However, these effects occur only at concentrations in excess of those achieved in vivo.⁵⁴ Moreover, a non-specific effect on DNA does not explain the selective action of these compounds at precise points in the plasmoidal life cycle or the differential activity of antimalarial quinolines.

Clarification of the mode of action of these compounds has proved elusive, but it now seems likely that chloroquine and related compounds act primarily by binding to ferriprotoporphyrin IX, preventing its polymerization by the parasite.^{54,55} Ferriprotoporphyrin IX, produced from hemoglobin in the food vacuole of the parasites, is a toxic metabolite which is normally rendered innocuous by polymerization.

Chloroquine achieves a very high concentration within the food vacuole of the parasite and this greatly aids its activity. However, quinine and mefloquine are not concentrated

to the same extent, and have much less effect on ferriproto-porphyrin IX polymerization, raising the possibility that other (possibly multiple) targets are involved in the action of these compounds.^{56,57}

8-Aminoquinolines like primaquine, which, at therapeutically useful concentrations exhibit selective activity against liver-stage parasites and gametocytes, possibly inhibit mitochondrial enzyme systems by poorly defined mechanisms. Furthermore, whether this action is due directly to the 8-aminoquinolines, or their metabolites, is unknown.⁵⁴

ARTEMISININ

Artemisinin, the active principle of the Chinese herbal remedy qinghaosu, and three derivatives of artemisinin are widely used antimalarial drugs.⁵⁴ These drugs are all converted in vivo to dihydroartemisinin which has a chemically reactive peroxide bridge.⁵⁴ This is cleaved in the presence of heme or free iron within the parasitized red cell to form a short-lived, but highly reactive, free radical that irreversibly alkylates malaria proteins.^{58,59} However, artemisinin may have other mechanisms of action, including modulation of the host's immune response.⁵⁹

ATOVAQUONE

The hydroxynaphthoquinone atovaquone, which exhibits anti-malarial and anti-*Pneumocystis* activity, is an electron transport inhibitor that causes depletion of the ATP pool. The primary effect is on the iron flavoprotein dihydro-orotate dehydrogenase, an essential enzyme in the production of pyrimidines. Mammalian cells are able to avoid undue toxicity by use of preformed pyrimidines.⁶⁰ Dihydro-orotate dehydrogenase from *Plasmodium falciparum* is inhibited by concentrations of atovaquone that are very much lower than those needed to inhibit the *Pneumocystis* enzyme, raising the possibility that the antimicrobial consequences might differ in the two organisms.⁶¹ Although atovaquone was originally developed as a monotherapy for malaria, high level resistance readily emerges in *Plasmodium falciparum* when the drug is used alone.⁵⁴ Consequently, atovaquone is now combined with proguanil.

OTHER ANTIPROTOZOAL AGENTS

Arsenical compounds, which are still the mainstay of treatment of African sleeping sickness, appear to poison trypanosomes by affecting carbohydrate metabolism through inhibition of glycerol-3-phosphate, pyruvate kinase, phosphofructokinase and fructose-2,6-biphosphatase.^{62,63} This is achieved through binding to essential thiol groups in the enzymes. This mechanism of action accounts for the poor selective toxicity of the arsenicals, since they also inhibit many mammalian enzymes through the same mechanism.⁶²

The actions of other agents with antitrypanosomal activity, including suramin and pentamidine, are also poorly characterized.^{62,64} Various cell processes, mainly those involved in glycolysis within the specialized glycosomes of protozoa of the trypanosome family, have been implicated in the action of suramin.⁶⁵ However, a variety of other unrelated biochemical processes are also inhibited.^{62,63} Consequently, the mode of action of suramin remains obscure. However, suramin appears to be more effectively accumulated by trypanosomes compared to mammalian cells and this may account for the selective toxicity of the drug.⁶²

Pentamidine and other diamidines disrupt the trypanosomal kinetoplast, a specialized DNA-containing organelle, probably by binding to DNA, though they also interfere with polyamine synthesis and have been reported to inhibit RNA editing in trypanosomes.^{61,62,65,66}

Laboratory studies of *Leishmania* are hampered by the fact that in-vitro culture yields promastigotes that are morphologically and metabolically different from the amastigotes involved in disease. Such evidence as is available suggests that the pentavalent antimonials commonly used for treatment inhibit ATP synthesis in the parasite.⁶⁷ Whether this is due to a direct effect of the antimonials or conversion to trivalent metabolites is uncertain.⁶⁷ Antifungal azoles take advantage of similarities in sterol biosynthesis among fungi and leishmanial amastigotes.⁶⁸

Eflornithine (difluoromethylornithine) is a selective inhibitor of ornithine decarboxylase and achieves its effect by depleting the biosynthesis of polyamines such as spermidine, a precursor of trypanothione.^{62,69} The corresponding mammalian enzyme has a much shorter half-life than its trypanosomal counterpart, and this may account for the apparent selectivity of action.⁶² The preferential activity against *Trypanosoma brucei gambiense* rather than the related *rhodesiense* form may be due to reduced drug uptake or differences in polyamine metabolism in the latter subspecies.⁷⁰

Several of the drugs used in amoebiasis, including the plant alkaloid emetine and diloxanide furoate appear to interfere with protein synthesis within amoebic trophozoites or cysts.⁷¹

ANTHELMINTIC AGENTS

Just as the cell wall of bacteria is a prime target for selective agents and the cell membrane is peculiarly vulnerable in fungi, so the neuromuscular system appears to be the Achilles' heel of parasitic worms. Several anthelmintic agents work by paralyzing the neuromusculature. The most important agents are those of the avermectin/milbemycin class of anthelmintics including ivermectin, milbemycin oxime, moxidectin and selamectin.⁷² These drugs bind to, and activate, glutamate-gated chloride channels in nerve cells, leading to inhibition of neuronal transmission and paralysis of somatic muscles in the parasite, particularly in the pharyngeal pump.^{72,73}

The benzimidazole derivatives, including mebendazole and albendazole, act by a different mechanism. These broad-spectrum anthelmintic drugs seem to have at least two effects

on adult worms and larvae: inhibition of the uptake of the chief energy source, glucose; and binding to tubulin, the structural protein of microtubules.^{74,75}

The basis of the activity of the antifilarial drug diethylcarbamazine has long been a puzzle, since the drug has no effect on microfilaria *in vitro*. Consequently it seems likely that the effect of the drug observed *in vivo* is due to alterations in the surface coat of the microfilariae, making them more responsive to immunological processes from which they are normally protected.^{76,77} This may be mediated through inhibition of arachidonic acid synthesis, a polyunsaturated fatty acid, present in phospholipids.⁷⁷

ANTIVIRAL AGENTS

The prospects for the development of selectively toxic anti-viral agents were long thought to be poor, since the life cycle of the virus is so closely bound to normal cellular processes. However, closer scrutiny of the relationship of the virus to the cell reveals several points at which the viral cycle might be interrupted.⁷⁸ These include:

- Adsorption to and penetration of the cell
- Uncoating of the viral nucleic acid
- The various stages of nucleic acid replication
- Assembly of the new viral particles
- Release of infectious virions (if the cell is not destroyed).

NUCLEOSIDE ANALOGS

In the event, it is the process of viral replication (which is extremely rapid relative to most mammalian cells) that has proved to be the most vulnerable point of attack, and most clinically useful antiviral agents are nucleoside analogs. Aciclovir (acycloguanosine) and penciclovir (the active product of the oral agent famciclovir), which are successful for the treatment of herpes simplex, achieve their antiviral effect by conversion within the cell to the triphosphate derivative. In the case of aciclovir and penciclovir, the initial phosphorylation, yielding aciclovir or penciclovir monophosphate, is accomplished by a thymidine kinase coded for by the virus itself. The corresponding cellular thymidine kinase phosphorylates these compounds very inefficiently and thus only cells harboring the virus are affected. Moreover, the triphosphates of aciclovir and penciclovir inhibit viral DNA polymerase more efficiently than the cellular enzyme; this is another feature of their selective activity. As well as inhibiting viral DNA polymerase, aciclovir and penciclovir triphosphates are incorporated into the growing DNA chain and cause premature termination of DNA synthesis.⁷⁹

Other nucleoside analogs – including the anti-HIV agents zidovudine, didanosine, zalcitabine, stavudine, lamivudine, abacavir and emtricitabine, and the anti-cytomegalovirus agents ganciclovir and valganciclovir are phosphorylated by cellular enzymes to form triphosphate derivatives.^{79,80} In their triphosphate forms the anti-HIV compounds are recognized by

viral reverse transcriptase and are incorporated as monophosphates at the 3' end of the viral DNA chain, causing premature chain termination during the process of DNA transcription from the single-stranded RNA template.^{79,80} Consequently, the triphosphate derivatives of the anti-HIV compounds act both as competitors of the normal deoxynucleoside substrates and as alternative substrates being incorporated into the DNA chain a deoxynucleoside monophosphates. Similarly, ganciclovir acts as a chain terminator during the synthesis of cytomegalovirus DNA.⁷⁹ Since these compounds lack a hydroxyl group on the deoxyribose ring, they are unable to form phosphodiester linkages in the viral DNA chain.⁷⁹⁻⁸¹ Ribavirin is also a nucleoside analog with activity against orthomyxoviruses (influenza A and B) and paramyxoviruses (measles, respiratory syncytial virus). In its 5' monophosphate form ribavirin inhibits inosine monophosphate dehydrogenase, an enzyme required for the synthesis of GTP and dGTP, and in its 5' triphosphate form it can prevent transcription of the influenza RNA genome.⁷⁹ *In vitro*, ribavirin antagonizes the action of zidovudine, probably by feedback inhibition of thymidine kinase, so that the zidovudine is not phosphorylated.⁸²

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

Although they are structurally unrelated, the non-nucleoside reverse transcriptase inhibitors nevirapine, delavirdine and efavirenz all bind to HIV-1 reverse transcriptase in a non-competitive fashion.^{79,80}

PROTEASE INHIBITORS

An alternative tactic to disable HIV is to inhibit the enzyme that cleaves the polypeptide precursor of several essential viral proteins. Such protease inhibitors in therapeutic use include saquinavir, ritonavir, indinavir, nelfinavir, amprenavir, lopinavir and atazanavir.^{79,80}

NUCLEOTIDE ANALOGS

The nucleotide analog cidofovir is licensed for the treatment of cytomegalovirus disease in AIDS patients.⁷⁹ It is phosphorylated by cellular kinases to the triphosphate derivative, which then becomes a competitive inhibitor of DNA polymerase.

PHOSPHONIC ACID DERIVATIVES

The simple phosphonoformate salt foscarnet and its close analog phosphonoacetic acid inhibit DNA polymerase activity of herpes viruses by preventing pyrophosphate exchange.⁷⁹ The action is selective in that the corresponding mammalian polymerase is much less susceptible to inhibition.

AMANTADINE AND RIMANTIDINE

The anti-influenza A compound amantadine and its close relative rimantidine act by blocking the M2 ion channel which is required for uptake of protons into the interior of the virus to permit acid-promoted viral uncoating (decapsidation).^{79,83}

NEURAMINIDASE INHIBITORS

Two drugs target the neuraminidase of influenza A and B viruses: zanamivir and oseltamivir. Both bind directly to the neuraminidase enzyme and prevent the formation of infectious progeny virions.^{79,83}

ANTISENSE DRUGS

Fomivirsen is the only licensed antisense oligonucleotide for the treatment of cytomegalovirus retinitis. The nucleotide sequence of fomivirsen is complementary to a sequence in the messenger RNA transcript of the major immediate early region 2 of cytomegalovirus, which is essential for production of infectious virus.⁷⁹

CONCLUSION

The modes of action of the majority of antibacterial, antifungal and antiviral drugs are well understood, reflecting our sophisticated knowledge of the life cycles of these organisms and the availability of numerous biochemical and molecular microbiological techniques for studying drug interactions in these microbial groups. In contrast, there are many gaps in our understanding of the mechanisms of action of antiprotozoal and anthelmintic agents, reflecting the more complex nature of these organisms and the technical difficulties of studying them.

Olivier Denis, Hector Rodriguez-Villalobos and Marc J. Struelens

Antibiotic resistance is increasing worldwide at an accelerating pace, reducing the efficacy of therapy for many infections, fuelling transmission of pathogens and majoring health costs, morbidity and mortality related to infectious diseases.¹ This public-health threat has been recognized as a priority for intervention by health agencies at national and international level.^{2,3} In this chapter we will address the definition of resistance, its biochemical mechanisms, genetic basis, prevalence in major human pathogens, epidemiology and strategies for control.

DEFINITION OF RESISTANCE

Antibiotic resistance definitions are based on in-vitro quantitative testing of bacterial susceptibility to antibacterial agents. This is typically achieved by determination of the minimal inhibitory concentration (MIC) of a drug; that is, the lowest concentration that inhibits visible growth of a standard inoculum of bacteria in a defined medium within a defined period of incubation (usually 18–24 h) in a suitable atmosphere (see Ch. 9). There is no universal consensus definition of bacterial resistance to antibiotics. This is related to two issues: first, the resistance may be defined either from a biological or from a clinical standpoint; secondly, different ‘critical breakpoint’ values for categorization of bacteria as resistant or susceptible were selected by national reference committees. In recent years, major advances toward international harmonization of resistance breakpoints have been made thanks to the consensus achieved within the European Committee for Antimicrobial Susceptibility Testing (EUCAST).⁴

According to the Clinical Laboratory Standards Institute (CLSI), formerly known as the US National Committee for Clinical and Laboratory Standards (NCCLS), infecting bacteria are considered *susceptible* when they can be inhibited by achievable serum or tissue concentration using a dose of the antimicrobial agent recommended for that type of infection and pathogen.⁴ This ‘target concentration’ will not only depend on pharmacokinetic and pharmacodynamic properties of the

drug (see Ch. 4), but also on recommended dose, which may vary by country. EUCAST⁵ developed distinct definitions for microbiological and clinical resistance. The *microbiological definition* of *wild type* (or naturally susceptible) bacteria includes those that belong to the most susceptible subpopulations and lack acquired or mutational mechanisms of resistance. The *definition of clinically susceptible* bacteria is those that are susceptible by a level of in-vitro antimicrobial activity associated with a high likelihood of success with a standard therapeutic regimen of the drug. In the absence of this clinical information, the definition is based on a consensus interpretation of the antibiotic’s pharmacodynamic and pharmacokinetic properties. The clinically susceptible category may include fully susceptible and borderline susceptible, or moderately susceptible, bacteria which may have acquired low-level resistance mechanism(s) (Figure 3.1).

Clinical resistance is defined by EUCAST as a level of antimicrobial activity associated with a high likelihood of therapeutic failure even with high dosage of a given antibiotic. EUCAST defines as *microbiologically resistant* bacteria that possess any resistance mechanism demonstrated either phenotypically or genotypically. These may be defined statistically by an MIC higher than the ‘epidemiological cut-off value’ that separates the normal distribution of wild type versus non-wild type bacterial strains, irrespective of source or test method.^{4–6}

The *clinically intermediate* (EUCAST) or *intermediate* (CLSI) category is used for bacteria with an MIC that lies between the breakpoints for clinically susceptible and clinically resistant. These strains are inhibited by concentrations of the antimicrobial that are close to either the usually or the maximally achievable blood or tissue level and for which the therapeutic response rate is less predictable than for infection with susceptible strains.⁶ This category also provides a technical buffer zone that should limit the probability of misclassification of bacteria in susceptible or resistant categories.

Some strains of species that are naturally susceptible to an antibiotic may *acquire* resistance to the drug. This phenomenon commonly arises when populations of bacteria have grown in the presence of the antibiotic which selects mutant

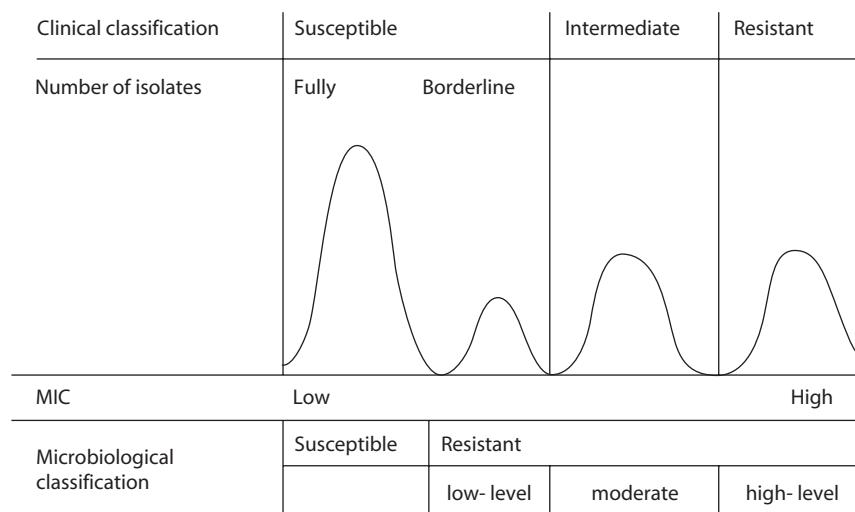

Fig. 3.1 Hypothetical distribution of MICs among clinical isolates of bacteria, classified clinically and microbiologically as susceptible or resistant. Adapted from European Committee for Antimicrobial Susceptibility Testing (EUCAST). Terminology relating to methods for the determination of susceptibility of bacteria to antimicrobial agents. *Clin Microbiol Infect.* 2000;6:503–508.⁶

strains that have increased their MIC by various adaptive mechanisms (*see below*). It may also result from horizontal gene transmission and acquisition of a resistance determinant, for example a β -lactamase, from a bacterial donor (*see below*). The range of MIC distribution of ‘clinically susceptible’ isolates of a given species may include ‘microbiologically resistant’ strains based on standard breakpoints, although revisions of breakpoints toward lower values have recently been made so as to minimize the probability of this occurring.⁷ In such cases it is important to demonstrate that the isolates have an acquired resistance mechanism (*see below*) not present in others. This is particularly crucial if clinical studies demonstrate that such ‘low-level resistant’ strains are associated with an increased probability of treatment failure, as shown for bacteremia caused by *Escherichia coli* and *Klebsiella pneumoniae* strains producing extended-spectrum β -lactamase treated with cephalosporins.⁸

Unfortunately, definitions that relate clinical response to microbiological susceptibility are less useful than might be expected because of the many confounding factors that may be present in patients. These range from relative differences of drug susceptibility dependent on the inoculum size and physiological state of bacteria grown in logarithmic phase *in vitro* versus those of biofilm-associated, stationary phase bacteria at the infecting site, limited distribution or reduced activity of the antibiotic in the infected site due to low pH or high protein binding, competence of phagocytic and immune response to the pathogen, presence of foreign body or undrained collections, to misidentification of the infective agent and straightforward sampling or testing error.

From an early stage in the development of antibacterial agents it became clear that a knowledge of antibiotic pharmacokinetics and pharmacodynamics could be used to bolster the inadequate information gained from clinical use (*see Ch. 4*). It is assumed that if an antibiotic reaches a

concentration at the site of infection higher than the MIC for the infecting agent, the infection is likely to respond. Depending on the antibiotic class, maximal antibacterial activity, including the killing rate, may be related either to the peak drug concentration over MIC ratio (as with the aminoglycosides) or to the proportion of the time interval between two doses when concentration is above the MIC (as with the β -lactams). Assays of antibiotics in sites of infection are complex and serum assays have been widely used as a proxy, even though there may be substantial intra- and interindividual variation depending on the patient’s pathophysiological conditions.

Different breakpoint committees have used different pharmacokinetic parameters in their correlations with pharmacodynamic characteristics. The approach of the CLSI has been based on wide consultation, and includes strong input from the antibiotic manufacturers. In Europe, EUCAST has harmonized antimicrobial MIC breakpoints and set those for new agents by consensus of professional experts from national committees. EUCAST clinical breakpoints are published together with supporting scientific rationale documentation.⁴ Clearly, international consensus on susceptibility breakpoints is progressing, thereby reducing the confusion created by a given strain to be labeled antibiotic susceptible in some countries and resistant in others.

MECHANISMS OF RESISTANCE

For an antimicrobial agent to be effective against a given micro-organism, two conditions must be met: a vital target susceptible to a low concentration of the antibiotic must exist in the micro-organism, and the antibiotic must penetrate the bacterial envelope and reach the target in sufficient quantity.

There are six main mechanisms by which bacteria may circumvent the actions of antimicrobial agents:

- Specific enzymes may inactivate the drug before or after it enters the bacterial cell.
- The bacterial cell envelope may be modified so that it becomes less permeable to the antibiotic.
- The drug may be actively expelled from the cell by transmembrane efflux systems.
- The target may be modified so that it binds less avidly with the antibiotic.
- The target may be bypassed by acquisition of a novel metabolic pathway.
- The target may be protected by production of protein which prevents the antibiotic reaching it.

However, these resistance mechanisms do not exist in isolation, and two or more distinct mechanisms may interact to determine the actual level of resistance of a micro-organism to an antibiotic. Likewise, *multidrug resistance* is increasingly common in bacterial pathogens. It may be defined as resistance to two or more drugs or drug classes that are of therapeutic relevance. More recently, the terms *extensive drug resistance* and *pan-drug resistance* have been introduced to describe strains that have only very limited or no susceptibility to any approved and available antimicrobial agent.⁹ Classically, *cross-resistance* is the term used for resistance to multiple drugs sharing the same mechanism of action or, more strictly, belonging to the same chemical class, whereas *co-resistance* describes resistance to multiple antibiotics associated with multiple mechanisms.

DRUG-MODIFYING ENZYMES

β -LACTAMASES

The most important mechanism of resistance to β -lactam antibiotics is the production of specific enzymes (β -lactamases).¹⁰ These diverse enzymes bind to β -lactam antibiotics and the cyclic amide bonds of the β -lactam rings are hydrolyzed. The open ring forms of β -lactams cannot bind to their target sites and thus have no antimicrobial activity. The ester linkage of the residual β -lactamase acylenzyme complex is readily hydrolyzed by water, regenerating the active enzyme. These enzymes have been classified based on functional and structural characteristics (see Table 15.1).¹¹

Among Gram-positive cocci, the staphylococcal β -lactamases hydrolyze benzylpenicillin, ampicillin and related compounds, but are much less active against the antistaphylococcal penicillins and cephalosporins. Among Gram-negative bacilli the situation is complex, as these organisms produce many different β -lactamases with different spectra of activity. All β -lactam drugs, including the latest carbapenems, are degraded by some of these enzymes, many of which have recently evolved through stepwise mutations selected in patients treated with cephalosporins. Several of these β -lactamases are increasing in prevalence among Gram-negative pathogens in many parts of the world. The most widely dispersed are the group 2b

extended-spectrum β -lactamases (ESBLs) that include those derived by mutational modifications from TEM and SHV enzymes as well as the CTX-M enzymes that originate from *Kluyvera* spp. ESBLs can hydrolyze most penicillins and all cephalosporins except the cephemycins. These enzymes are plasmid-mediated in Enterobacteriaceae, notably in *Esch. coli* isolates from both community and hospital settings, and *K. pneumoniae* strains from hospital epidemics in all continents.¹² Another group of problematic β -lactamases is the group 1, which includes both the AmpC type, chromosomal, inducible cephalosporinases in *Enterobacter*, *Serratia*, *Citrobacter* and *Pseudomonas aeruginosa* and similar plasmid-mediated enzymes that are now spreading among Enterobacteriaceae such as *Esch. coli* and *K. pneumoniae*.¹³ Both hyperproduction of the chromosomal enzyme and high-copy number plasmid encoded enzymes are causing an increasing prevalence of resistance to all β -lactam drugs except some carbapenems (see Chs 13 and 15). A third group of β -lactamases of emerging importance is the group 3 metalloenzymes that can hydrolyze all β -lactam drugs except monobactams.¹⁴ These β -lactamases, also called metallo-carbapenemases, include both diverse chromosomal enzymes found in aquatic bacteria such as *Stenotrophomonas maltophilia* and *Aeromonas hydrophila* and plasmid-mediated enzymes increasingly reported in clinical isolates of *Ps. aeruginosa*, *Acinetobacter* and Enterobacteriaceae in Asia, America and Europe.^{4,14} A group of β -lactamases that now constitute a major threat to available drug treatments is the class A, group 2f carbapenemases, of which KPC enzymes produced by *K. pneumoniae* have become widespread in parts of the USA and Europe.¹⁵ Likewise, many anaerobic bacteria also produce β -lactamases, and this is the major mechanism of β -lactam antibiotic resistance in this group. The classification and properties of β -lactamases are described more fully in Chapter 15.

AMINOGLYCOSIDE-MODIFYING ENZYMES

Much of the resistance to aminoglycoside antibiotics observed in clinical isolates of Gram-negative bacilli and Gram-positive cocci is due to transferable plasmid-mediated enzymes that modify the amino groups or hydroxyl groups of the aminoglycoside molecule (see Ch. 12). The modified antibiotic molecules are unable to bind to the target protein in the ribosome. The genes encoding these enzymes are often transposable to the chromosome. These enzymes include many different types of acetyltransferases, phosphotransferases and nucleotidyl transferases, which vary greatly in their spectrum of activity and in the degree to which they inactivate different aminoglycosides (see Ch. 12).¹⁶ Based on phylogenetic analysis, their origin is believed to be aminoglycoside-producing *Streptomyces* species. In recent years, the amikacin-modifying 6'-acetyltransferase tended to predominate and multidrug-resistant pathogens acquired multiple modifying enzymes, often combined with mechanisms of resistance such as

decreased uptake and active efflux (*see below*), rendering them resistant to all of the available aminoglycosides.

FLUOROQUINOLONE ACETYLTRANSFERASE

A plasmid-mediated mechanism of resistance to quinolones has been related to a unique allele of the aminoglycoside acetyltransferase gene designated as *aac(6')-Ib-cr*. Two amino acid substitutions in the AAC(6')-Ib-cr protein are associated with the capacity to *N*-acetylate ciprofloxacin at the amino nitrogen on its piperazinyl substituent, thereby increasing the MIC of ciprofloxacin and norfloxacin.¹⁷

CHLORAMPHENICOL ACETYLTRANSFERASE

The major mechanism of resistance to chloramphenicol is the production of a chloramphenicol acetyltransferase which converts the drug to either the monoacetate or the diacetate. These derivatives are unable to bind to the bacterial 50S ribosomal subunit and thus cannot inhibit peptidyl transferase activity. The chloramphenicol acetyltransferase (CAT) gene is usually encoded on a plasmid or transposon and may transpose to the chromosome. Surprisingly, in view of the very limited use of chloramphenicol, resistance is not uncommon, even in *Esch. coli*, although it is most frequently seen in organisms that are multiresistant.

LOCATION AND REGULATION OF EXPRESSION OF DRUG-INACTIVATING ENZYMES

In Gram-positive bacteria β -lactam antibiotics enter the cell easily because of the permeable cell wall, and β -lactamase is released freely from the cell. In *Staphylococcus aureus*, resistance to benzylpenicillin is caused by the release of β -lactamase into the extracellular environment, where it reduces the concentration of the drug. This is a population phenomenon: a large inoculum of organisms is much more resistant than a small one. Furthermore, staphylococcal penicillinase is an inducible enzyme unless deletions or mutations in the regulatory genes lead to its constitutive expression.

In Gram-negative bacteria the outer membrane retards entry of penicillins and cephalosporins into the cell. The β -lactamase needs only to inactivate molecules of drug that penetrate within the periplasmic space between the cytoplasmic membrane and the cell wall. Each cell is thus responsible for its own protection – a more efficient mechanism than the external excretion of β -lactamase seen in Gram-positive bacteria. Enzymes are often produced constitutively (i.e. even when the antibiotic is not present) and a small inoculum of bacteria may be almost as resistant as a large one. A similar functional organization is exhibited

by the aminoglycoside-modifying enzymes. These enzymes are located at the surface of the cytoplasmic membrane and only those molecules of aminoglycoside that are in the process of being transported across the membrane are modified.

ALTERATIONS TO THE PERMEABILITY OF THE BACTERIAL CELL ENVELOPE

The bacterial cell envelope consists of a capsule, a cell wall and a cytoplasmic membrane. This structure allows the passage of bacterial nutrients and excreted products, while acting as a barrier to harmful substances such as antibiotics. The capsule, composed mainly of polysaccharides, is not a major barrier to the passage of antibiotics. The Gram-positive cell wall is relatively thick but simple in structure, being made up of a network of cross-linked peptidoglycan complexed with teichoic and lipoteichoic acids. It is readily permeable to most antibiotics. The cell wall of Gram-negative bacteria is more complex, comprising an outer membrane of lipopolysaccharide, protein and phospholipid, attached to a thin layer of peptidoglycan. The lipopolysaccharide molecules cover the surface of the cell, with their hydrophilic portions pointing outwards. Their inner lipophilic regions interact with the fatty acid chains of the phospholipid monolayer of the inner surface of the outer membrane and are stabilized by divalent cation bridges. The phospholipid and lipopolysaccharide of the outer membrane form a classic lipid bilayer, which acts as a barrier to both hydrophobic and hydrophilic drug molecules. Natural permeability varies among different Gram-negative species and generally correlates with innate resistance. For example, the cell walls of *Neisseria* species and *Haemophilus influenzae* are more permeable than those of *Esch. coli*, while the walls of *Pseudomonas aeruginosa* and *Stenotrophomonas maltophilia* are markedly less permeable.

Hydrophobic antibiotics can enter the Gram-negative cell by direct solubilization through the lipid layer of the outer membrane, but the dense lipopolysaccharide cover may physically block this pathway. Changes in surface lipopolysaccharides may increase or decrease permeability resistance. However, most antibiotics are hydrophilic and cross through the outer membrane of Gram-negative cells via water-filled channels created by membrane proteins called porins. The rate of diffusion across these channels depends on size and physicochemical structure, small hydrophilic molecules with a zwitterionic charge showing the faster penetration. Some antimicrobial resistance in Gram-negative bacteria is due to reduced drug entry caused by decreased amounts of specific porin proteins, usually in combination with either overexpression of efflux pumps or β -lactamase production. This phenomenon is associated with significant β -lactam resistance, such as low-level resistance to imipenem in strains of *Ps. aeruginosa* and *Enterobacter* spp. that are hyperproducing chromosomal cephalosporinase and deficient in porins.^{18,19} Porin-deficient mutant strains emerge sporadically during therapy and were thought to be unfit to spread. However, multidrug-resistant, porin-deficient strains of *Ps. aeruginosa* have caused nosocomial outbreaks.²⁰

The target molecules of antibiotics that inhibit cell wall synthesis, such as the β -lactam antibiotics and the glycopeptides, are located outside the cytoplasmic membrane, and it is not necessary for these drugs to pass through this membrane to exert their effect. Most other antibiotics must cross the membrane to reach their intracellular sites of action. The cytoplasmic membrane is freely permeable to lipophilic agents such as minocycline, chloramphenicol, trimethoprim, fluoroquinolones and rifampicin (rifampin), but poses a significant barrier to hydrophilic agents such as aminoglycosides, erythromycin, clindamycin and the sulphonamides. These drugs are actively transported across the membrane by carrier proteins, and some resistances have been associated with various changes in these transporters. Resistance to aminoglycosides in both Gram-positive and Gram-negative bacteria may be mediated by defective uptake due to the mutational inactivation of proton motive force-driven cytoplasmic pump systems, a defect which is associated with slow growth rate and production of ‘small colony variants’.

RESISTANCE DUE TO DRUG EFFLUX

Single drug and multidrug efflux pumps have been recognized to be ubiquitous systems in micro-organisms, and have been found in all bacterial genomes.²¹ These systems are involved in the natural resistance phenotype of many bacteria. Furthermore, they may produce clinically significant acquired resistance by mutational modification of the structural gene, overexpression due to mutation in regulatory genes or horizontal transfer of genetic elements. Most of the bacterial efflux pumps belong to the class of secondary transporters

that mediate the extrusion of toxic compounds from the cytoplasm in a coupled exchange with protons.

Multidrug pumps can be subdivided into several superfamilies, including the major facilitator superfamily (MFS), small multidrug-resistance family (SMR), resistance-nodulation-cell division family (RND) and multidrug and toxic compound extrusion family (MATE) (Table 3.1). RND and MATE systems appear to function as detoxifying systems and transport heavy metals, solvents, detergents and bile salts, whereas MFS pumps are closely related to specific efflux pumps and appear to function as major Na^+/H^+ transporters. MFS and SMR pumps are mostly found in Gram-positive bacteria, whereas RND pumps are mostly found in Gram-negative bacteria, in which they function in association with special outer membrane channel proteins and periplasmic membrane fusion proteins, forming a tripartite transport system spanning both the inner and outer membranes (Table 3.1 and Figure 3.2). This allows the pumps to expel their substrates directly from the inner membrane or cytoplasm into the extracellular space. Although these pumps confer resistance mostly to a range of lipophilic and amphiphilic drugs (including β -lactams, fluoroquinolones, tetracyclines, macrolides and chloramphenicol) some pumps, such as MexY of *Ps. aeruginosa*, also transport aminoglycosides.

Among the best studied systems are the AcrB system of *Esch. coli* and the MexB system of *Ps. aeruginosa*. The AcrB pump is controlled by the Mar regulon, which is widespread among enteric bacteria. The MarA global activator, which can be derepressed by tetracycline or chloramphenicol, simultaneously upregulates the AcrAB-TolC transport complex and downregulates the synthesis of the larger porin OmpF, thereby acting in a synergistic manner to block the drug penetration

Table 3.1 Selected multidrug efflux systems determining multiple antibiotic resistance in pathogenic and commensal bacteria

Transporter		Associated proteins				
Class	Pump	Periplasmic	OM Channel	Regulator(s)	Organism	Antibiotic resistance profile
MFS	NorA	–	–	–	<i>Staphylococcus aureus</i>	Fluoroquinolones, chloramphenicol
MATE	NorM	–	–	–	<i>Vibrio parahaemolyticus</i>	Fluoroquinolones, aminoglycosides

into the cell. Constitutive overexpression of AcrAB is present in most ciprofloxacin-resistant *Esch. coli* clinical isolates.²² In *Ps. aeruginosa*, overexpression of the MexAB-OprM transport complex occurs commonly during β-lactam therapy by selection of mutants with altered specific repressor gene *mexR*. This increased efflux determines resistance to fluoroquinolones, penicillins, cephalosporins and meropenem. Another cause for concern is the selection of multidrug pumps by disinfectants such as triclosan, which is increasingly used in housekeeping products.

Active efflux of the drug from the bacterial cell is one of the major resistance mechanisms to tetracyclines, the second being 30S ribosome protection by elongation factor G-like proteins.²³ Efflux can be mediated either by tetracycline-specific efflux pumps or by multidrug transporter systems. Specific pumps of the TetA-E and TetG-H families are widespread in Gram-negative bacteria, whereas the specific pumps TetK and TetL are common in Gram-positive bacteria. These determinants are often encoded by genes located on plasmids or transposons. These specific pumps are single proteins located on the inner membrane that export the drug into the periplasm, in contrast with multidrug transporter systems that extrude tetracyclines from the cytoplasm directly outside the cell.

Specific efflux proteins have been shown to play a major role in macrolide resistance, including the Mef(A) transporters of the MFS that determine resistance to 14-C macrolides in pneumococci, β-hemolytic and oral streptococci and enterococci, and the Msr(A) ATP-binding transporters that confer resistance to erythromycin and streptogramin B in staphylococci.²⁴ The *mef* genes are located on conjugative elements that readily transfer across Gram-positive genera and species.

Finally, a plasmid-mediated QepA efflux pump belonging to the MFS transporters was recently shown to be capable of extruding hydrophilic fluoroquinolones and conferring low-level resistance to these drugs.²⁵

RESISTANCE DUE TO ALTERATIONS IN TARGET MOLECULES

β-LACTAM RESISTANCE DUE TO ALTERATIONS TO PENICILLIN-BINDING PROTEINS

These proteins are associated with the bacterial cell envelope and are the target sites for β-lactam antibiotics. Each bacterial cell has several penicillin-binding proteins (PBPs), which vary with the species. PBPs are transpeptidases, carboxypeptidases and endopeptidases that are required for cell-wall synthesis and remodeling during growth and septation. Some, but not all, PBPs are essential for cell survival (see Ch. 2). PBPs are related to β-lactamases, which also bind β-lactam antibiotics. However, unlike β-lactamases, PBPs form stable complexes with β-lactams and are themselves inactivated. β-Lactam antibiotics thus inactivate PBPs, preventing proper cell growth and division, and producing cell-wall defects that lead to death by osmotic lysis. Alterations in PBPs, leading to decreased binding affinity with β-lactam antibiotics, are important causes of β-lactam resistance in a number of species, most commonly Gram-positive bacteria.

Penicillin-resistant strains of *Streptococcus pneumoniae* produce one or more altered PBPs that have reduced ability to bind penicillin. Stepwise acquisition of multiple changes in the genes encoding these PBPs produce various levels of penicillin resistance.²⁶ The genetic sequences encoding normal PBPs in sensitive strains of *Str. pneumoniae* are highly conserved; the genes in resistant strains are said to be ‘mosaics’ since they consist of blocks of conserved sequences interspersed with blocks of variant sequences. As more variant blocks are introduced into the mosaic, the more penicillin resistant the recipient strain tends to become. These gene sequences have probably been derived by transformation from

oral streptococcal species such as *Str. mitis* and *Str. oralis*.²⁷ Whereas high-level resistance to penicillin involves changes in at least PBP 1a, PBP 2x and PBP 2a that require multiple transformation events, resistance to group 4 cephalosporins (see Ch. 13) can result from a single transformation event through co-transformation of the closely linked genes encoding PBP 1a and PBP 2x.

The relative penicillin resistance of enterococci is due to the normal production of PBPs with low binding affinity. The higher levels of penicillin and ampicillin resistance often seen in *Enterococcus faecium* are the result of overexpression of PBP 5 (which exhibits a lower affinity for penicillin than other PBPs), which can be further decreased by point mutations in the very high level resistant strains. Other species showing β -lactam resistance due to altered PBPs include group B *Streptococcus*, *Neisseria gonorrhoeae*, *N. meningitidis* and *Haemophilus influenzae*. The genes encoding altered PBPs in both *Neisseria* species appear to be mosaics, and the variant blocks may have been derived from *N. flavescens* and other commensal *Neisseria*.

Methicillin resistance in *Staph. aureus* and in coagulase-negative staphylococci is caused by an acquired chromosomal gene (*mecA*) which results in the synthesis of a fifth penicillin-binding protein (PBP 2a), with decreased affinity for methicillin and other β -lactam agents, in addition to the intrinsic PBP 1 to 4.²⁸ Many methicillin-resistant *Staph. aureus* (MRSA) strains exhibit heterogeneity in the expression of resistance, with only a small proportion of the total cell population expressing high-level resistance. The proportion of resistant cells is dependent on environmental conditions such as temperature and osmolality. This phenomenon is related to the presence of the regulatory loci *mecI* and *mecR1* upstream of *mecA*, which exhibit significant sequence and functional homology with the β -lactamase regulators *blaI*-*blaR1*. Deletion of these elements produces homogeneous expression of methicillin resistance. The *mecA* gene is located on an antibiotic resistance island, called the staphylococcal cassette chromosome *mec* (SCC*mec*), a mobile element driven by site-specific recombinases.²⁹

GLYCOPEPTIDE RESISTANCE DUE TO METABOLIC BYPASS

Glycopeptides are large hexapeptides that inhibit bacterial peptidoglycan synthesis by binding the carboxy-terminal D-alanyl-D-alanine dipeptide residue of the muramyl pentapeptide precursor, thereby blocking access to three key steps in the peptidoglycan polymerization: transglycosylation, transpeptidation and carboxypeptidation (see Ch. 2). Most clinically important Gram-positive bacteria build their peptidoglycan from this conserved pentapeptide precursor and are naturally sensitive to the glycopeptides vancomycin and teicoplanin. Acquired glycopeptide resistance was described in enterococci in 1986 and in coagulase-negative staphylococci in 1987. Decreased susceptibility and resistance to

vancomycin were reported in *Staph. aureus* in 1997 and 2003, respectively.

In enterococci, seven different glycopeptide resistance genotypes are now recognized:³⁰

1. VanA, inducible high-level transferable resistance to both vancomycin and teicoplanin; usually seen in *E. faecium*, sometimes in *E. faecalis* and rarely in *E. avium*, *E. hirae*, *E. casseliflavus*, *E. mundtii* and *E. durans*.
2. VanB, inducible low-level transferable resistance, usually to vancomycin alone; found in *E. faecium*, sometimes in *E. faecalis*.
3. VanC, constitutive low-level vancomycin resistance, seen in *E. gallinarum*, *E. casseliflavus* and *E. flavescentis*.
4. VanD, constitutive or inducible moderate-level resistance, usually to vancomycin alone; rarely acquired in *E. faecium*.
- 5–7. VanE, VanG and VanL, low-level resistance to vancomycin alone; rarely acquired in *E. faecalis*.

Enterococcal resistance to glycopeptides is due to multienzymatic metabolic bypass, mediated by replacement of the normal D-alanyl-D-alanine termini of peptidoglycan precursors by abnormal precursors with D-alanyl-D-lactate, or D-alanyl-D-serine termini, none of which can bind glycopeptides. The *vanA* gene cluster is carried by a 10.8 kb transposon (Tn1546) that contains nine functionally related genes encoding mobilization of the element (resolvase and transposase) and co-ordinated replacement of muramyl pentapeptides.³⁰ The *vanA* gene encodes an abnormal D-alanine-D-alanine ligase that synthesizes the D-alanine-D-lactate dipeptide. The *vanH* gene codes for a dehydrogenase that generates D-lactate. The *vanX* and *vanY* genes encode two enzymes that hydrolyze normal precursors: VanX, a D, D-dipeptidase that hydrolyzes D-alanyl-D-alanine dipeptides and VanY, a D, D-carboxypeptidase that cleaves terminal alanine from normal precursors. The *vanR* and *vanS* genes regulate the expression of the *vanHAX* operon through a two-component sensor system for glycopeptides. The *vanB* gene cluster has a similar organization, albeit with more heterogeneity, and is located on a large conjugative transposon (Tn1547) that is usually integrated in the chromosome and occasionally plasmid borne.

Over the past decade, the prevalence of glycopeptide resistance has increased markedly in clinical isolates of enterococci, particularly *E. faecium*, as a result of nosocomial spread of transposons, plasmids and multiresistant clones. In the USA, the *vanA* and *vanB* genotypes are widespread in many hospitals and frequently cause nosocomial infection but are rarely found in the community. In Europe, the *vanA* genotype was initially predominant in the healthy population and in farm animals due to the widespread use of avoparcin (a glycopeptide related to vancomycin) as a growth promoter between 1970 and 1998. The *vanA* gene cluster has been transferred experimentally to other Gram-positive bacteria where it is expressed.³¹ It has been found in clinical isolates of *Staph. aureus*, *Bacillus circulans*, *Oerskovia turbata*, and *Arcanobacterium haemolyticum*.

Glycopeptide resistance in *Staph. aureus* could be classified into low-level and high-level resistance. Since their first description in 1997 from Japan,³² vancomycin-intermediate *Staph. aureus* (VISA) isolates have been reported worldwide.^{30,33} These isolates were recovered in chronically ill patients failing prolonged glycopeptide therapy of infections with indwelling devices or undrained collections. In addition to VISA, other strains, named hetero-VISA, appear to be susceptible to vancomycin (MIC <4 mg/L) but exhibit low-level subpopulations (10^{-6} cells) able to grow at concentrations of 4–8 mg/L. Those strains could represent first-step mutants that develop into VISA strains under selective pressure. Recently, the CLSI lowered vancomycin breakpoints for staphylococci and many of these hetero-VISA isolates would now be accordingly reclassified as VISA.

Low-level resistance to glycopeptides in VISA strains has been associated with stepwise mutations in several loci, including global regulator systems, such as *agr*, *vra* and *gra*, and genes encoding proteins of the cell wall and membrane biosynthesis pathways.³⁰ Phenotypic abnormalities reported in VISA strains include increased cell-wall thickness, reduced autolytic activity, increased production of glutamine non-amidated muropeptides and D-Ala-D-Ala residues, and reduced peptidoglycan cross-linking.³³ These abnormalities suggest that the increased production of dipeptides acts as false targets which trap the antibiotic away from its lethal target site of cell-wall synthesis adjacent to the membrane. In addition, VISA strains show decreased susceptibility to daptomycin, despite its different mechanisms of action.

The experimental transfer of the *vanA* operon from *E. faecalis* to *Staph. aureus* by conjugation was reported in 1992. In 2002, the first clinical vancomycin-resistant *Staph. aureus* (VRSA) strain was isolated in the USA.³⁴ Since then, eight other cases have been confirmed in the USA.³⁴ All isolates carried the *vanA* gene on Tn1546-like elements integrated into staphylococcal plasmids and had an MIC to vancomycin ranging from 32 to 1024 mg/L. All patients with VRSA had a history of MRSA and vancomycin-resistant enterococci (VRE) co-colonization or infection; underlying conditions included chronic skin ulcers, diabetes, chronic renal failure and obesity.³⁵ Most had received vancomycin. No secondary transmission was observed after implementation of infection control measures.³⁵

AMINOGLYCOSIDE RESISTANCE DUE TO RIBOSOMAL MODIFICATION

Aminoglycoside resistance may be produced by alterations in specific ribosomal binding proteins or ribosomal RNA, although this is still uncommon in clinical isolates. Recently, plasmid-mediated 16S rRNA methylases that exert methylation of the G1405 residue of 16S rRNA have been reported to confer broad aminoglycoside co-resistance in Gram-negative bacilli due to loss of affinity for these drugs.³⁶ These

determinants, especially ArmA, are commonly found in association with CTX-M ESBL production.

QUINOLONE RESISTANCE DUE TO ALTERED TOPOISOMERASES

The main targets for quinolones are the type II topoisomerase DNA gyrase and type IV topoisomerase, both of which are essential enzymes involved in chromosomal DNA replication and segregation (see Ch. 2). Fluoroquinolones exert their bactericidal action by trapping topoisomerase–DNA complexes, thereby blocking the replication fork. Both of these structurally related target enzymes are tetrameric. DNA gyrase is composed of two pairs of GyrA and GyrB subunits while topoisomerase type IV is composed of two pairs of the homologous ParC and ParE subunits.

Bacterial resistance to fluoroquinolones is generally mediated by chromosomal mutations leading either to reduced affinity of DNA gyrase and/or topoisomerase IV, or to over-expression of endogenous MDR efflux systems (see above).³⁷ Plasmid-mediated resistance was first reported in *K. pneumoniae*.³⁸ The commonest target-resistance modifications arise from spontaneous mutations, occurring at a frequency of 1 in 10^6 to 1 in 10^9 cells, that substitute amino acids in specific domains of GyrA and ParC subunits and less frequently in GyrB and ParE. These regions of the enzymes, called the quinolone resistance-determining regions, either contain the active site, a tyrosine that covalently binds to DNA, or constitute parts of quinolone binding sites.

Fluoroquinolones have different potencies of antibacterial activity against different bacteria, a variance which is to a large part related to the different potency against their enzyme targets. The more sensitive of the two enzymes is the primary target. In general, DNA gyrase is the primary target in Gram-negative bacteria and topoisomerase IV is the primary target in Gram-positive bacteria. Resistance develops progressively by stepwise mutations. The first step in increasing resistance level results from amino acid change in the primary target and is followed by second-step mutational modifications of amino acid in the secondary target. The higher the difference in drug potency against the two enzymes, the higher the MIC increase provided by first-step mutation. Fluoroquinolones with a low therapeutic index (defined as the drug concentration at the infected site divided by the MIC of that drug) are more likely to select first-step mutants. This explains why resistance to quinolones has emerged rapidly after the introduction of ciprofloxacin and ofloxacin for human therapeutics in two species, *Ps. aeruginosa* and *Staph. aureus*, which develop significant resistance after only a single mutation in *gyrA*. In *Staph. aureus*, fluoroquinolone resistance quickly became associated with methicillin resistance. This was the consequence of two factors: increased likelihood of exposure of multiresistant strains to therapy with these drugs, leading to multiple mutations and high-level resistance; and the further selective advantage for nosocomial spread conferred by this resistance.³⁹ In organisms

in which multiple mutational changes are required to reach clinical resistance to these drugs, such as *Esch. coli*, *Campylobacter jejuni* and *N. gonorrhoeae*, it appeared later and was accelerated by other epidemiological factors. For *C. jejuni*, this was related to the massive use of the cross-selecting fluoroquinolone enrofloxacin in the poultry industry followed by food-borne transmission to humans.⁴⁰ For *N. gonorrhoeae*, the emergence of fluoroquinolone resistance was soon followed by outbreaks of person-to-person transmission.

MLS AND LINEZOLID RESISTANCE DUE TO RIBOSOMAL MODIFICATION

Macrolides inhibit protein synthesis by dissociation of the peptidyl-tRNA molecule from the 50S ribosomal subunit. Macrolides bind to a ribosomal site that overlaps with the binding site of the structurally unrelated lincosamide and streptogramin B antibiotics. The most common type of acquired resistance to erythromycin and clindamycin (and other macrolides and lincosamides) is seen in streptococci, enterococci and staphylococci, and is called macrolide-lincosamide-streptogramin B (MLS_B) resistance. This is due to the production of enzymes that methylate a specific adenine residue in 23S rRNA, resulting in reduced ribosomal binding of the three antibiotic classes.²⁴ Low concentrations of erythromycin induce resistance to all the macrolides and lincosamides (so-called 'dissociated' resistance), but some strains may produce the methylase constitutively following mutations or deletions in the regulatory genes. More than 20 *erm* genes encode MLS_B resistance. Most are located on conjugative and non-conjugative transposons that predominantly insert in the chromosome and are occasionally plasmid borne. They are frequently associated with other resistance genes, particularly those encoding tetracycline resistance by ribosomal protection. Increased use of macrolides has been related to spread of MLS_B resistance in group A β-hemolytic streptococci and pneumococci.⁴¹

Linezolid is an oxazolidinone which acts on Gram-positive bacteria by ribosome inhibition following fixation on a 23S rRNA residue which is specific to the attachment of *N*-formylmethionyl transfer RNA (fMet-tRNA). In staphylococci, linezolid resistance can be mediated by mutations of the target 23S rRNA gene or by horizontal acquisition of the *cfr* gene which encodes an rRNA methyltransferase. Mutations in the domain V region of 23S rDNA, particularly G2447T, T2500A and G2576T, have been associated with resistance to linezolid.⁴² The level of linezolid resistance correlates with the number of 23S rRNA genes carrying the point mutations. The *cfr* gene encodes for a 23S rRNA methyltransferase which confers cross-resistance to oxazolidinones, lincosamides, streptogramin A, phenicols and pleuromutilins but not to macrolides. This enzyme involves methylation of 23S rRNA at position A2503.⁴³ The *cfr* gene is carried on plasmids in *Staph. aureus* and coagulase-negative staphylococci (CNS). In enterococci, linezolid resistance is conferred

by mutation of the domain V region (mutation G2576T) of 23S rRNA.

In bacteria with a low copy number of ribosomal operons, such as the mycobacteria and *C. jejuni* and *Helicobacter pylori*, macrolide resistance is commonly caused by mutational modification of the 23S rRNA peptidyl transferase region at the same adenine that is modified by *erm* methylases or adjacent nucleotides (A2057 to A2059). In most other bacteria, such mutations are recessive due to multi-copy rRNA genes.

RIFAMPICIN (RIFAMPIN) RESISTANCE DUE TO MODIFICATION OF RNA POLYMERASE

Rifampicin resistance is commonly the result of a mutation that alters the β-subunit of RNA polymerase, reducing its binding affinity for rifampicin. Mutation usually produces high-level resistance in a single step, but intermediate resistance is sometimes seen. Mutational resistance occurs relatively frequently, and for this reason rifampicin is combined with other agents for the treatment of tuberculosis and staphylococcal infection. Meningococcal carriers treated with rifampicin alone have readily shown the emergence of rifampicin resistance.

MUPIROCIN RESISTANCE DUE TO METABOLIC BYPASS

Mupirocin (pseudomonic acid) is widely used for topical treatment of Gram-positive skin infections and the clearance of nasal carriers of methicillin-sensitive and methicillin-resistant *Staph. aureus*. It acts by inhibiting bacterial isoleucyl-tRNA synthetase, and resistance is mediated by the production of modified enzymes. Isolates showing low-level resistance have a single chromosomally encoded synthetase modified by point mutation, while those with high-level resistance have a second enzyme that cannot bind the drug and is encoded on a transferable plasmid.⁴⁴

SULFONAMIDE AND TRIMETHOPRIM RESISTANCE DUE TO METABOLIC BYPASS

Acquired sulfonamide resistance is usually due to the production of an altered dihydropteroate synthetase that has reduced affinity for sulfonamides. Resistance is encoded on transferable plasmids and associated with transposons. Trimethoprim resistance occurs much less commonly. It is usually due to plasmid-mediated synthesis of new dihydrofolate reductases, which are much less susceptible to trimethoprim than the

natural ones. The resistance genes are again associated with transposons.

FUSIDIC ACID RESISTANCE DUE TO MODIFICATION OF ELONGATION FACTOR G

Fusidic acid acts by inhibiting protein synthesis by interfering with ribosome translation. Mutation alteration of the target molecule, the elongation factor G (EF-G), confers resistance by decreasing the affinity of fusidic acid to its target.⁴⁵ This occurs at high frequency in *Staph. aureus* in vitro, and therefore it is recommended that fusidic acid should not be used alone to treat staphylococcal infections. Resistance to fusidic acid can also result from the horizontal acquisition of the *fusB* gene which encodes an EF-G binding protein that protects the translation from inhibition by fusidic acid.⁴⁵

FAILURE TO METABOLIZE THE DRUG TO THE ACTIVE FORM

Both metronidazole and nitrofurantoin must be converted to an active form within the bacterium before they can have any effect. Resistance arises if the pathogen cannot effect this conversion. Aerobic organisms cannot reduce metronidazole to its active form and are therefore inherently resistant, but resistance in anaerobic organisms is very uncommon. Resistant strains of *Bacteroides fragilis* that have been investigated have reduced levels of pyruvate dehydrogenase; the enzyme necessary for the reduction of metronidazole to the active intermediate. Nitrofurantoin must be reduced to an active intermediate by nicotinamide adenine dinucleotide (NADH) or nicotinamide adenine dinucleotide phosphate (NADPH) reductases. Resistance to nitrofurans is uncommon, since such strains must lose more than one reductase to become resistant.

TARGET PROTECTION

In 1998, the plasmid-encoded Qnr protein was discovered in *K. pneumoniae* and shown to increase fluoroquinolone MICs eight-fold to 64-fold below the level of the clinical resistance breakpoint.³⁸ Since then, four types of *qnr* gene have been described: *qnrA* (six variants), *qnrB* (19 variants), *qnrC* and *qnrD* (one variant each), and *qnrS* (three variants). Qnr proteins are capable of binding and protecting DNA gyrase and type IV topoisomerase from quinolone inhibition. They show a global distribution across a variety of plasmids and bacterial genera. Recent homology data suggest that they have originated from environmental bacteria.⁴⁶ Their prevalence is unknown but can exceed 20% among ESBL-producing Enterobacteriaceae, mostly in association with CTX-M and CMY enzymes.¹⁷

GENETIC BASIS OF RESISTANCE

INTRINSIC RESISTANCE

Resistance of bacteria to antimicrobial agents may be intrinsic or acquired. Intrinsic resistance to some antibiotics is the natural resistance possessed by most strains of a bacterial species and is part of their genetic make-up, encoded on the chromosome. Intrinsic multiresistance is characteristic of free-living organisms, which may have evolved because of metabolic polyvalence and exposure to natural antibiotics and other toxic compounds in the environment. Multiresistance is due mostly to decreased antibiotic uptake by highly selective outer membrane porins and multiple efflux systems. Although these organisms have low virulence, their multiresistance allows them to persist in hospital environments and cause nosocomial infections. An example of a free-living opportunistic pathogen with a high degree of intrinsic resistance is *Ps. aeruginosa*.

MUTATIONAL RESISTANCE

Acquired resistance may be due to mutations affecting genes on the bacterial chromosome, to acquisition of mobile foreign genes or to mutation in acquired mobile genes. Mutations usually involve deletion, substitution or addition of one or a few base pairs, causing substitution of one or a few amino acids in a crucial peptide. Mutational resistance can affect the structural gene coding for the antibiotic target. This usually results in a gene product with reduced affinity for the antibiotic. An example is fluoroquinolone resistance from alterations in DNA topoisomerases. Mutational resistance can also involve regulatory loci, leading to overproduction of detoxifying systems such as the multiple resistance expressed by the MexAB-OprD efflux pump overproducing mutants of *Ps. aeruginosa*.

Although the basal rate of mutation is low in bacterial genomes, it is not constant but varies by a factor of 10 000 according to a number of intrinsic and external factors.⁵ Among these factors are the sequence of the gene, with some hypermutable loci associated with short tandem repeats that are prone to deletions and duplications by slipped-strand mispairing; the mutator phenotype associated with a defective mismatch repair system; and stress-induced mutagenesis, including exposure to antibiotics and host defenses. Once a resistant mutant has been selected during exposure to the antibiotic, it usually shows a decreased fitness for competing with the wild-type ancestor, defined as the competitive efficiency of multiplication in the absence of the antibiotic. This deficiency is called the biological cost of resistance. It has been observed, however, that this reduction in fitness may be compensated by secondary mutations in other chromosomal loci, thereby ensuring the persistence of the mutant. The probability that antibiotic treatment will select a resistant

mutant depends on a complex network of factors including the drug, its concentration, the organism, its resistance mutation rate, inoculum size, physiological state and structure of the bacterial population.⁴⁷

TRANSFERABLE RESISTANCE

Horizontal spread of a resistance gene from organism to organism occurs by conjugation (intercellular passage of plasmid or transposon), transduction (DNA transfer via bacteriophage) or transformation (uptake of naked DNA). The acquisition of resistance by transduction is rare in nature (the most important example is the transfer of the penicillinase plasmid in *Staph. aureus*). Transformation of resistance factors is an important mechanism in the few bacterial species that are readily transformable during part of their life cycle and are said to be naturally competent. These organisms, which include *Str. pneumoniae*, *H. influenzae*, *Helicobacter*, *Acinetobacter*, *Neisseria* and *Moraxella* spp., show extensive genetic variation resulting from natural transformation. They may also acquire chromosomally encoded antimicrobial resistance. Examples, as discussed above, include penicillin- or ampicillin-resistant *Str. pneumoniae* and *N. meningitidis* that acquired mosaic genes for the production of altered PBPs by transformation and site-specific recombination from phylogenetically related, co-resident commensal bacteria.

PLASMIDS

These are molecules of DNA that replicate independently from the bacterial chromosome. 'R-plasmids' carry one or more genetic determinants for drug resistance. This type of resistance is due to a dominant gene, usually one resulting in production of a drug-inactivating or drug-modifying enzyme.

Conjugation is the most common method of resistance transfer in clinically important bacteria.⁴⁸ Conjugative plasmids, which are capable of self-transmission to other bacterial hosts, are common in Gram-negative enteric bacilli, whereas non-conjugative plasmids are common in Gram-positive cocci, *H. influenzae*, *N. gonorrhoeae* and *Bacillus fragilis*. Non-conjugative plasmids can transfer to other bacteria if they are mobilized by conjugative plasmids present in the same cell, or by transduction or transformation. Large plasmids are usually present at one or two copies per cell, and their replication is closely linked to replication of the bacterial chromosome. Small plasmids may be present at more than 30 copies per cell, and their distribution to progeny during cell division is ensured by the large number present.

Plasmids tend to have a restricted host range: for example, those from Gram-negative bacteria cannot generally transfer to or maintain themselves in Gram-positive organisms, and vice versa. Conjugative transfer of plasmids has been observed, however, between these distant bacterial groups and even between bacteria and eukaryotic cells such as yeasts.

TRANSPOSONS

These are discrete sequences of DNA, capable of translocation from one replicon (plasmid or chromosome) to another – hence the epithet 'jumping gene'. They may encode genes for resistance to a wide variety of antibiotics, as well as many other metabolic properties. They are circular segments of double-stranded DNA, 4–25 kb in length, and usually consist of a functional central region flanked by long terminal repeats, usually inverted repeats. Complex transposons also carry genes for the transposition enzymes transposase and resolvase and their repressors. They need not share extensive regions of homology with the replicon into which they insert, as is required in classic genetic recombination. Depending upon the transposon involved, they may transpose into a replicon randomly or into favored sites, and they may insert at only a few or at many different places.

A special type of element, called a conjugative transposon, can transfer directly between the chromosome of one strain to the chromosome of another without a plasmid intermediate. Antibiotics can function as pheromones that are capable of inducing conjugation of conjugative transposons that in turn mobilize the transfer of co-resident R-plasmids. These transposons are less restrictive than plasmids in the host range. A well-studied example is Tn416, which has spread the *tetM* gene from Gram-positive cocci to diverse bacteria such as *Neisseria*, *Mycoplasma* and *Clostridium*.⁴⁹

Other important genetic elements by which transposons and plasmids acquire multiple antibiotic resistance determinants are called integrons. These are site-specific recombination systems that recognize and capture antibiotic resistance gene cassettes in a high-efficiency expression site.^{48,50} The structure of class 1 integrons (Figure 3.3) includes an integrase gene (*int*), an adjacent integration site (*attI*) that can contain one or more gene cassettes, and one or more promoters. Class 1 integrons, the most frequently observed type, also contain a 3' conserved segment that includes the genes encoding resistance to quaternary ammonium compounds (*qacEΔ*) and sulfonamides (*sulI*). The integrase is capable of excision and integration of up to five gene cassettes, each of which is associated with a related 59 bp palindromic element that acts as a recombination hotspot. Gene cassettes include determinants of β-lactamases, aminoglycoside-modifying enzymes, chloramphenicol acetyltransferase and trimethoprim-resistant DFR enzymes. Integrons are widespread among antibiotic-resistant clinical isolates of diverse Gram-negative species and have also been reported in Gram-positive bacteria. The genetic linkage of resistance to sulfonamides and to newer antibiotics in these integrons may explain the persistence of sulfonamide resistance in *Esch. coli* in spite of a huge decrease in sulfonamide use.⁵¹ Likewise, mercury released from dental amalgams has been suggested to select for antibiotic resistance in the oral and intestinal flora of humans because of the physical linkage between integron

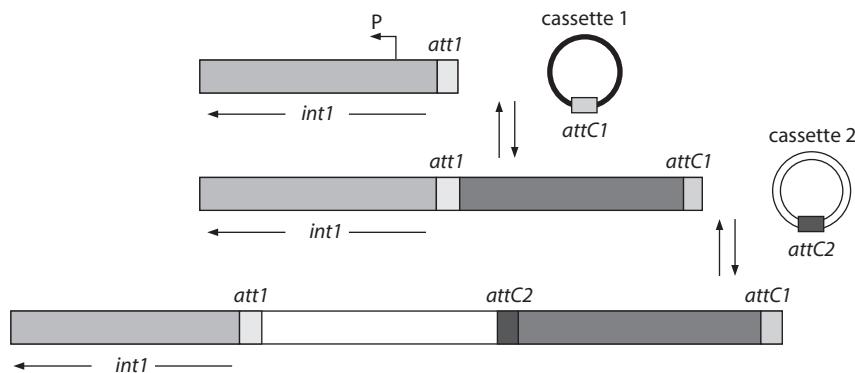

Fig. 3.3 Integron structure and gene cassette movement. The *int1* gene encodes the integrase that mediates site-specific integration of circular gene cassettes between the *att1* and *attC* sites. P denotes the common promoter. Adapted from Ploy MC, Lambert T, Couty JP et al. Integrons: an antibiotic resistance gene capture and expression system. *Clin Chem Lab Med.* 2000;38:483–487.⁵⁰

and mercury resistance in the ubiquitous Tn21-like transposons.⁵² Clearly, transposons and integrons are responsible for much of the diversity observed among plasmids, and play a major role in the evolution and dissemination of antibiotic resistance among bacteria.^{49,52}

STAPHYLOCOCCAL CASSETTE CHROMOSOME

Staphylococcal cassette chromosome (SCC) elements are always inserted in one copy into a specific region of the *Staph. aureus* genome, the attBsc at the 3' end of the *orfX* gene, near the origin of replication. They carry recombinase (*ccr*) genes that catalyze excision and integration of the element. The mechanism of horizontal transfer of SCC elements between staphylococci is unknown. The SCC elements may encode antibiotic resistance genes such as the SCCmec and SCCfar for methicillin and fusidic acid resistance, respectively.

The SCCmec elements have been grouped into types I–VIII, which range in size from 20.9 kb to 66.9 kb (Figure 3.2)^{53,54} They are classified according to the combination of *ccr* genes and *mec* complex that they carry. Five major *mec* complexes (A–E) have been described but only three (A–C) have been identified in *Staph. aureus*. The *mec* complexes differ by integration of IS1272 and IS431 elements and by deletion of *mecI* and a part of *mecR*. The *ccr* genes are classified into five allotypes which have been designated *ccrAB1*, *ccrAB2*, *ccrAB3*, *ccrAB4* and *ccrC*. The SCCmec type III prototype is a composite element that consists of the recombination of two SCC elements, i.e. SCCmec type III and SCCmercury. The SCCmec complexes often carry plasmids (e.g. pUB110, pI258 and pT181) and transposons (e.g. Tn554 and ΨTn554) integrated into them.

The SCCmec elements also comprise three junkyard (J) regions. The variations in the J regions within the same *mec* and *ccr* combination define the SCCmec subtypes within a type.

CURRENT THERAPEUTIC PROBLEMS WITH RESISTANCE

STAPHYLOCOCCUS AUREUS

Approximately 85% of *Staph. aureus* are resistant to penicillin by plasmid-mediated β-lactamase. During the 1950s, large epidemics of hospital infection were caused by ‘the hospital staphylococcus’, a virulent strain of *Staph. aureus* resistant to penicillin, tetracycline, erythromycin, chloramphenicol and other drugs. After the introduction of the penicillinase-stable penicillins, the incidence of hospital infection with multiresistant staphylococci gradually declined during the 1960s and 1970s. Although strains of methicillin-resistant *Staph. aureus* (MRSA) were seen as early as 1961, gentamicin-resistant MRSA emerged later as a major pathogen of hospital infection in the 1980s. Since then, MRSA has continued to increase in prevalence in several countries, including the USA, UK and countries in Southern and Eastern Europe, but was well contained in others such as Scandinavian countries and the Netherlands (Figure 3.4). Epidemic strains of MRSA have been associated with large nosocomial outbreaks spreading to whole regions by interhospital transfer of colonized patients or staff.^{55,56} Deep-seated MRSA infections have been associated with increased mortality compared with oxacillin-susceptible *Staph. aureus* infection in some settings.⁵⁷ After becoming endemic in many acute care hospitals in the 1980s and 1990s, MRSA strains have disseminated into long-term care facilities which have become a reservoir of carriers. In the 1990s, community-acquired (CA-) MRSA infections have been reported from Australia, the USA and Europe in populations lacking previous contact with healthcare facilities.⁵⁸ CA-MRSA strains are unrelated to nosocomial strains and frequently produce the Panton–Valentine leukocidin (PVL) exotoxin. Recently, MRSA carriage has been reported with unexpected high prevalence among livestock animals, farmers and veterinarians in Europe and the USA.⁵⁹ These MRSA strains appear clonal and unrelated to either nosocomial or CA-MRSA clones.

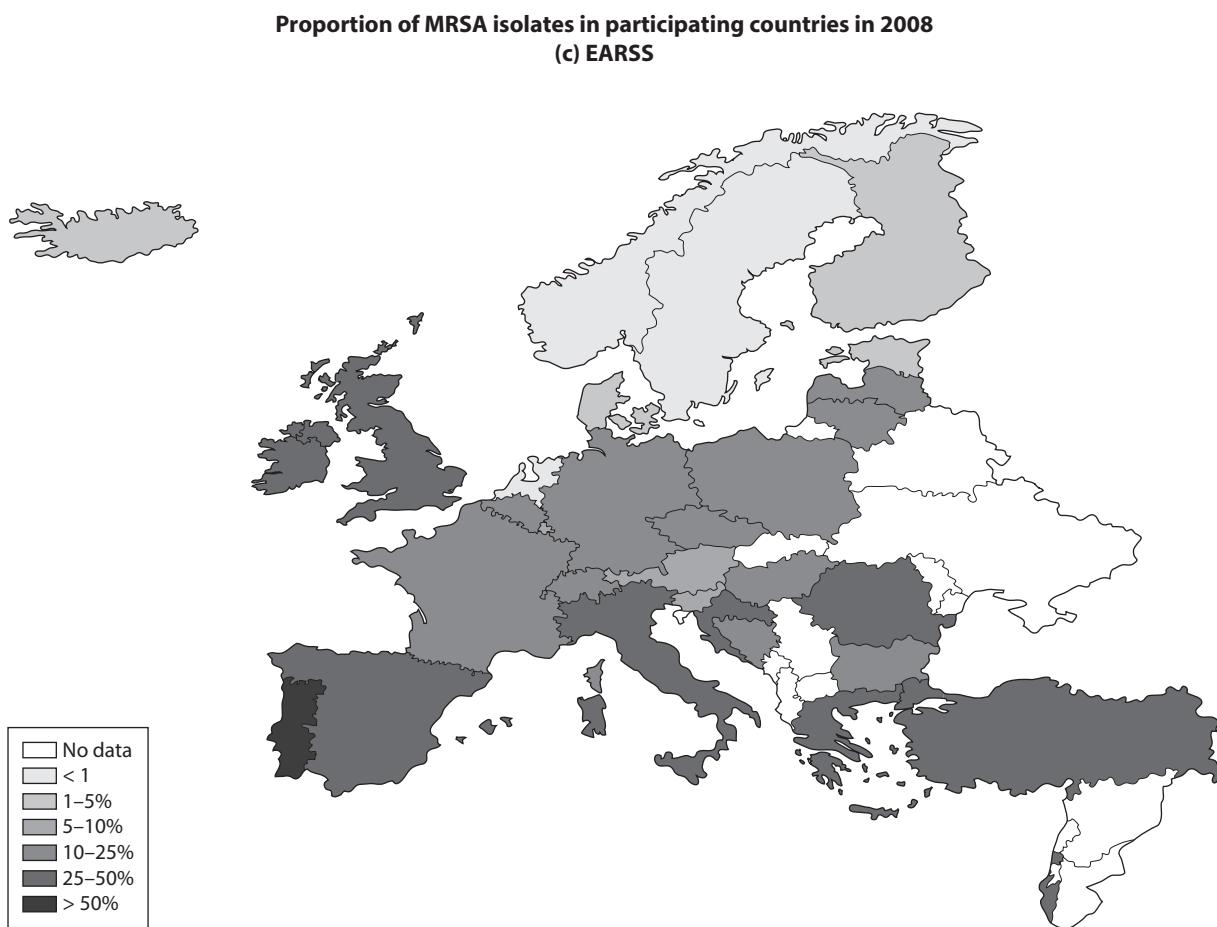

Fig. 3.4 Proportion of methicillin-resistant *Staph. aureus* isolates from bloodstream infections, EARSS participating countries, 2008.
 Available at <http://www.earss.rivm.nl>.

MRSA strains have become multiresistant by a number of mechanisms. The chromosomal DNA region harboring the *mecA* gene, the staphylococcal cassette chromosome *mec*, contains a number of insertion sites. These permit the accumulation of multiple mobile genetic elements encoding resistance to other classes of antibiotics such as macrolides, lincosamides, streptogramins, sulfonamides and tetracyclines. In addition, MRSA may acquire other resistances encoded on plasmids and transposons, including β -lactamase production and resistance to trimethoprim and the aminoglycosides. Aminoglycoside resistance is mediated by at least six aminoglycoside-modifying enzymes. Following the rapid emergence of mutational resistance to quinolones and to other drugs such as rifampicin and mupirocin, fuelled by clonal spread,⁵⁹ many strains of MRSA remain sensitive only to the glycopeptides vancomycin and teicoplanin. The recent recognition of MRSA strains with reduced susceptibility or high resistance to glycopeptides (see above) is likely to further complicate therapy of serious staphylococcal infection. Among the recently available antistaphylococcal antibiotics, such as linezolid, quinupristin-dalfopristin, tigecycline and daptomycin, partial or full resistance by mutational mechanisms has already been reported in clinical isolates.

COAGULASE-NEGATIVE STAPHYLOCOCCI

These organisms are important causes of nosocomial infections associated with prosthetic and indwelling devices. In the community, people are normally colonized by relatively sensitive strains of *Staph. epidermidis*; after admission to hospital and treatment with antibiotics, patients often become colonized with more resistant strains of *Staph. epidermidis* or *Staph. haemolyticus*. A majority of coagulase-negative staphylococci isolated in hospitals show multiple antibiotic resistance, including resistance to methicillin (and other β -lactams), gentamicin and quinolones. *Staph. haemolyticus* frequently shows low-level, inducible, teicoplanin resistance.⁶⁰ Multiresistant strains may act as a reservoir of resistance genes that can be transferred to *Staph. aureus* and enterococci.

ENTEROCOCCI

The enterococci are naturally sensitive to ampicillin, but are intrinsically relatively resistant to other β -lactams such as cloxacillin, the cephalosporins and the carbapenems. They

are also usually resistant to trimethoprim and the sulfonamides, quinolones and aminoglycosides. These organisms have a remarkable ability to acquire new resistances to ampicillin, vancomycin and teicoplanin, chloramphenicol, erythromycin, tetracyclines, high levels of aminoglycosides and clindamycin.⁶¹

E. faecalis is the most common enterococcal species to be isolated from clinical specimens, but *E. faecium* is increasing in frequency. *E. faecium* is inherently more resistant to penicillin and ampicillin than *E. faecalis*, and hospital isolates tend to show increasing high-level resistance due to altered PBPs (see above). The production of β-lactamase and the overproduction or alteration of penicillin-binding proteins has been reported in ampicillin-resistant *E. faecalis* strains that have caused large hospital outbreaks in the USA.⁶²

In the USA, acquired vancomycin resistance increased more than 40-fold among nosocomial isolates of enterococci, from 0.3% in 1989 to over 70% in 2007.⁶³ This rise followed an increase by more than 100-fold in the use of vancomycin in hospitals in the last 20 years. Initially, clonal epidemics of vancomycin-resistant enterococci broke out in intensive care units and later in whole hospitals. This was followed by spread of resistance plasmids and transposons among multiple strains of *E. faecium* and *E. faecalis*.⁶¹ In Europe, the incidence of nosocomial infection caused by VRE varies widely from <1% to >40%.³⁰ Outbreaks have also been reported in Europe, especially in hematological, transplant and intensive care units. Transmission occurs by cross-contamination via the hands of healthcare personnel and the environment, and is enhanced by exposure to therapy with glycopeptides, cephalosporins and drugs with anti-anaerobic activity.⁶⁴ The phylogenetic analysis of a large collection of *E. faecium* isolates from humans and animals showed the worldwide expansion of complex-17 lineage causing hospital outbreaks and characterized by ampicillin resistance and specific virulence factors.⁶⁵

In the USA, most of the vancomycin-resistant strains are resistant to all other available antimicrobials, making therapy extremely difficult and requiring combinations of drugs or the use of new drugs such as quinupristin–dalfopristin, daptomycin and linezolid.⁶³ Resistance to these new antimicrobials has already been reported in clinical isolates. As the consumption of linezolid increased, several outbreaks of linezolid- and vancomycin-resistant *E. faecium* have been reported in hematological and transplant wards in Europe and the USA.⁶⁶ In a meta-analysis of enterococcal bloodstream infection, the mortality attributable to the infection was independently associated with vancomycin resistance, although the specific impact of antibiotic therapy is difficult to ascertain because of the severity of the underlying disease.⁶⁷

STREPTOCOCCUS PNEUMONIAE

Acquired multidrug resistance in *Str. pneumoniae* has become a worldwide health problem, with increasing incidence of resistance to β-lactams, macrolides, lincosamides and tetracyclines

in most parts of the world in the last three decades.^{68–71} The MIC of penicillin for sensitive strains of pneumococci is <0.01 mg/L; the first penicillin-resistant isolates, reported in 1967 from Papua New Guinea, showed ‘low-level’ resistance with MICs of up to 1 mg/L, but in 1977 pneumococci were isolated in South Africa showing ‘high-level’ resistance with penicillin MICs of >1 mg/L. High-level penicillin resistance has so far been confined to a few serotypes, whereas low-level resistance is now found in nearly all the common serotypes. There is a wide geographical variation in the prevalence of penicillin-resistant pneumococci, even between regions of a particular country.

There is conclusive evidence of international spread of multiresistant clones, such as the Spanish serotype 23F clone that was apparently ‘exported’ from Spain to the USA.⁷² Several serotypes, showing multiresistance, significantly decreased in incidence after the introduction of the 7-valent conjugate vaccine in both the USA and Europe.⁶⁹ These strains were replaced by non-vaccine serotypes such as the multidrug-resistant serotype 19A in the USA and Europe.⁷⁰ According to two recent worldwide surveys and Europe-wide surveillance data (<http://www.eurss.rivm.nl>), in some countries, such as in Northern Europe, only a few percent of pneumococcal isolates show low-level penicillin resistance and high-level resistance is rare; however, in other countries such as France, Poland, Turkey, Israel and the USA, 25% or more of isolates are penicillin resistant, of which up to 15% of isolates are high-level resistant.⁷¹ In recent surveys, resistance to third-generation cephalosporins varied between <1% and 15%.^{70,71}

A high prevalence (from 10% to >50%) of macrolide resistance among *Str. pneumoniae* strains is reported from all continents. The predominant mechanisms of resistance to macrolides are ribosomal methylation conferred by the *ermB* gene, followed by drug efflux pump encoded by the *mefA* gene.⁷³ In North America, macrolide resistance is more frequently caused by MefA, which does not affect lincosamides. However, the proportion of isolates positive for both ErmB and MefA is increasing. In Europe and the Asia-Pacific regions the predominant mechanism of resistance is ErmB conferring the MLS_B phenotype. There is a strong association of co-resistance to penicillin, macrolides, lincosamides, chloramphenicol, tetracycline and co-trimoxazole.

The resistance of *Str. pneumoniae* to fluoroquinolones is due to chromosomal mutations in the DNA gyrase (*gyrA* and *gyrB*) and topoisomerase IV (*parC* and *parE*) and/or active efflux. Both mechanisms have so far been reported at low prevalence (<1%) in a majority of countries but with higher frequency in China (4–14%), Japan (0.5–6%) and Italy (6%).⁷⁴ This is a cause for concern, given the usefulness of newer generation fluoroquinolones for the treatment of lower respiratory tract infections.

Respiratory and bloodstream infections with strains of pneumococci showing low- to moderate-level penicillin resistance (MIC <4.0 mg/L) can be treated with high doses of penicillin, amoxicillin or cephalosporins as there is no firm evidence that this level of penicillin resistance is associated

with increased risk of treatment failure. On the other hand, meningitis treatment failures have been documented in infections with even low-level penicillin-resistant strains. Therefore, initial treatment of meningitis in areas with high levels of penicillin and cephalosporin resistance includes high-dose cefotaxime or ceftriaxone in association with vancomycin. Both drugs should be continued in case of infection with cefotaxime-intermediate resistant pneumococci (MIC of 1.0 mg/L), and rifampicin should be added if the cefotaxime MIC is ≥ 2 mg/L (see Ch. 50).

HAEMOPHILUS INFLUENZAE

Ampicillin resistance due to plasmid-mediated TEM-1 β -lactamase production was first noted in 1972, and is now widespread, ranging from 3% in Germany to 65% in South Korea in lower respiratory and blood specimens. The prevalence of β -lactamase-producing strains rose in the 1990s, followed by a subsequent decline in the 2000s in the USA, Canada, Japan and Spain.⁷⁵ In 1981, Rubin et al. reported a novel β -lactamase in *H. influenzae*, later called ROB-1.⁷⁶ The recent prevalence of this enzyme varies greatly (from 4% to 30%) and was found with the highest frequency in Mexico and USA.⁷³

β -Lactamase-negative, ampicillin-resistant (BLNAR) strains are associated with changes in penicillin-binding proteins, especially PBP 3. This form of ampicillin resistance appears to be globally rare (<0.5%) but was reported locally at much higher rates (10–40%) in recent surveys from Europe and Japan, possibly due to differences in the methods and definitions used.⁷⁵ Cephalosporins and amoxicillin-clavulanate remain very active (>99% sensitivity), as are fluoroquinolones, tetracyclines, rifampicin and chloramphenicol. Rates of chloramphenicol resistance in excess of 10% were occasionally found in some Latin American and Asian countries. Co-trimoxazole resistance rates vary markedly by region, with the highest rates reported from Latin America, the Middle East and Spain (about 30%), followed by Eastern Europe and North America (10–20%).

NEISSERIA MENINGITIDIS

The emergence of sulfonamide resistance in *N. meningitidis*, due to mutational or recombinational modification of the target dihydropteroate synthase, emerged in the early 1960s and is now widespread. Of greater concern today is the emergence of penicillin resistance. The MIC of penicillin for meningococci is usually <0.08 mg/L, but this may be increased in moderately susceptible isolates up to 0.5 mg/L. These strains were first reported in the 1960s but have increased in frequency in some countries, especially in Spain. This low-level penicillin resistance is due to alterations in PBP 2, with a mosaic gene structure arising as a result of transformation from commensal *Neisseria* species. In the 1990s, Spain suffered a clonal

epidemic associated with a moderately susceptible penicillin strain that accounted for more than 60% of invasive serogroup C isolates. There are only scant clinical data indicating that meningitis with the moderately susceptible meningococcal strains may be associated with penicillin treatment failures. Third-generation cephalosporins remain very active on these strains. In addition, β -lactamase production by meningococci has been reported in four cases and appears to be encoded on a gonococcal plasmid. Chloramphenicol resistance has been reported recently from Vietnam and was determined by a *catP* gene located on a defective transposon from *Clostridium perfringens*. Although up to 10% of carriers treated with rifampicin are subsequently found to harbor rifampicin-resistant meningococci, caused by a point mutation in the *rpoB* gene, such strains remain extremely rare in invasive disease. Four cases of meningococcal disease caused by ciprofloxacin-resistant *N. meningitidis* serogroup B have been reported in the USA.⁷⁷ They were caused by the same strain which revealed a *gyrA* mutation that was possibly acquired by horizontal gene transfer from the commensal *N. lactamica*.⁷⁷

NEISSERIA GONORRHOEAE

Low-level resistance to benzylpenicillin (MIC 0.1–2 mg/L) has been increasing in strains of *N. gonorrhoeae* for several decades, and is now very common. This type of resistance is due to mutational alterations in the penicillin-binding proteins PBP 1 and PBP 2 and to impermeability associated with alteration of PI porin. Alterations in *penA* genes conferring decreased susceptibility to third-generation oral cephalosporins has been documented in Japan, Hong Kong and the Western Pacific Region.⁷⁸ Since 1976, a high-level plasmid-mediated type of resistance to penicillin, caused by production of TEM-1 β -lactamase, appeared in South East Asia and West Africa and spread to Western countries.⁷⁹ These penicillinase-producing strains of *N. gonorrhoeae* remain common (30–65%) in many developing countries, but account for only 5–10% of gonococcal isolates in the West. Low-level resistance to tetracyclines is often associated with multiple resistance to penicillin, erythromycin and fusidic acid. It is caused by mutational derepression of the MtrRCDE efflux system.²¹ Plasmid-mediated high-level resistance to all tetracyclines, including doxycycline, determined by the ribosomal protection protein TetM carried on a transposon, emerged in 1985. It has reached a high prevalence, which unfortunately reduces the clinical utility of this group of drugs for the treatment of dual infection with gonococci and chlamydia.⁸⁰ Spectinomycin resistance, due to mutational alteration of the 30S ribosomal subunit, remains rare. Resistance to fluoroquinolones, due to GyrA and/or ParC mutational alteration, emerged in several countries during the 1990s and increased globally by clonal spread to reach prevalence rates up to 94% in South East Asia and more than 50% in some European countries.⁸⁰ This dramatic increase in resistance has markedly reduced the value of fluoroquinolones for empirical treatment of urethritis.

ESCHERICHIA COLI

Acquired resistance to ampicillin is conferred to *Esch. coli* by a plasmid-encoded, Tn3-associated TEM-1 β-lactamase. First described in 1965, this mobile gene has spread so extensively throughout the world that 40–60% of both hospital and community strains are now resistant by this mechanism. Up to 50% of these ampicillin-resistant organisms are also resistant to the combination of amoxicillin with clavulanic acid, either because of hyper-production of TEM-1 β-lactamase or by production of a mutant, inhibitor-resistant TEM enzyme. Other plasmid-encoded β-lactamases are seen in *Esch. coli* with increasing frequency, including extended-spectrum β-lactamases of the TEM, SHV and AmpC families. Fluoroquinolone resistance in *Esch. coli* is an increasingly common problem in Europe and has reached prevalence rates as high as 50% in Turkey, and 40% in Hong Kong. Intestinal carriage was found in 25% of healthy individuals in Spain.⁸¹ Fluoroquinolone-resistant *Esch. coli* is particularly common in patients with complicated urinary tract infections and in neutropenic patients developing bacteremia during fluoroquinolone prophylaxis.

Esch. coli has been recognized as the major source of ESBLs with a higher increase in prevalence in the community than in the hospital setting.¹² This increase was initially due to the spread of multiple clones harboring different CTX-M enzymes into diverse genetics elements (integrons and transposons). These enzymes show higher hydrolyzing activity against cefotaxime than ceftazidime. They display high homology with chromosomal β-lactamases from *Kluyvera* species. The insertion sequences ISEcp1 and Orf513 contribute to their mobilization. Among the CTX-M, CTX-M-15 is the predominant enzyme found in the community and in long-term care facilities. This enzyme harbors the Asp240Gly substitution that confers an eight-fold higher level of resistance to ceftazidime than its parental CTX-M-3 enzyme. CTX-M-15 *Esch. coli* has emerged globally by acquisition of epidemic plasmids into highly virulent strains of the B2 phylogenetic subgroup, sequence type ST131, serogroup O25:H4.⁸² Co-resistance to fluoroquinolones is frequently mediated by *qnr* genes and *aac* (6')-*Ib-cr* in these ESBL-producing strains.

In addition to ESBL, new variants of cephalosporinases called extended-spectrum AmpC (ESAC) β-lactamases, which confer resistance against oxyimino-cephalosporins including cefepime and cefpirome, have been described since 1995 in *Ent. cloacae*, *Serratia marcescens* and *Esch. coli*.⁸³ Plasmid-encoded AmpC enzymes conferring resistance to third-generation cephalosporins (such as CMY-2) have become frequent in the USA but remain rare in Europe. Resistance to carbapenems by metallo-β-lactamase production (VIM-1) has been reported sporadically in clinical *Esch. coli* isolates from Spain and Greece.

KLEBSIELLA, ENTEROBACTER AND SERRATIA spp.

These organisms are intrinsically resistant to ampicillin, and *Enterobacter* and *Serratia* spp. are resistant to older cephalosporins. They all have the ability to cause hospital outbreaks of opportunistic infection, and they often exchange plasmid-borne resistances. *K. pneumoniae* is the most common nosocomial pathogen of the three, and appears to have the greatest ability to receive and disseminate multiresistance plasmids. The ampicillin resistance of *K. pneumoniae* is mediated by chromosomal SHV-1 β-lactamase. In the 1970s, organisms carrying plasmid-borne aminoglycoside resistance often caused large outbreaks of hospital infection and sometimes disseminated their resistances to *Enterobacter*, *Serratia* and other enterobacterial species. These outbreaks diminished when the newer cephalosporins and aminoglycosides became available.

Starting in the mid-1980s in Europe and Latin America and in the 1990s in the USA, hospital outbreaks due to *K. pneumoniae* with resistance to third-generation cephalosporins by plasmid-borne production of extended-spectrum β-lactamases (ESBL) were reported, particularly in intensive care units (ICUs). ESBL-encoding plasmids were also transferred to *K. oxytoca*, *Citrobacter* spp., *Esch. coli*, *Proteus mirabilis* and *Enterobacter* spp. Pan-European surveys in ICUs showed that the proportion of ESBL-producing klebsiellae varies markedly by hospital and by country, from 3% in Sweden to 60% in Turkey.⁸⁴ Co-resistance to aminoglycosides, co-trimoxazole, tetracyclines and fluoroquinolones is common.

Resistance to carbapenems has been reported increasingly in *K. pneumoniae* (Figure 3.5). In the majority of cases, this was related to the spread of plasmid-encoded class A carbapenemases (KPC) and class B carbapenemases (VIM), especially in *K. pneumoniae*.¹⁵ Less commonly, carbapenem-resistant Enterobacteriaceae were due to high-level production of cephalosporinase- or oxacillinase-mediated resistance combined with other β-lactamases and porin mutation.⁸⁵ The *K. pneumoniae* carbapenemase (KPC) was initially reported in North Carolina in 1996 and subsequently worldwide.¹⁵ Six variants of the *bla*_{KPC1/2} gene have been reported. Although these enzymes confer decreased susceptibility to all β-lactams, impaired outer membrane permeability is often required to achieve full resistance to carbapenems. The *bla*_{KPC} genes have been identified within a Tn3-type transposon (Tn4001) in large transferable plasmids. These plasmids frequently carry aminoglycoside determinants and have been associated with ESBL (CTX-M-15) and the quinolone-resistance proteins QnrA and QnrB. Co-resistance to other non-β-lactam antibiotics limits therapeutic options for these strains. The *bla*_{KPC} genes have been reported in other Enterobacteriaceae (*Enterobacter* spp., *Esch. coli*, *K. oxytoca*, *C. freundii*, *P. mirabilis*, *Salmonella* spp. and *S. marcescens*) and at chromosomal and plasmid locations in *Ps. aeruginosa*.

**Proportion of carbapenems-resistant *K. pneumoniae* isolates in participating countries in 2008
(c) EARSS**

Fig. 3.5 Proportion of carbapenem-resistant *K. pneumoniae* isolates from bloodstream infections, EARSS participating countries, 2008.
Available at <http://www.earss.rivm.nl>.

The KPC-producing bacteria are widespread in the USA, Israel, China, Latin America and Greece, but remain rare in western and northern Europe.¹⁵ Since 2001 sporadic isolates and small outbreaks of multiresistant VIM-producing *K. pneumoniae* have been reported in some European countries (France, Spain, Italy, Greece, Turkey and Belgium). In several cases these strains were traced back to patient transfer from hospitals in Greece, where the proportion of resistance to imipenem increased from <1% in 2001 to >70% in isolates from ICUs and to >20% in isolates from hospital wards from 2001 to 2007 (<http://www.earss.rivm.nl>). Co-resistance to colistin has been reported in some of these strains, leaving very few active therapeutic options.

About 30% of hospital isolates of *Enterobacter* spp. show cephalosporinase hyperproduction.⁸⁴ In the 1990s, ESBL-producing (mostly TEM-24), multiresistant *Ent. aerogenes* strains emerged as a common cause of nosocomial infection in France, Spain and Belgium. Epidemic strains were first reported in ICUs and have since disseminated hospital-wide to cause large regional epidemics.⁸⁶ Many of these ESBL-producing strains remain susceptible only to carbapenems, which are the drugs of choice for treatment of serious infection with these organisms. In *Enterobacter* strains with high-level cephalosporinase combined with ESBL production,

however, emergence of porin-resistant mutants during imipenem therapy may lead to treatment failure, requiring the use of colistin or doxycycline for infections with strains resistant to all β -lactams and fluoroquinolones.⁸⁷ The resistance to carbapenems by enzymes of class A (SME, IMI, NMC, GES) and Class B (IMP, VIM, SPM) in species such as *Ent. cloacae*, *K. oxytoca*, *Citrobacter* spp., *P. mirabilis*, *Providencia stuartii* and *S. marcescens* is a growing problem worldwide.¹⁴

SHIGELLA

Shigellae were among the first organisms to be shown in the 1950s to harbor transferable antibiotic resistance determinants on conjugative plasmids. In developing countries, rates of multiple resistance are high, with >50% of isolates resistant to ampicillin, chloramphenicol, tetracycline, co-trimoxazole or nalidixic acid. In the last few years, fluoroquinolone resistance in *Shigella* spp. increased in the Indian subcontinent as a result of both *gyrA* and *parC* mutations,⁸⁸ compromising the use of fluoroquinolones as the first line of treatment for dysentery in that region. Multiresistance is most common in *Shigella dysenteriae*, followed by *Shigella flexneri* and *Shigella*

sonnei. In developed countries rates of resistance are higher in shigellosis patients with a history of travel abroad.

SALMONELLA

Salmonella enterica serotype Typhi has developed multiple resistance to first-line antibiotics in many developing countries. In the 1970s, strains with plasmid-mediated resistance to ampicillin and chloramphenicol caused epidemics in Latin America. In the 1980s, strains with plasmid-mediated resistance to ampicillin, chloramphenicol and co-trimoxazole emerged in South East Asia and have since become widespread in Asia and Latin America, where rates of 30–70% multiresistant *Salmonella* Typhi were reported in the 1990s. Fluoroquinolone resistance is now emerging in MDR strains and has been associated with recent outbreaks of typhoid fever in Tajikistan, Vietnam and the Indian subcontinent. The proportion of *Salmonella* Typhi with low-level resistance to ciprofloxacin showed a rapid increase to more than 20% in 1999 in the UK, and was mostly seen in travelers returning from the Indian subcontinent.⁸⁹

In the 1990s, multiple resistance also rose rapidly in non-typhoidal salmonellae in Europe and in the USA. There is conclusive evidence that antibiotics used in animal husbandry have contributed to antibiotic resistance in human isolates. In the UK and other European countries, the incidence of human infections with multiresistant *Salmonella* ser. Typhimurium DT104 resistant to ampicillin, chloramphenicol, streptomycin, co-trimoxazole and tetracycline increased markedly during the period 1990–1996, at a time when penicillin and tetracycline were commonly used in cattle feed. In Denmark, an outbreak of food-borne salmonellosis caused by a multidrug and low-level fluoroquinolone-resistant *Salmonella* ser. Typhimurium was traced to an infected swine herd. This strain was nalidixic acid resistant and showed increased ciprofloxacin MIC (0.06–0.12 mg/L). Although this level of susceptibility is categorized as sensitive by current breakpoints, patients treated with fluoroquinolones showed poor clinical response.⁹⁰

Soon after the introduction of enrofloxacin for veterinary use in the UK in 1993, human *Salmonella* isolates with decreased susceptibility to ciprofloxacin increased 10-fold from 1994 to 1997. In 1999, soon after the introduction of codes of good practice for the prophylactic use of fluoroquinolones in animal husbandry in the UK, there was a 75% decline in isolations of multiresistant *Salmonella* ser. Typhimurium DT104 from clinical specimens, which may indicate a favorable impact of more prudent antibiotic use.⁹¹ The extended-spectrum β-lactamases have appeared in some *Salmonella* strains, possibly as a result of plasmid transfer from commensal enterobacteria in the human gut. ESBL-producing salmonellae caused epidemics in Greece and spread to other European countries in the 1990s.⁹² The first case of infection by ceftriaxone-resistant *Salmonella* reported in the USA was linked to contact with infected cattle treated with cephalosporins on a Nebraska farm.⁹³

CAMPYLOBACTER

Campylobacter spp. have also shown increasing antimicrobial resistance in the past decade, and again much of this resistance appears related to the veterinary use of antibiotics. Although there is considerable geographic variation, macrolide resistance in *C. jejuni*, which is mainly due to mutational alteration of domain V of 23S rRNA, is increasing worldwide, including in Europe and the USA.⁹⁴ *C. coli* shows higher erythromycin resistance rates (4–50%) than *C. jejuni* (0–20%). The proportion of isolates resistant to fluoroquinolones, which is caused by stepwise mutations in *gyrA* and/or *parC* genes, has increased dramatically around the world over the last 20 years (from 0% to over 80% in some areas). There is consistent evidence that this is a result of the addition of quinolones to chicken feed.^{40,95} In every country where this has been investigated, quinolone resistance in human *Campylobacter* isolates increased in frequency soon after the introduction of these drugs in animal husbandry, but long after their licensing in human medicine. In the USA, domestic chickens were determined by epidemiological and molecular investigations as the predominant source of quinolone-resistant *C. jejuni* infection in the years after these drugs were licensed for use in poultry in 1995.⁹⁵ In South Africa, Thailand and Taiwan, very high rates of multiple resistance to quinolones, macrolides, tetracyclines and ampicillin often leave no effective antimicrobial treatment for *Campylobacter* enteritis.⁹⁶

HELICOBACTER PYLORI

Peptic ulcer disease caused by *H. pylori* infection is treated by associations of antibiotics, which may include amoxicillin, tetracyclines, clarithromycin and metronidazole. Eradication fails, however, in 10–30% of cases. This is in part due to primary or secondary resistance to one or more of these drugs, most commonly to metronidazole or clarithromycin.⁹⁷ Development of secondary resistance may occur in over 50% of cases with suboptimal regimens. Nitroimidazole resistance is mostly related to mutational inactivation of the *rdxA* gene encoding an oxygen-sensitive NADPH nitroreductase. The cure rate with most combination regimens drops by about 50% in case of nitroimidazole resistance. The prevalence of this resistance is rising and currently ranges from 10% to 40% of isolates in the West and from 50% to 80% in developing countries. Resistance to clarithromycin is caused by a mutation at position 2142 or 2143 in 23S rRNA. Its impact on cure rate appears similar to that of nitroimidazole resistance for most treatment regimens. The prevalence of primary macrolide resistance varies by region between 3% and 25% and is increasing. Standardization of resistance detection methods for this pathogen is much needed to assess the efficacy of treatment regimens based on primary resistance patterns and to guide local recommendations based on surveillance data.⁹⁸ The prevalence of resistance to amoxicillin and to tetracycline is very low (<1%) in *H. pylori* except in a few countries

like South Korea. In contrast, resistance to fluoroquinolones, mainly caused by mutation in the *gyrA* gene, shows a higher prevalence (9–20%).

PSEUDOMONAS AERUGINOSA

Ps. aeruginosa is a leading cause of nosocomial infection in critically ill patients and is associated with the highest attributable mortality among opportunistic Gram-negative bacteria. It is intrinsically resistant to most β -lactam antibiotics, tetracyclines, chloramphenicol, sulfonamides and nalidixic acid, due to the interplay of impermeability with multidrug efflux, principally mediated by MexAB-OprM.⁹⁹ Acquired resistance to anti-pseudomonal antibiotics develops rapidly in more than 10% of patients during treatment. This occurs most commonly with imipenem and ciprofloxacin.¹⁰⁰ Multiple types of acquired β -lactam resistance are expressed by this adaptable organism, often in combination: hyperproduction of AmpC cephalosporinase, acquisition of transposon and plasmid-mediated ESBLs, oxacillinases or carbapenemases; mutational loss of porins or upregulation of efflux pumps.¹⁸

Three types of aminoglycoside resistance are seen: high-level, plasmid-mediated resistance to one or two aminoglycosides, due to the production of aminoglycoside-modifying enzymes, and broad-spectrum resistance to all the aminoglycosides, due to a reduction in the permeability of the cell envelope and/or overexpression of an efflux pump. Fluoroquinolone resistance is mediated by topoisomerase gene mutations, decreased permeability and efflux overexpression. Surveys of clinical isolates of *Ps. aeruginosa* from ICUs have indicated resistance rates >10% to all drugs in European countries.⁸⁴ Resistance rates varied by region, with Latin America showing the highest prevalence, followed by Europe with high β -lactam resistance (>25% to ceftazidime) and fluoroquinolone resistance rates (>30% to ciprofloxacin), particularly in Southern Europe. Multidrug-resistant strains were found in 1% of isolates from the USA, 5% from Europe and 8% from Latin America, and their distribution by participating center suggested local outbreaks.

Only 10 years after the first description of VIM-1 in a *Ps. aeruginosa* isolate in 1997, the VIM-2 variant has become the most widespread metallo- β -lactamase (MBL) among *Ps. aeruginosa* strains.¹⁰¹ VIM-producing strains have caused hospital outbreaks worldwide. IMP enzymes have also been reported in this organism. The *bla*_{IMP} and *bla*_{VIM} genes are inserted into class 1 integrons. Other mobile genes encoding MBL enzymes were reported in *Ps. aeruginosa*, including the SMP (endemic in Brazil) and GIM (reported in Germany) enzymes.¹⁰¹ These carbapenemase-producing *Ps. aeruginosa* strains are multiresistant and on many occasions susceptible to colistin only. Class A β -lactamases such as VEB have been described with increasing frequency in this organism, whereas the GES and KPC enzymes were found in Latin America.¹⁰¹ Multiresistant *Ps. aeruginosa* is becoming one of the most problematic nosocomial pathogens, particularly in view of the

lack of new antimicrobial classes in clinical development that are active on this organism.

ACINETOBACTER SPP

Acinetobacters are free-living, non-fermenting organisms that often colonize human skin and cause opportunistic infections. Furthermore, these organisms are able to survive for prolonged periods in inanimate environments. The most frequently isolated species, and one most likely to acquire multiple antibiotic resistance, is *Acinetobacter baumannii*. In the early 1970s, acinetobacters were usually sensitive to many common antimicrobial agents but many hospital strains are now resistant to most available agents, including co-trimoxazole, aminoglycosides, cephalosporins, quinolones and, to a lesser extent, carbapenems. The mechanisms and genetics of resistance in this species are complex, but they involve several plasmid-borne β -lactamases and aminoglycoside-modifying enzymes, as well as alterations in membrane permeability and penicillin-binding proteins. The acquisition of these multiple mechanisms may be due to the fact that this group of organisms is physiologically competent and can acquire DNA by transformation in vivo.

Multiresistant *A. baumannii* strains have caused epidemics in several countries and nosocomial infections with these strains have been associated with excess mortality. Although not exclusively, many MDR *A. baumannii* strains are associated with epidemic lineages (EU clones I, II and III) that were found to spread in many European countries.

A. baumannii naturally harbor a carbapenem-hydrolyzing oxacillinase (OXA-51/69 variants) which, when overexpressed, confers a decreased susceptibility to carbapenem. Class D (OXA-type) β -lactamases conferring resistance to carbapenems have been widely reported in *A. baumannii*. These enzymes belong to three unrelated groups (represented by OXA-23, OXA-24 and OXA-58) that can be either plasmid (OXA-23 and OXA-58) or chromosomally encoded. OXA-23- and OXA-58-producing *Acinetobacter* have been associated with outbreaks in several countries such as the UK, China, Brazil and France.¹⁰¹ Class B metallo- β -lactamases (VIM, IMP, SIM) that confer resistance to all β -lactams except aztreonam have been reported worldwide in *Acinetobacter* strains, especially in Asia and Western Europe. Other mechanisms of carbapenem resistance in this organism include the reduced expression of several outer membrane proteins (porins) such as CarO.¹⁰² Active efflux of carbapenems may be associated.

Colistin, sulbactam and tigecycline may be the only active drugs available to treat infections caused by multiresistant strains. The activity of sulbactam against carbapenem-resistant isolates is decreasing. Clinical reports support the effectiveness of colistin for treating infection with multiresistant acinetobacters whereas clinical evidence with tigecycline is still scarce in spite of its good antimicrobial activity. High-level resistance to tigecycline mediated by upregulation

of chromosomally encoded efflux pumps has been reported among MDR strains. Strains resistant to all available antimicrobial agents have been reported.¹⁰³

OTHER NON-FERMENTING ORGANISMS

Sten. maltophilia and *Burkholderia cepacia* are intrinsically resistant to many of the antimicrobial agents used for infection with Gram-negative organisms, including the aminoglycosides and cephalosporins, and often acquire further resistance to co-trimoxazole and fluoroquinolones. Because of this, and despite their relatively low virulence, they are seen with increasing frequency in areas of high antibiotic usage such as ICUs. *Sten. maltophilia* is intrinsically resistant to all the aminoglycosides, to imipenem and most β -lactams, and up to 30% of isolates have acquired resistance to co-trimoxazole and tetracyclines. It has considerable ability to develop further multiple resistances by several mechanisms, including decrease in outer membrane permeability, active efflux and the production of inducible broad-spectrum β -lactamases. Bacteria of the *B. cepacia* complex are also generally resistant to the aminoglycosides and most β -lactam antibiotics, but sensitive to ciprofloxacin, temocillin and meropenem. However, acquired multiple resistance was found in epidemic strains that are associated with rapid deterioration in infected cystic fibrosis patients.

MYCOBACTERIUM TUBERCULOSIS

M. tuberculosis has limited susceptibility to standard antimicrobial agents, but can be treated by combinations of anti-tuberculosis drugs, of which the common first-line agents are rifampicin, isoniazid, ethambutol and pyrazinamide (see Chs 33 and 58). Resistance is the result of spontaneous chromosomal mutations at various loci. Mutational resistance occurs at the rate of about 1 in 10^8 for rifampicin, 1 in 10^8 to 1 in 10^9 for isoniazid, 1 in 10^6 for ethambutol and 1 in 10^5 for streptomycin. Since a cavitating lung lesion contains up to 10^9 organisms, mutational resistance appears quite frequently when these drugs are used singly for treatment, but is uncommon if three or more are used simultaneously.

The action of isoniazid against *M. tuberculosis* may involve multiple mechanisms, including transport and activation of the drug by mechanisms involving catalase-peroxidase, pigment precursors, nicotinamide adenine dinucleotide (NAD) and peroxide; generation of reactive oxygen radicals; and inhibition of mycolic acid biosynthesis. Mutations at several loci might be involved in decreased susceptibility to isoniazid, including the *katG* gene that encodes catalase-peroxidase activity, the *inhA* gene which is involved in mycolic acid synthesis, and the *aphC* gene which encodes alkylhydroperoxide reductase.¹⁰⁴ Likewise, resistance to ethambutol may result from diverse mutations in the *embCAB* operon, which is involved in the biosynthesis of cell-wall arabinan, or in other genes.

Resistance to rifampicin, fluoroquinolones and streptomycin appears to be caused in *M. tuberculosis* by mechanisms similar to those seen in other species, as the result of mutations in the *rpoB* gene that encodes the β -subunit of RNA polymerase, the *gyrA* gene encoding the A subunit of DNA gyrase and either the *rrs* gene encoding 16S rRNA or the *rpsL* gene encoding the S12 ribosomal protein, respectively. Resistance to pyrazinamide, however, does not appear to be due to altered target but to inactivation of the *pncA* gene encoding pyrazinamidase, an enzyme which is necessary for transformation of the prodrug into active pyrazinic acid.¹⁰⁴ An open access database of putative and well-established tuberculosis resistance mutations is available.¹⁰⁴

In 2007, *M. tuberculosis* caused 9.27 million new cases of tuberculosis and 1.78 million deaths according to the World Health Organization (WHO). The main factors for the appearance of tuberculosis drug resistance are the emergence of drug-resistant mutants from wild-type susceptible strains during treatment (acquired resistance), increasing development of resistance in drug-resistant strains because of inappropriate treatment (amplified resistance) and direct transmission of drug-resistant strains (transmitted resistance). Multidrug-resistant tuberculosis (MDR-TB) implies resistance to at least two of the first-line antituberculosis drugs: rifampicin and isoniazid. These two drugs are essential for initial or short-course treatment regimens, and strains of *M. tuberculosis* resistant to them soon develop resistance to other drugs. Patients with MDR-TB thus fail to respond to standard therapy and disseminate resistant strains to their contacts (including healthcare workers), both before and after the resistance is discovered. MDR-TB emerged in the 1990s and today represents a major problem in several parts of the world, such as some countries from the former Soviet Union and in China.^{105,106} Although the median worldwide prevalence of MDR-TB among new cases of tuberculosis is 1%, these rates can reach 22% in some areas of Eastern Europe, Russia, Iran and China.¹⁰⁶ A higher prevalence of drug resistance is also seen in immigrants to Western countries.

Extensively drug-resistant *M. tuberculosis* (XDR-TB), which is defined as bacteria resistant to at least isoniazid and rifampicin, any fluoroquinolone, and at least one of three injectable second-line drugs (amikacin, capreomycin or kanamycin), has recently emerged as a major public health threat.¹⁰⁶ By the end of 2008, 55 countries reported at least one case of XDR-TB. Five countries from the former Soviet Union documented 25 cases or more with a prevalence of XDR-TB ranging from 7% to 24% among MDR-TB.¹⁰⁶

MDR-TB is difficult and expensive to treat and is associated with high mortality rates in immunocompromised patients, especially in people infected with HIV, which is a common association. Large nosocomial and community outbreaks of MDR-TB were seen in some American cities in the early 1990s, and later reported in Europe, Asia and Brazil.¹⁰⁷ The clinical outcome of patients infected with XDR-TB is even poorer than with MDR-TB. The mortality rate of XDR-TB is particularly high in patients co-infected with

HIV.¹⁰⁶ Epidemic and clinically highly virulent MDR- and XDR-TB strains are associated with successful clones such as Beijing/W and KwaZulu-Natal genotypes which have accumulated resistance to second-line drugs. Factors that contribute to this situation include insufficient public health services directed towards control of tuberculosis; inadequate training of healthcare workers in the diagnosis, treatment and control of tuberculosis; laboratory delays in the detection and sensitivity testing of *M. tuberculosis*; admission to hospitals unprepared for control of airborne transmission of pathogens; addition of single drugs to failing treatment regimens; an increase in the number and promiscuity of individuals at high-risk of acquiring and disseminating tuberculosis, including those infected with HIV, the poor and the homeless; and increasing migration of people from areas where tuberculosis is common.¹⁰⁷ The single most important factor in the prevention and successful control of further emergence of MDR/XDR-TB is probably the re-introduction of supervised observed therapy. In addition, substantial commitment of resources, healthcare planning, surveillance of drug resistance and the use of appropriate hospital isolation facilities have brought nosocomial MDR-TB under control.¹⁰⁷

EPIDEMIOLOGY OF ANTIBIOTIC RESISTANCE

Epidemiological and biological studies have shown that the rise of antibiotic resistance among human pathogenic bacteria is a global phenomenon which is related to the interplay of several factors in different ecosystems (Figure 3.6).¹ These factors include the development of environmental and human reservoirs of antibiotic resistance genes and resistant bacteria, patterns of antibiotic use in medicine and agriculture that select for and amplify these reservoirs, and socioeconomic changes that influence the transmission of pathogens. The genetic

mechanisms that confer antibiotic resistance on bacteria must have existed long before the antibiotic era. Conjugative plasmids devoid of resistant genes were detected in clinical isolates of bacteria collected before the 1940s. Many resistance genes have presumably evolved from detoxifying mechanisms in antibiotic-producing fungi and streptomycetes living in soil and water and were later mobilized by genetic transfer to commensal and pathogenic bacteria.⁴⁸ Whatever the origins of resistance genes, there has clearly been a major increase in their prevalence during the past 60 years. This can be closely correlated with the use of antibiotics in humans and animals, and it is clear that resistance has eventually emerged to each new agent.

Antibiotic use is the driving force that promotes the selection, persistence and spread of resistant organisms. The phenomenon is common to hospitals, which have seen the emergence of a range of multidrug-resistant pathogens,¹⁰⁸ to the community at large, where respiratory and gut pathogens have become resistant to often freely available antibiotics,¹⁰⁹ and to animal husbandry, where the use of antibiotics for growth promotion and for mass therapy has promoted resistance in *Salmonella* and *Campylobacter*,⁹⁴ and created a reservoir of glycopeptide-resistant enterococci that can be transmitted to humans.³⁰

In the community, where about 80–90% of human antibiotic consumption takes place, a large proportion of antibiotics is inappropriately prescribed for upper respiratory infections. Patients' misperceptions about the utility of antibiotics in self-resolving viral infections, commercial promotion, poor compliance with prescriptions and over-the-counter sales of antibiotics in some countries are contributing to this misuse of antimicrobials.¹⁰⁹ The factors relating prescription patterns to increasing resistance are only incompletely understood. Low dosage and prolonged administration have been associated with increased risk of development of β-lactam resistance in pneumococci.¹¹⁰ Finnish surveillance data show that macrolide resistance in *Str. pyogenes* has increased as the national use has increased – and, conversely, has declined as a result of the much diminished use of erythromycin.⁴¹ There are wide variations in per capita antibiotic consumption in Europe, with lowest levels of consumption in the Nordic countries correlating with a much lower prevalence of resistance in most bacterial pathogens than in the other parts of Europe (see Figure 3.4). Socioeconomic changes are also powerful drivers of the resurgence of infectious diseases and drug resistance.¹¹³ The impoverishment of large sections of the population and disruption of the healthcare system in the former Soviet Union has had a clear impact on the spread of MDR-TB. Globalization is stimulating international circulation of goods and people, and plays a role in accelerating the dissemination of pathogens, including resistant strains.

The hospital, particularly the intensive care unit, is a major breeding ground for antibiotic-resistant bacteria. Here, a high-density population of patients with compromised host defenses is exposed to a usage of antibiotics that is about 100 times more concentrated than in the community, and

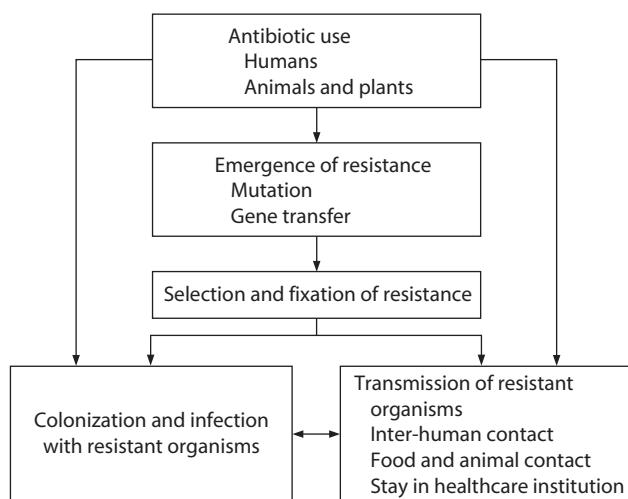

Fig. 3.6 Factors contributing to the emergence and spread of antibiotic resistance in interconnected ecosystems.

frequent contact with healthcare personnel creates ceaseless opportunities for cross-infection.¹⁰⁸ Most new drugs and injectable agents are first administered to hospital patients. Topical antibiotics are particularly likely to select for resistance, as illustrated by the emergence of gentamicin-resistant *Ps. aeruginosa* and fusidic acid- or mupirocin-resistant *Staph. aureus* that has often followed heavy topical use of gentamicin in burns and fusidic acid or mupirocin in dermatological patients. Multiple drug resistance can be encouraged by the use of a single agent, since this may select for plasmids conferring resistance to multiple antibiotics.

Selection of resistance during antibiotic therapy in infecting or colonizing bacteria is enhanced by factors related to the patient: immune suppression, presence of a large bacterial inoculum, and biofilm-associated infection of foreign bodies which impede local host defenses.⁴⁷ Other resistance-predisposing factors relate to the modalities of treatment: drug underdosing or inappropriate route of administration which causes failure to achieve bactericidal drug levels at the site of infection.¹¹¹ Alteration of the endogenous microflora during antibiotic therapy also enhances replacement of susceptible organisms by resistant strains from the hospital microflora.

Nosocomial transmission of MDR bacteria occurs most commonly by indirect contact between patients (via the contaminated hands of healthcare personnel) and, less commonly, by contaminated fomites. Patient factors predisposing to this transmission include the severity of underlying illness, length of stay in hospital, intensity and duration of exposure to broad-spectrum antibiotics, and use of invasive devices (such as intravenous catheters) or procedures.¹⁰⁸ Hospital patients and staff colonized with resistant bacteria, especially in the feces or on the skin, further disseminate these organisms both within the hospital and into the community. Cost containment in hospitals has resulted in chronic understaffing, increased patient turnover and inter-institutional transfer, factors which have been well documented to enhance nosocomial transmission of MDR bacteria such as MRSA and ESBL-producing Gram-negative bacteria.¹⁰⁸

About 30% of the patients in acute care hospitals receive antibiotics for therapy or prophylaxis. Although antibiotics are essential for modern hospital care, many studies have shown that up to 50% of these prescriptions may be unnecessary or inappropriate. Insufficient training in antibiotic therapy, difficulty of selecting the appropriate anti-infective drugs empirically, underuse of microbiological testing, drug promotion by pharmaceutical companies and fear of litigation are some of the factors that are stimulating the use of broad-spectrum drugs.

PUBLIC HEALTH AND ECONOMIC IMPACT

Antibiotic resistance places an increasing burden on society in terms of increased morbidity, mortality and costs. In spite of the methodological complexities in studying the impact of antibiotic resistance on clinical outcomes, it is recognized

that, for many diseases, individuals infected with resistant pathogens are more likely to receive ineffective therapy, to more frequently require hospital care, to stay in for longer, to develop complications and to die of the disease.^{1,2} The cost of care is also increased for such patients, due to the need for more costly second-line drugs, longer duration of hospital stay, increased need for intensive care and diagnostic testing, higher incidence of complications, and expenses incurred by use of isolation precautions. There are also longer-term costs for society related to patient disability from the increased incidence of acute infectious diseases and their sequelae.

CONTROL AND PREVENTION

Learned societies and expert panels have published guidelines for optimizing antibiotic use and curtailing antibiotic resistance in hospitals.¹¹²⁻¹¹⁸ Key components of these guidelines include:

- better undergraduate and postgraduate training in healthcare;
- establishment of hospital antimicrobial stewardship programs, involving multidisciplinary cooperation between hospital administrators, clinicians, infectious disease specialists, infection control team, microbiologists and hospital pharmacists;
- formulary-based local guidelines on anti-infective therapy and prophylaxis, education and regulation of prescriptions by consultant specialists, monitoring and auditing drug use, surveillance and reporting of resistance patterns of the hospital flora;
- surveillance and early detection of outbreaks by molecular typing, detection and notification of patients colonized with communicable resistant bacteria to the infection control team when useful for patient isolation and/or decolonization;
- promotion and monitoring of basic hospital infection control practices such as hand hygiene.

These guidelines are mostly based on local experience and on the results of before-after and analytic studies.¹¹²⁻¹¹⁷ Few strategies have been formally tested for cost-effectiveness in controlled intervention studies. Mathematical modeling provides interesting insights into the prediction of epidemiological factors that are the most vulnerable to effective interventions.^{55,64} Because each hospital has its own ecosystem and micro-society where determinants of antibiotic resistance are quite specific and evolve rapidly, effective solutions should be tailored to local circumstances and resources. On the other hand, early coordination of policies at regional or national level has been successful in controlling the transmission of emerging MDR nosocomial pathogens.¹¹⁵

In the past few years, antibiotic resistance has been universally identified as a public health priority and action plans to combat resistance have been developed by several national health agencies and international organizations such as the US Centers for Disease Control and Prevention (CDC),

the WHO and the European Union (EU).^{2,3,118} These strategic plans call for:

- public and professional education toward rational use of antimicrobials;
- coordination of surveillance of antibiotic resistance and antibiotic use in human and animal health sectors;
- refined regulation of antibiotic registration for use in both sectors;
- development and evaluation of improved diagnostic methods;
- promotion and evaluation of medical and veterinary practice guidelines;
- restriction of antibiotic use as growth promoters in food animals;
- promotion of infection control practice in healthcare institutions;
- development of novel antimicrobial drugs and vaccines;
- closer international cooperation.

A number of national action plans and international surveillance systems are now in development to implement these strategies and provide early warning of the emergence of threatening antibiotic-resistant bacteria to guide timely interventions.

Physicians can no longer avoid their responsibilities as antibiotic prescribers and their impact on the global ecosystem of microbial pathogens. If we want to prove wrong the prediction of an impending post-antibiotic era, we must strive to continuously improve our antibiotic prescribing and infection control practices and develop new strategies for controlling resistance.

4 Pharmacodynamics of anti-infective agents: target delineation and susceptibility breakpoint selection

Johan W. Mouton

The goal of anti-infective chemotherapy is to administer the drug in such a way that it will generate the highest probability of a good therapeutic outcome while at the same time having the lowest probability of a drug-related toxicity event that is related to the time-concentration profile of the drug. In order to reach that goal, it is therefore necessary to determine the concentration-effect relationship of the drug over time, determine which concentration profile ensures this to become true and design dosing regimens that bring about this concentration profile. This approach applies to all anti-infectives, whether they are antibacterials, antivirals, antifungals or antiparasitic agents. In this chapter the discussion and examples are mainly taken from the antibacterial scene, but it should be emphasized that the concepts can be applied to all anti-infective agents.

One of the unique features of anti-infectives is that the target of the drug – the receptor of the molecule – is located on the micro-organism rather than in humans. This stands out against virtually all other drugs where the receptor of the drug is located in humans themselves. Unfortunately, for some anti-infectives there are also receptors in humans, resulting in toxicity, and for some drug classes this is a major limitation to their use. Since the receptor of the anti-infective is on the microbe, it is relatively easy to study the effect of antimicrobials in model systems, both in in-vitro systems as well as in in-vivo infection models. The downside is that, because there are as many different receptors as there are different species, exposure-response relationships cannot always be generalized and need to be studied in detail for various drug-micro-organism combinations. The primary focus of this chapter is to describe the approach to determine exposure-response relationships of anti-infectives and to translate these to optimal dosing regimens and the choice of anti-infective.

PHARMACODYNAMIC TARGETS AND TARGET DELINEATION

EXPOSURE-RESPONSE RELATIONSHIPS IN VIVO

Figure 4.1A shows a diagram of the concentration-time curve of an anti-infective agent. Two major pharmacokinetic parameters describe this profile: the peak concentration (C_{max}) and the area under the concentration-time curve (AUC). These in turn are the result of the pharmacokinetic properties of the drug, clearance and volume of distribution. However, a pharmacokinetic description as such does not convey any information with respect to the activity of the drug in vivo. One way to do this is to use the relationship between the exposure of the anti-infective and the activity (or potency) of the drug as determined in an in-vitro system such as minimum inhibitory concentration (MIC) testing. Other measures of potency include the half maximal effective concentration (EC_{50}) in vitro for antivirals and some antifungals. Figure 4.1B shows the same diagram as in Figure 4.1A but includes the MIC of a micro-organism. Instead of two pharmacokinetic parameters there are now three pharmacodynamic indices (PIs) that can be recognized: the AUC and the C_{max} , both relative to the MIC, and in addition the time the concentration of the drug remains above the MIC ($T_{>MIC}$). The latter is usually expressed as the $\%T_{>MIC}$ of the dosing interval. These three PI values – AUC/MIC , C_{max}/MIC and $\%T_{>MIC}$ – thus describe the relationship between exposure of the anti-infective over a

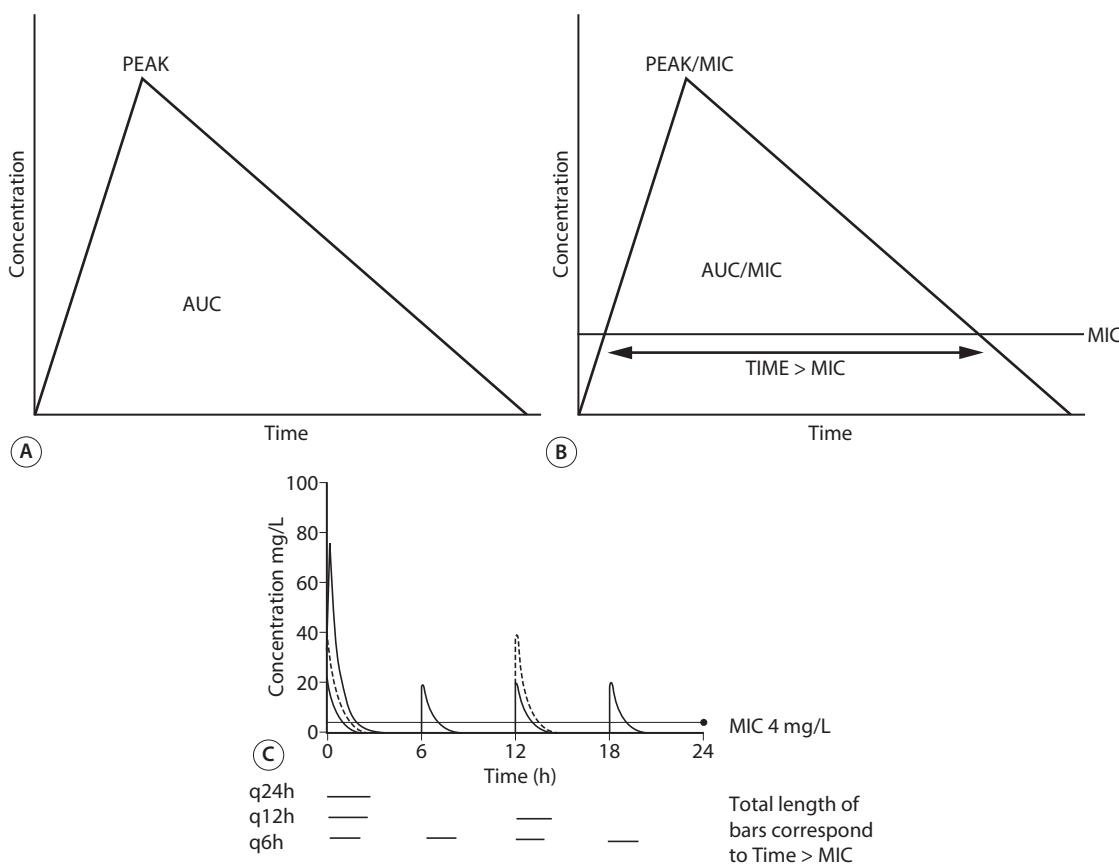

Fig. 4.1 (A) Diagram of a concentration–time curve showing the pharmacokinetic parameters Peak (or C_{\max}) and AUC. (B) The PK/PD indices are derived by relating the pharmacokinetic parameter to the MIC: AUC/MIC, C_{\max}/MIC and $T_{>\text{MIC}}$. (C) Diagram showing that the $T_{>\text{MIC}}$ increases if daily doses are divided. The length of the bars beneath Figure 4.1C correspond to the $T_{>\text{MIC}}$.

defined time interval in relation to the potency of the anti-microbial as defined by the MIC. For the AUC/MIC and the C_{\max}/MIC , it follows that the value of the PI is proportional to the AUC and C_{\max} . Since the pharmacokinetic profile for most antimicrobials is proportional to dose in a linear fashion, it follows that: (1) doubling the dose usually results in a doubling of AUC/MIC and C_{\max}/MIC , and (2) administration of the dose twice will double the AUC/MIC while the C_{\max} will not change. For the % $T_{>\text{MIC}}$, dividing the same dose over multiple smaller doses will result in an increased % $T_{>\text{MIC}}$ while retaining the same AUC/MIC (Figure 4.1C).

Using different dosing regimens in animal models of infection by varying both the frequency and the dose of the drug, and thereby different exposures and corresponding PIs, it has been shown that there is a clear relationship between a pharmacokinetic/pharmacodynamic (PK/PD) index and efficacy.¹ Figure 4.2 shows the relationship for two drugs belonging to different classes of antimicrobials, the quinolones and the β -lactams. In general, for concentration-dependent drugs there is a clear relationship between AUC:MIC ratio and/or $C_{\max}:\text{MIC}$ ratio and efficacy, while for time-dependent drugs it is the % $T_{>\text{MIC}}$ that is best correlated with effect.

CURVE-EFFECT DESCRIPTION AND PHARMACODYNAMIC TARGETS IN ANIMAL MODELS

In most cases, the relationship between exposure and effect can be described by a sigmoid curve. The E_{\max} model with varying slope, or Hill equation, is most commonly used to describe this sigmoid relationship. An example is shown in Figure 4.3, displaying the relationship between AUC/MIC ratio and effect. The effect here is the number of colony forming units (CFU) after 24 h of treatment with different dosing regimens of levofloxacin. Apart from the parameter estimates that describe the curve, such as the EC_{50} and the E_{\max} , there are other parameters related to the curve, the most important of which is the net static effect. This is the dose or exposure resulting in the measure of effect being unchanged from baseline to the time of evaluation (e.g. the number of CFU at $t = 0$ h [baseline, start of treatment] and $t = 24$ h [time of sampling]). The use of the term ‘static’ does not imply that no changes have occurred during the period of reference; indeed kill and regrowth may have occurred (repeatedly) during this period.⁴ Other characteristics include exposures that result in the E_{\max} , 90% of the E_{\max} , or a 2 log drop. The PI value that

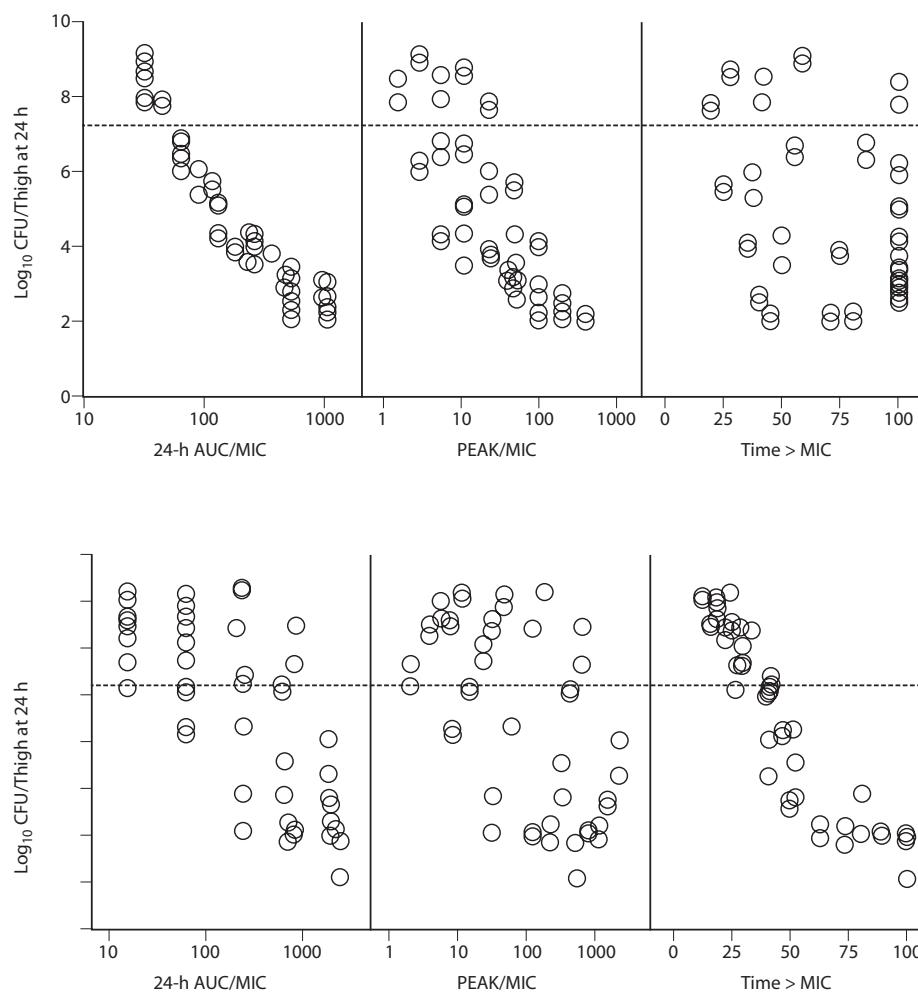

Fig. 4.2 Relationship between $T_{>\text{MIC}}$, AUC and peak of levofloxacin (upper) and ceftazidime (lower) in a mouse model of infection with *Streptococcus pneumoniae* as obtained by various dosing regimens and efficacy expressed as colony forming units (CFU). The best relationship is obtained with the AUC for levofloxacin and $T_{>\text{MIC}}$ for ceftazidime; the curve drawn represents a model fit of the Hill equation with variable slope to the data. Fig. 4.3 Diagram showing various characteristic effect levels of a sigmoid dose–response relationship, in this example levofloxacin. From F. Scaglione, J.W. Mouton, R. Mattina and F. Fraschini, Pharmacodynamics of levofloxacin and ciprofloxacin in a murine pneumonia model: peak concentration/MIC versus area under the curve/MIC ratios. *Antimicrob Agents Chemother*. 47 (2003), pp. 2749–2755. Copyright © 2003, American Society for Microbiology.³

will result in one of the effects described and is desired is also called the pharmacodynamic target (PT). Pharmacodynamic targets have been described for many micro-organism–anti-infective combinations and in general show a good concordance with survival and clinical cure (*see below*), in particular for the free, non-protein bound fraction of the drug. In the following, the prefix *f* indicates that the parameters or indices apply to the fraction unbound (*see also* ‘Exposure in first compartment’, below).

TARGETS AND TARGET DELINEATION IN HUMAN INFECTIONS

The relationship between PI and effect is increasingly being studied in humans. There are two major differences with animal models that need consideration and have, or may

have, a significant effect on conclusions. The first is that the outcome parameter is usually binomial instead of (semi) continuous. That is, instead of colony forming units, outcome is determined as cure versus no cure, persistence of colonization versus elimination, or mortality versus survival, and therefore the statistical and/or mathematical models that describe the relationship between PI and effect differ as well.

Binomial outcome

If outcome is measured at a single point in time, for instance clinical cure 28 days after the start of antimicrobial treatment, univariate or multivariate logistic regression is the analysis tool primarily used. Alternatively, if outcome is determined over time, such as time to defervescence or time to pathogen clearance, a Kaplan–Meier analysis can be applied and/or Cox regression. The advantage of determining outcome over time is that in general it is much more powerful to show differences between groups – if present – and therefore fewer patients are needed to determine differences in effects. This was shown in a study by Ambrose and colleagues, studying the effect of levofloxacin in maxillary sinusitis and taking serial sinus aspirates.⁵

While these methods do indicate differences between groups if present, and the models can also be used to estimate the parameters that determine outcome, they do not answer the question as to which *value* of the PI makes the difference between a high probability of cure and a low probability of cure. To that purpose, classification and regression tree analysis (CART) has been used increasingly. This tool uses exploratory non-parametric statistical algorithms that can accommodate continuous numerical data, as well as categorical data, as either independent or dependent variables. For a dependent variable that is categorical such as clinical response, it can be used to identify threshold values in an independent continuous variable such as an AUC:MIC ratio that separates groups with a high probability of cure from those with a low probability of cure. The results can subsequently be used to test for significance in univariate or multivariate logistic regression analyses.

One of the first exposure–response analyses of clinical data that utilized this approach was by Forrest et al.⁶ Intravenous ciprofloxacin was studied in critically ill patients with pneumonia involving predominantly Enterobacteriaceae and *Pseudomonas aeruginosa*. Multivariate logistic regression analyses identified the $AUC_{0-24}:\text{MIC}$ ratio as being predictive of clinical and microbiological response ($p < 0.003$). Recursive partitioning identified a threshold $AUC_{0-24}:\text{MIC}$ ratio value of 125. Patients who had an $AUC_{0-24}:\text{MIC}$ ratio of 125 or greater had a significantly higher probability of a positive therapeutic response than those patients in whom lesser exposures were attained. Another example is provided in Figure 4.4 showing a jitter plot of the relationship between the $fAUC_{0-24}:\text{MIC}$ ratio of five quinolones and microbiological response. CART analysis indicates that patients with an AUC:MIC ratio above 34 (cure rate 92.6%) had a significantly ($p = 0.01$) increased probability of cure compared to those that had not (cure rate 66.7%).⁷

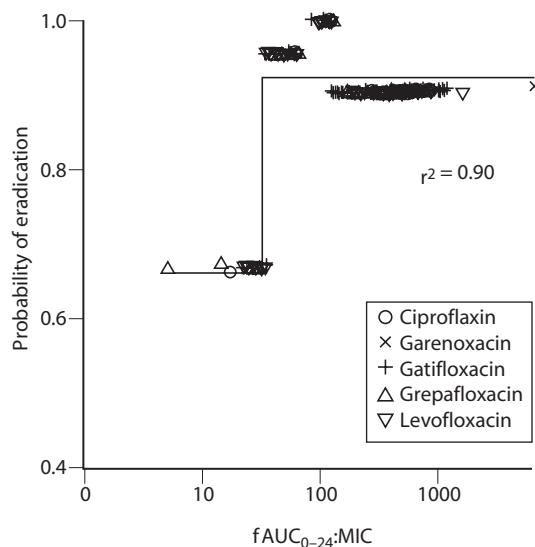

Fig. 4.4 Jitter plot of the relationship between the ratio of free drug area under the concentration–time curve at 24 h to the MIC ($fAUC_{0-24}:\text{MIC}$) for five quinolones (ciprofloxacin, garenoxacin, gatifloxacin, grepafloxacin and levofloxacin) and microbiological response in 121 patients with respiratory tract infection pneumonia, acute exacerbation of chronic bronchitis or acute maxillary sinusitis associated with *Streptococcus pneumoniae*. Reproduced from Rodriguez-Tudela JL, Almirante B, Rodriguez-Pardo D, et al. Correlation of the MIC and Dose/MIC ratio of fluconazole to the therapeutic response of patients with mucosal candidiasis and candidaemia. *Antimicrob Agents Chemother*. 2007;51(10):3599–3604. Copyright © 2007, American Society for Microbiology.⁷

(Semi)-continuous outcome

There are an increasing number of studies that have strived to look for outcome data that are continuous or semi-continuous. These have the advantage that they are much more informative, and therefore fewer subjects are needed to show an exposure–response relationship. In addition, E_{\max} models can be fit to the data to show exposure–response relationships in a more meaningful manner than binomial data.

An approach for a semi-continuous outcome was the exposure–response relationship of fluconazole for the treatment of oropharyngeal candidiasis (Figure 4.5). Patients were treated with various doses of fluconazole and outcome recorded, while MICs were determined from cultures taken before and after treatment. Because of the variation in doses and MICs, a large number of groups could be distinguished, with each group designated by a specific dose:MIC ratio or AUC:MIC ratio. The percentage cure per group was plotted, and the E_{\max} model fitted to the data. This resulted in a clear exposure–response relationship. The authors concluded that the pharmacodynamic target would be an AUC:MIC ratio of near 100, corresponding to the near maximum effect in this study.

It is, however, not easy to find an outcome variable that is continuous in humans that is meaningful. One example is the use of the relative increase in FEV1 (the forced volume of expiration during the first second) after a specified period of treatment

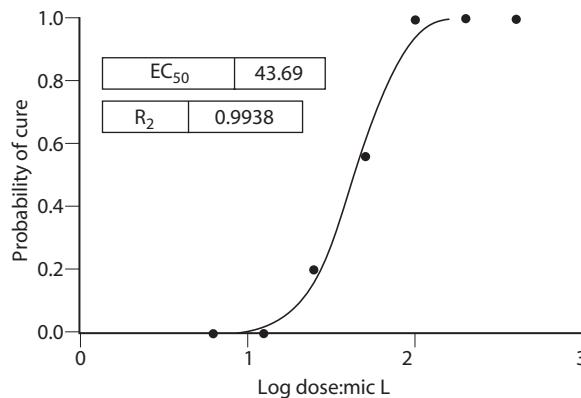

Fig. 4.5 Dose/MIC-response relationship for fluconazole in patients with oropharyngeal candidiasis. The dose:AUC ratio for fluconazole is 1, thus the plot for AUC/MIC is similar. Reproduced from Rodriguez-Tudela JL, Almirante B, Rodriguez-Pardo D, et al. Correlation of the MIC and Dose/MIC ratio of fluconazole to the therapeutic response of patients with mucosal candidiasis and candidaemia. *Antimicrob Agents Chemother.* 2007;51(10):3599–3604. Copyright © 2007, American Society for Microbiology.⁸

with antipseudomonal therapy in patients with cystic fibrosis as shown in Figure 4.6. An E_{max} model fitted the data well, and by using a continuous variable instead of a dichotomous one, the authors could show an exposure-response relationship in a limited number of patients, indicating the significant increase in power if a continuous outcome variable is used.

Variance in exposure

The second major difference between human studies and animal models, or in-vitro pharmacokinetic models, is the variance in exposure. With some exceptions, such as the relationship between fluconazole exposure and effect (see Figure 4.5), only one or two different dosing regimens can be analyzed, resulting in a significant correlation between the various

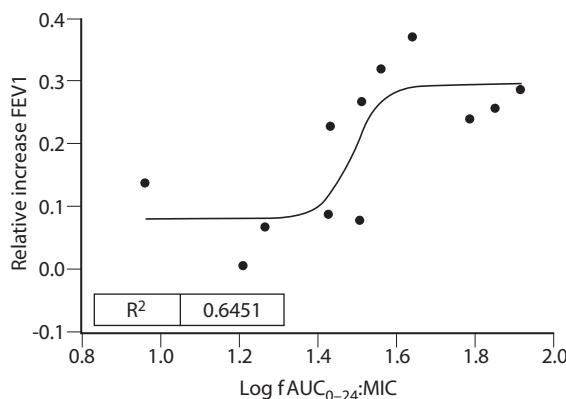

Fig. 4.6 Relationship between $fAUC_{0-24}$:MIC ratio of tobramycin as a measure of exposure and relative increase in FEV1 as a measure of effect in patients with cystic fibrosis. Reproduced from Preston SL, Drusano GL, Berman AL, et al. Pharmacodynamics of levofloxacin: a new paradigm for early clinical trials [see comments]. *Journal American Medical Association.* 1998;279(2):125–129.⁹

PIs. While this does not affect the estimate of the pharmacodynamic target if the PI that drives the effect is known, this co-linearity makes it almost impossible to determine the PI that drives outcome. This information thus needs to be derived from other sources. Alternatively, if different drugs from the same class with the same mechanism of action are analyzed simultaneously, this will result in the variety of exposures being sought. A clear example is the study of Ambrose and colleagues who looked at the exposure-response relationship of various quinolones as discussed above (see Figure 4.4).

CONCORDANCE BETWEEN TARGETS IN ANIMAL MODELS AND HUMAN INFECTIONS

In general, there is a rather good concordance between PK/PD animal studies and data from infected patients, as shown by Ambrose and colleagues¹⁰ in Table 4.1. With the exception of telithromycin, the magnitudes of the PK/PD measure necessary for clinical effectiveness were similar to those identified from animal data across drug classes and across multiple clinical indications. As illustrated in Table 4.1, the magnitude of exposure identified for a 2 log unit reduction in bacterial burden in immunocompromised animals was similar to the exposure threshold associated with good clinical outcomes for patients with hospital-acquired pneumonia associated with Gram-negative bacilli treated with ciprofloxacin or levofloxacin. For instance, Drusano and colleagues (Jumbe et al.¹¹) demonstrated that for levofloxacin and *Ps. aeruginosa*, a total drug AUC_{0-24} :MIC ratio of 88 in immunosuppressed mice was associated with a 99% reduction in bacterial burden, while Craig¹² showed that for fluoroquinolones and primarily Gram-negative bacilli in immunosuppressed animals, the AUC_{0-24} :MIC ratio was predictive of survival. Thus, it can be inferred that the exposure target in immunocompromised animals predictive of an adequate response in humans with such pneumonias is a minimum 2 log unit reduction in bacterial burden. This means that, in the circumstance where human exposure-response data are unavailable, as is the case in newly developed anti-infectives, we can use the PT in animals to predict clinical effectiveness in humans.

OPTIMIZING DOSING REGIMENS: TRANSLATING PHARMACODYNAMIC TARGETS TO OPTIMIZING THERAPY

In the first part of the chapter the relationship between exposure and response was discussed, both in models of infection as well as in the treatment of human infections. Using those relationships, PI values were derived that could differentiate between the probability of a good outcome versus a worse outcome, and these are pharmacodynamic targets one aims to attain in patients. Once this PT is known, a dosing regimen to optimally treat infections can be determined by optimizing the exposure of the drug to the micro-organism in the patient. Since the value of the PT is dependent on both the

Table 4.1 Pharmacodynamic targets derived from animal infection models and clinical data

Disease state	Drug	Clinically derived PK/PD target	Animal infection model; organism studied	Animal-derived PK/PD target
Hospital-acquired pneumonia	Quinolones	$fAUC_{0-24}$:MIC ratio: 62–75	Neutropenic mouse thigh; Gram-negative bacilli	$fAUC_{0-24}$:MIC ratio: 70–90 for 90% animal survival or 2 log-unit kill
Community-acquired respiratory tract infections	Quinolones	$fAUC_{0-24}$:MIC ratio: 34	Immunocompetent mouse thigh; <i>Streptococcus pneumoniae</i>	$fAUC_{0-24}$:MIC ratio: 25–34 for 90% animal survival or 2 log-unit kill
	β -Lactams	$T_{>MIC}$: 40% of the dosing interval	Immunocompetent mouse thigh; <i>Str. pneumoniae</i>	$T_{>MIC}$: 30–40% of the dosing interval for 90% animal survival
	Telithromycin	AUC_{0-24} :MIC ratio: 3.375	Neutropenic mouse thigh; <i>Str. pneumoniae</i>	AUC_{0-24} :MIC ratio: 1000 for stasis
Bacteremia	Oritavancin	$fT_{>MIC}$: 22% of the dosing interval for <i>Staphylococcus aureus</i>	Neutropenic mouse thigh; <i>Staph. aureus</i>	$fT_{>MIC}$: 20% of the dosing interval for a 0.5 log-unit kill
	Linezolid	AUC_{0-24} :MIC ratio: 85 for <i>Staph. aureus</i> or <i>Enterococcus faecium</i>	Neutropenic mouse thigh; <i>Staph. aureus</i>	AUC_{0-24} :MIC ratio: 83 for stasis
Complicated skin and skin structure infections	Tigecycline	AUC_{0-24} :MIC ratio: 17.9	Neutropenic mouse thigh; <i>Staph. aureus</i>	AUC_{0-24} :MIC ratio: 20 for stasis
	Linezolid	AUC_{0-24} :MIC ratio: 110	Neutropenic mouse thigh; <i>Staph. aureus</i>	AUC_{0-24} :MIC ratio: 83 for stasis

From Ambrose et al.¹⁰

exposure as such, as well as the MIC of the micro-organism, it follows that the pharmacokinetic profile has to be optimized accordingly.

TARGET ATTAINMENT

The simplest method to determine the dosing regimen required to obtain a certain exposure or PT is to tabulate or plot the PI as a function of MIC for a number of dosing regimens. Pharmacokinetic parameters are used to calculate the pharmacokinetic profiles using standard equations and the PI calculated for a range of MICs. An example is provided in Figure 4.7, showing the $T_{>MIC}$ for amoxicillin-clavulanic acid.¹³ If the MICs that need to be covered are known, MICs that can supposedly be covered with a certain dosing regimen can be read directly from the figure for a certain PT. Although there are other factors that need to be considered to optimize dosing regimens, this approach yields a straightforward comparison of exposures of various dosing regimens (or drugs within the same class; see for instance Mouton et al.¹⁴).

PROBABILITY OF TARGET ATTAINMENT

When a specific pharmacodynamic index value is used as a pharmacodynamic target to predict the probability of successful treatment, this should be true not only for the population mean, but also for each individual within the population. Since the pharmacokinetic behavior differs for each individual, the PK part of the PI differs as well. An example

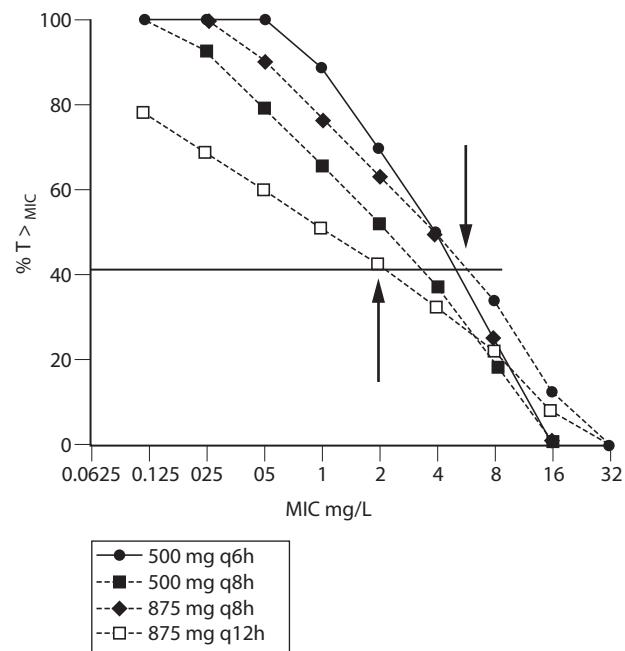

Fig. 4.7 Diagram showing the relationship between $T_{>MIC}$ and MIC of amoxicillin for four different dosing regimens of amoxicillin-clavulanic acid to demonstrate that the clinical breakpoint is dependent on the dosing regimen. Assuming that 40% $T_{>MIC}$ is the time of the dosing regimen needed for effect, the breakpoint for the 875 mg every 12 h is 2 mg/L while for the dosing regimen of 500 mg every 6 h it is 8 mg/L. Based on Mouton JW, Punt N. Use of the $T_{>MIC}$ to choose between different dosing regimens of beta-lactam antibiotics. *J Antimicrob Chemother.* 2001;47(4):500–501. © 2001 The British Society for Antimicrobial Chemotherapy.¹³

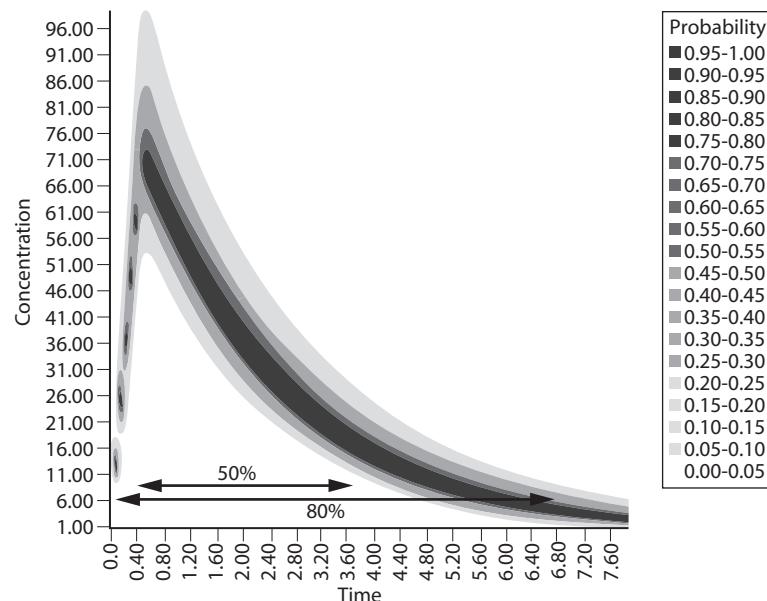

Fig. 4.8 Simulation of ceftazidime after a 1 g dose. The grayscale indicates the probability of presence of a certain concentration. Due to interindividual variability, some individuals in the population will have a $T_{>\text{MIC}}$ of 50%, while others will have a value of 80%. The population mean is in the middle of the black area. Reproduced from Mouton JW. Impact of pharmacodynamics on breakpoint selection for susceptibility testing. *Infect Dis Clin North Am.* 2003;17(3):579–598, with permission of Elsevier.¹⁵

is given in Figure 4.8. The figure shows the proportion of the population reaching a certain concentration of ceftazidime after a 1 g dose. It is apparent from Figure 4.8 that there are individuals with a $T_{>\text{MIC}}$ of 50%, while others have, with the same dosing regimen, a $T_{>\text{MIC}}$ of more than 80%. Thus, when designing the dosing regimen that should result in a certain pharmacodynamic target, this interindividual variation should be taken into consideration.

The most popular method to do this is to use Monte Carlo simulations (MCS). This approach was first used by Drusano et al. who presented an integrated approach of population pharmacokinetics and microbiological susceptibility information to the US Food and Drug Administration (FDA) Anti-infectives Product Advisory Committee.^{16,17} The first step in that approach is to obtain estimates of the pharmacokinetic parameters of the population, using population pharmacokinetic analysis. Importantly, not only the estimates of the parameters are obtained, but also estimates of dispersion. These are then applied to simulate multiple concentration-time curves by performing Monte Carlo simulation. This is a method which takes the variability in the input variables into consideration in the simulations.¹⁸ For each of the pharmacokinetic curves generated, all of which are slightly different because the input parameters vary to a degree in relation to the variance of the parameters, the value of the PK/PD index is determined for a range of MICs. For each MIC value, the proportion of the population that will reach a specific pharmacodynamic target is displayed in tabular or graphical form. As an example, Table 4.2 displays the probability of target attainment (PTA) for various targets for a 1 g dose of ceftazidime. The optimal dosing regimen follows from the PTA that one considers necessary and the MIC range that needs to be

Table 4.2 Probability of target attainment for various pharmacodynamic targets for ceftazidime given three times daily

MIC (mg/L)	% Time > MIC

covered. Vice versa, existing dosing regimens can be evaluated bearing this in mind.

Another approach was presented at the Clinical and Laboratory Standards Institute (CLSI) in 2004 by the European Committee on Antimicrobial Susceptibility Testing (EUCAST)²⁰ as part of the method being used to evaluate susceptibility breakpoints. It has the advantage that it shows the total probability function irrespective of the target and therefore provides a more complete picture of the data.¹⁹ An example is shown in Figure 4.9. In the figure, the $fT_{>\text{MIC}}$ of ceftazidime is displayed as a function of MIC for a 1 g dose. The middle line represents the values for the mean of the

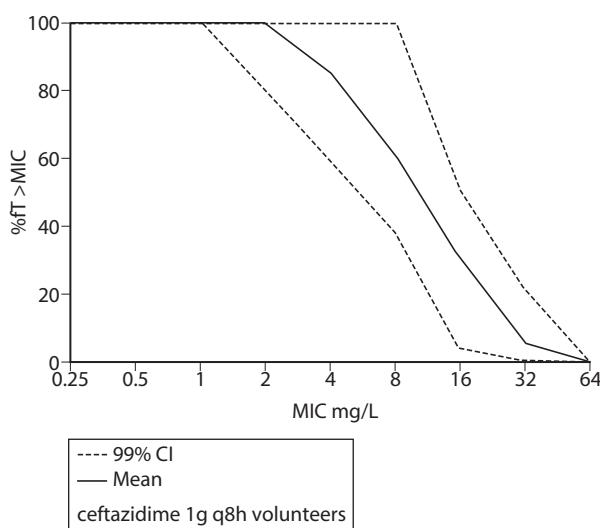

Fig. 4.9 Means and 99% confidence interval estimates using Monte Carlo simulation for $\%fT_{>\text{MIC}}$ of ceftazidime, based on the population pharmacokinetic parameter estimates. Reproduced from Mouton JW, Punt N, Vinks AA. A retrospective analysis using Monte Carlo simulation to evaluate recommended ceftazidime dosing regimens in healthy volunteers, patients with cystic fibrosis, and patients in the intensive care unit. *Clin Ther.* 2005;27(6):762-772, with permission of Elsevier.¹⁹

population, similar to Figure 4.7. The lines on both sides represent the confidence interval estimations of the mean values. MICs that can supposedly be covered with the dosing regimen can be read directly from the figure at the intersection of the horizontal line concurring with the pharmacodynamic target and the lower confidence interval. Alternatively, the effect of choosing a different PT can be observed directly.

SELECTING DOSING REGIMENS OR DRUGS BASED ON PROBABILITY OF TARGET ATTAINMENT

With the information obtained by MCS, dosing regimens or drugs can be compared and selected (see above), but now taking the population variability into account. In drug development, this information can be used to select dosing regimens. An example is shown in Table 4.3 for two dosing regimens of ceftobiprole (BAL9141), a cephalosporin with anti-methicillin-resistant *Staphylococcus aureus* (MRSA) activity recently under clinical investigation. The PTA for two simulated dosing regimens, 250 mg every 12 h and 750 mg every 12 h, is displayed for several values of $T_{>\text{MIC}}$. Since the frequency distributions of the target pathogens indicate that the highest MIC is 2 mg/L for most species and only rare isolates of 4 mg/L, the dosing regimen of 250 mg every 12 h is clearly insufficient to obtain target attainment ratios nearing 100% for $\%T_{>\text{MIC}}$ as low as 30%. Of the two regimens compared here, it is recommended that the 750 mg every 12 h course of therapy is followed up in clinical trials.

Table 4.3 Probability of target attainment (%) for two dosing regimens of ceftobiprole using data from human volunteers. PTAs are displayed for 30, 40, 50 and 60% $fT_{>\text{MIC}}$

Dosing regimen MIC (mg/L)	250 mg every 12 h (%)				750 mg every 12 h (%)

Similar comparisons can be made for drugs within the same class to determine the optimal drug choice. The choice will also depend on the MIC distribution of the species to be covered. For instance, the PTA for ciprofloxacin is inferior to other quinolones for the treatment of pneumococci but superior for *Ps. aeruginosa* infections.

PREDICTED FRACTION OF RESPONSE: INTEGRATION OF MIC DISTRIBUTIONS AND PHARMACODYNAMIC DATA

The approach can be taken one step further by incorporating the frequency distribution of MIC values of the target pathogen. By multiplying the PTA and the relative frequency of the target pathogen, the fraction of target attainment is obtained at each MIC; by cumulating these, the cumulative fraction of target attainment is obtained. In this fashion, not only the variability in pharmacokinetic parameters is considered, but also the variance in susceptibility in the target pathogen population. The major drawback of this approach is that the MIC frequency distribution of the target micro-organism population has to be unbiased and this is almost never the case. The cumulative frequency of target attainment can be very useful, however, in the development phase of a drug to determine whether the response is sufficiently adequate for further follow-up. For instance, Drusano and colleagues showed that the cumulative fraction of target attainment for a 6 mg/kg dose of everninomycin would be 34% given the priors in the simulations and thereby concluded that further development of the drug was not justified.¹⁷

BREAKPOINTS

In choosing an antibiotic, the clinician is guided by reports from the microbiology laboratory. In the report, classifications of ‘susceptible’ (S) and ‘resistant’ (R) are used to indicate whether the use of an antimicrobial will have a reasonable probability of success or failure, respectively.^{20,22}

Ideally, when an anti-infective drug is developed, the pharmacodynamic target is determined in various models of infection. This provides the estimates of exposure required to treat infectious micro-organisms. Phase I trials provide information on pharmacokinetic parameters of the drug in humans. Using the derived population pharmacokinetic parameters and measures of dispersion, Monte Carlo simulations can subsequently be used to determine the dosing regimens needed to obtain the exposures required at a range of MICs. Then, the MICs that need to be covered – based on the indications of the antimicrobial and micro-organisms causing the infection – need to be established. Finally, the dosing regimen resulting in an exposure in a significant part of the patient population – using a diagram such as Figure 4.9 or Table 4.3 – can be derived that will cover the relevant wild-type (WT) distribution. This dosing regimen is then validated in phase II and phase III trials. It follows, therefore, that the clinical breakpoint of the species to be covered is at the right-end of the WT distribution. In other words, the breakpoint is the MIC for which the PTA was considered to choose the adequate dose.

Unfortunately, most of the anti-infective drugs that are available today were developed before this whole approach became feasible because the knowledge was not available at the time. Breakpoints derived in the past are therefore more the result of practical use, appropriate or less appropriate comparative trials, assumptions of efficacy *in vivo* and local history. A full discussion regarding this subject can be found in Mouton et al.²³ The essential difference with the procedure described above is that dosing regimens have been established for years and sometimes decennia ago without the pharmacokinetic/pharmacodynamic information that is presently available. Two clear examples are the evaluation of piperacillin breakpoints²⁴ and cefepime breakpoints.²⁵ In a retrospective analysis looking at mortality after 30 and 28 days, respectively, it was shown that current CLSI breakpoints are too high with respect to the dosing regimens commonly applied, and those breakpoints do not distinguish between a high and a lower probability of cure. This clearly indicates that periodic re-evaluation of breakpoints is necessary as science evolves.

SOME OTHER FACTORS TO BE CONSIDERED WHEN DEFINING OPTIMAL EXPOSURES

TARGET DELINEATION

The pharmacodynamic target to select a dosing regimen and a susceptibility breakpoint is based on the information that we have (*see above*), but the true value is unknown. For

instance, the target value for the AUC is usually taken as 100–125 for Gram-negatives, because that value has been found to be discriminative between groups of patients responding to therapy and those who did not. However, there are several reports that in some cases higher values are clearly necessary, while lower values have also been described. In the study published by Forrest et al.,⁴ 125 (notably, total drug) was the cut-off value below which the probability of cure was distinctly lower, but values above 250 resulted in a faster cure rate. Thus, although the final effect was more or less equal for patients with AUC/MIC values of 125 and above, the rate at which the effect was achieved differed. Similarly, although the current assumption is that the PK/PD index value necessary for (bacteriological) cure is similar for most infections, this is not necessarily the case. For instance, it has been shown that PK/PD index values needed to reach a maximum effect in sustained abscesses is higher.²⁶ Thus, the target value may be different by micro-organism as well as by clinical indication.

EMERGENCE OF RESISTANCE

While the above discussion was focused on efficacy, and pharmacodynamic targets based on cure (either clinical or microbiological), other factors should also be considered. One of the most important factors is emergence of resistance. While hardly any data existed before the millennium change, it becomes increasingly clear that emergence of resistance is also dependent on exposure. Although space prohibits a full discussion, it must be noted that several authors have shown that the PT to prevent emergence of resistance has a different value from the one for efficacy. Most often it is higher and it may even be different from the PI best predicting efficacy.²⁷

POPULATION TO BE TREATED

The output of MCS is directly dependent on the pharmacokinetic parameter values and their measures of dispersion used for input. Thus, if pharmacokinetic parameter estimates are used from a small group of healthy young male volunteers obtained in phase I or phase II studies, the simulations will be biased towards relatively low PTAs, because the elimination rate of most drugs is higher in volunteers than in the average patient. On the other hand, there are patient groups such as patients with cystic fibrosis known to have higher clearances for most drugs, and specific analyses have been made for such specific patient groups.¹⁹ Comparing the results of Monte Carlo simulations of ceftazidime for three different populations – healthy volunteers, patients with cystic fibrosis and intensive care unit patients – significant differences in PTA were shown, in particular at the extremes of the distribution.¹⁹

EXPOSURE IN FIRST COMPARTMENT (SERUM) AS OPPOSED TO CONCENTRATIONS AT THE SITE OF INFECTION

While most of the exposure–response relationships have been drawn from concentrations in serum, these are – except for bacteremias – used as a surrogate for concentrations at the actual receptor site. While these relationships show a marked consistency, it has to be borne in mind that the actual concentration–effect relationships at the site of infection are usually unknown. However, most bacterial infections are located in the extracellular compartment and it is those concentrations that are of primary interest. Most antibiotics have been shown to reach the extracellular fluid rapidly, with concentrations in extracellular fluid comparable to the non-protein-bound concentration in serum or plasma,²⁸ although there seem to be some exceptions such as cerebrospinal fluid (CSF) and epithelial lining fluid (ELF) concentrations.²⁹ Nowadays, microdialysis techniques which only measure unbound drug concentrations are increasingly being used to obtain concentration–time profiles in interstitial fluid.³⁰ Thus, the strong relationship between unbound drug concentrations in serum or plasma with those in extracellular fluid explains the good correlation found between unbound serum concentrations and in-vivo effects. Using data obtained from in-vitro time kill curves, we have shown that the predicted $fT_{>MIC}$ for a static

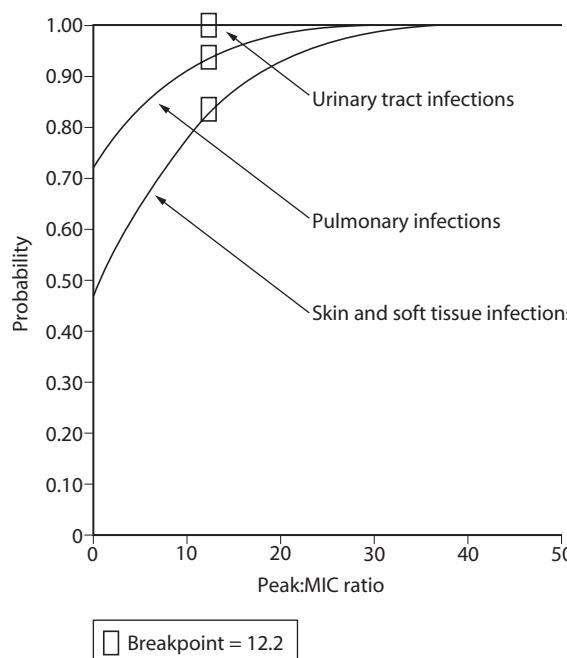

Fig. 4.10 Exposure–response relationship for different sites of infection. Reproduced from Preston SL, Drusano GL, Berman AL, et al. Pharmacodynamics of levofloxacin: a new paradigm for early clinical trials [see comments]. *Journal American Medical Association*. 1998;279(2):125-129.³³

effect in an animal model of infection was between 35% and 40%, substantiating the paradigm that effects *in vivo* can be predicted by exposures in serum.³¹

There are, however, differences that should be considered. The equilibrium and the type of infection do matter. There are several papers which clearly show that the exposure–response relationship differs by type and site of infection, in particular pulmonary infections.^{32,33} An example is shown in Figure 4.10.

TOXICITY

The approach to pharmacodynamic targets for toxicity is essentially similar to that for efficacy as described above, in that the exposure–response description is sought for, and PTAs are determined. The conclusions from this relationship, however, are fundamentally different in that the PT is at the minimum part of the curve instead of the maximum. For some drugs, optimizing the PT for efficacy and toxicity results are clearly at odds with each other and a compromise then needs to be sought in a conflict. An excellent paper discussing this issue is focused on optimizing aminoglycoside therapy.³⁴

CONCLUSION

As our understanding of the processes underlying antimicrobial activity evolves and more information becomes available it allows for improved antimicrobial treatment. The major advances over the last two decades have been to describe exposure–response relationships for anti-infectives in a meaningful manner. This has resulted in a more rational approach to the design of dosing regimens and it applies, as indicated at the start of the chapter, to all anti-infective agents. It has also changed the way we look at antimicrobial breakpoints and how antimicrobials can be developed. While the main focus of target delineation has been on efficacy of antimicrobials, the primary challenge during the present era is to uncover pharmacodynamic targets that prevent emergence of resistance. This is a fast developing field that needs continuous attention.

Antimicrobial agents and the kidneys

S. Ragnar Norrby

Antimicrobial drugs may interact with the kidneys in several ways. Decreased renal function often results in slower excretion of drugs or their metabolites. In the extreme situation the patient lacks renal function and is treated with hemodialysis, peritoneal dialysis or hemofiltration; since most antimicrobial drugs are low-molecular-weight compounds they are often readily eliminated from blood by such treatments. However, more and more drugs (e.g. the fluoroquinolones and many of the macrolides) are so widely distributed in tissue compartments and/or so highly protein bound that only a small fraction is available for elimination from the blood. Moreover, many antimicrobials are eliminated by liver metabolism and can be administered at full doses, irrespective of renal function, provided their metabolites are not toxic.

Another type of interaction between drugs and the kidneys is nephrotoxicity. Some of the most commonly used antimicrobial drugs (e.g. the aminoglycosides and amphotericin B) are also nephrotoxic when used in normal doses relative to the patient's renal function.

This chapter deals with general aspects on interactions between antimicrobial drugs and the kidneys. The readers are referred to section 2 for details about dosing in patients with reduced renal function.

RENAL FUNCTION AND AGE

The prematurely born child has reduced renal function. Thereafter the glomerular filtration rate (GFR) is higher than in the adult. The young, healthy adult has a GFR of about 120 mL/min. Creatinine clearance overestimates GFR by 8–10%. With increasing age GFR becomes markedly reduced and in the very old (>85 years) is often lower than 30 mL/min, even if there are no signs of renal disease. For drugs that are excreted only by glomerular filtration, which are not metabolized and which have low protein binding (e.g. the aminoglycosides and many of the cephalosporins), the renal clearances are normally directly proportional to the GFR. As shown in Figure 5.1,¹ the elimination time (the plasma half-life) of the drug increases slowly in the range from normal

GFR to markedly reduced GFR but then increases drastically. Clinically this means that the drug will not accumulate markedly until renal function is profoundly decreased. However, when that is the case, only very slight further reductions of renal function will result in a marked increase in the elimination time and an obvious risk of accumulation to toxic levels.

Measurement of GFR is difficult because it requires precise collection and volume measurement of urine over time for determination of creatinine clearance or repeated plasma samples when ⁵¹Cr clearance or inulin clearance are studied. For ⁵¹Cr clearance there is also a need to administer and handle an isotope, and none of these methods is suitable for routine clinical use. The most frequently used way to measure renal function is by serum creatinine assay, which in the last decades has replaced blood urea nitrogen. However, serum creatinine depends on renal function and muscle mass. Therefore, in a very old person with reduced muscle mass, serum creatinine may be within normal values despite the fact that GFR is <25 mL/min. As a consequence, serum creatinine must be related to age, sex and weight (or preferably lean body mass). Two widely used routine methods are available: the Cockcroft and Gault formula (Figure 5.2)² and a nomogram (Figure 5.3).³

ELIMINATION OF ANTIMICROBIAL DRUGS IN RENAL FAILURE

GENERAL ASPECTS

Only water-soluble drugs are eliminated via the kidneys: liver metabolism normally aims at producing water-soluble metabolites that can be excreted renally. In the kidneys water-soluble compounds that are not bound to protein are eliminated by glomerular filtration, tubular secretion or both of these mechanisms. For protein-bound drugs, only the free fraction is available for glomerular filtration. Following glomerular filtration some drugs (e.g. the aminoglycosides) are reabsorbed into, and sometimes accumulate in, proximal tubular cells.

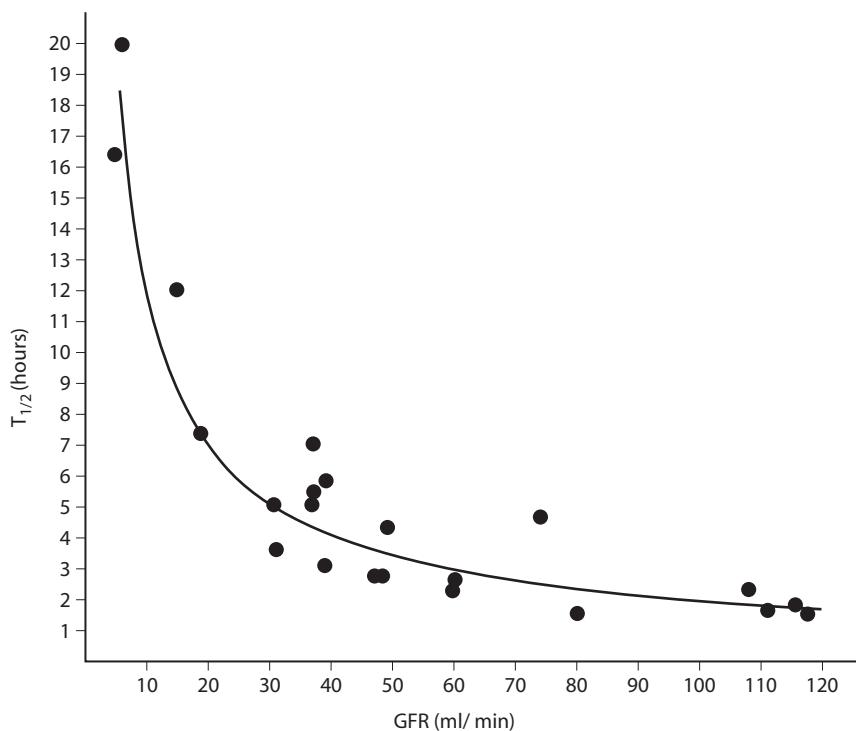

Fig. 5.1 Correlation between glomerular filtration rate (GFR) and serum half-life ($t_{\frac{1}{2}}$) of ceftazidime. After Alestig et al. Ceftazidime and renal function. *Journal of Antimicrobial Chemotherapy* 1989; 13: 177–181 with permission of Oxford University Press.

In renal failure glomerular filtration is reduced while tubular secretion is often maintained. The effect of renal failure depends to a large degree on whether the drug is also metabolized or eliminated through the bile. For example, among the cephalosporins, cefuroxime has low protein binding and is not metabolized; its plasma clearance will be virtually identical to creatinine clearance. Ceftriaxone, on the other hand, has a relatively high protein binding and is eliminated via the bile; in patients with renal failure the elimination half-life of ceftriaxone will not increase markedly because the proportion of drug eliminated by biliary excretion will increase. Another example is imipenem, which is excreted by glomerular filtration but which also has a (non-hepatic) metabolism that is constant over time. In renal failure the plasma half-life of imipenem will increase, but only to about 3 h in the anuric patient (compared with 1 h in an individual with normal renal function). In contrast, cilastatin, the enzyme inhibitor administered with imipenem, has relatively little metabolism and low protein binding, and its half-life will increase from about 1 h to more than 10 h in severe renal failure.

$$\text{Creatinine clearance (mL/min)} = \frac{f \times (140 - \text{age (years)}) \times \text{Body weight (kg)}}{\text{Serum creatinine } (\mu\text{mol/L})}$$

$f = 1.23$ for men and 1.04 for women

Fig. 5.2 Cockcroft and Gault² formula for estimation of creatinine clearance.

It is essential to know the mode of elimination of all antimicrobial drugs used as well as the effects on elimination time of renal failure. Many compounds are toxic if given in overdose, and failure to correct dosages in patients with markedly reduced renal function may result in serious adverse effects.

ANTIMICROBIAL DRUGS THAT ARE INDEPENDENT OF RENAL FUNCTION FOR THEIR ELIMINATION

Some antimicrobial drugs can be given at full doses even to patients with severe renal failure (Table 5.1). However, also in such patients elimination by hemodialysis or hemofiltration should be considered. A relatively simple rule of thumb is that drugs that are highly protein bound ($\geq 90\%$) and drugs that have a large volume of distribution tend not to be eliminated. Alternatively, for most drugs with low protein binding and/or low volume of distribution, a further dose should be considered after peritoneal dialysis, hemodialysis or hemofiltration.

ANTIMICROBIAL DRUGS THAT SHOULD BE AVOIDED IN SEVERE RENAL FAILURE

Nephrotoxic drugs should not be used in patients with renal failure unless they are anephric. When using formulations that are combinations of two drugs, it should be noted that the pharmacokinetics of the two components in renal failure

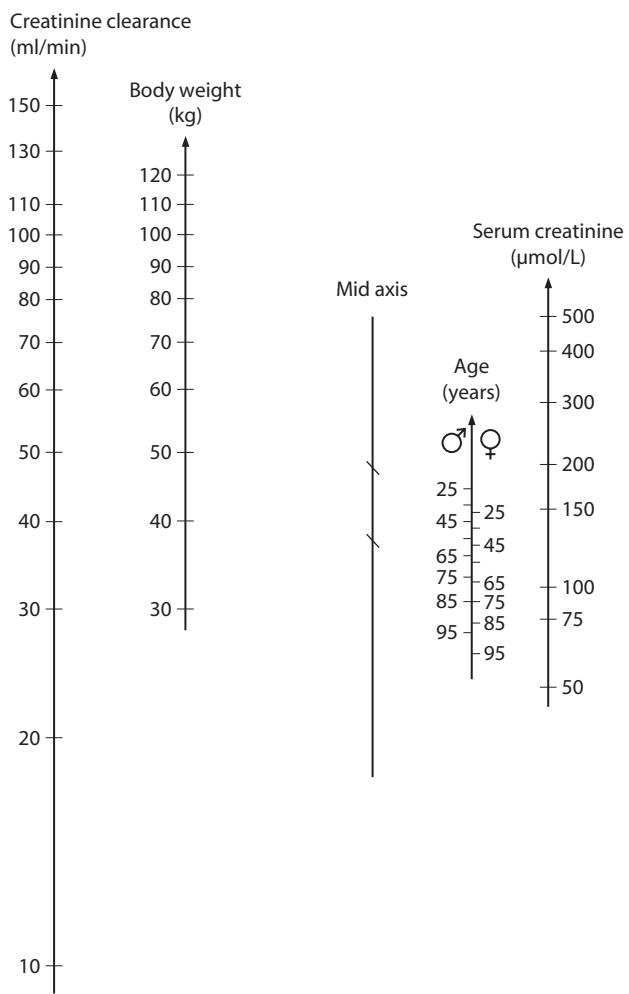

Fig. 5.3 Nomogram for calculation of creatinine clearance. Connect body weight and age with a ruler and mark the crossing on the mid axis. Connect the crossing with the serum creatinine value and read the estimated creatinine clearance. After Siersbaek-Nielsen K, Mølholm Hansen J, Kampmann J, Kristensen M. Rapid evaluation of creatinine clearance. *Lancet*. 1971;ii:1333–1334.

may differ from those in patients with normal kidney function. Examples are imipenem–cilastatin and piperacillin–tazobactam: the elimination times of cilastatin and tazobactam increase far more drastically than those of imipenem and piperacillin, which both undergo substantial metabolism.

PERITONEAL DIALYSIS

Modern medicine offers several replacement treatments of severe renal failure: hemodialysis, continuous ambulatory peritoneal dialysis (CAPD), continuous arteriovenous hemofiltration (CAVHF), continuous venovenous hemofiltration (CVVHF) and continuous venovenous hemodiafiltration (CVVHDF). The degrees of elimination of individual antimicrobial drugs by these methods vary and are sometimes incompletely studied.

In terms of reproducibility of the elimination rate, CAPD is likely to be the least reproducible, both with the same patient

Table 5.1 Antimicrobial drugs that can be given at full doses to patients with severe renal failure

Drug	Comments
Anidulafungin	
Atazanavir	
Azithromycin	
Caspofungin	
Ceftriaxone	The manufacturer recommends a maximum daily dose of 2 g if glomerular filtration rate is <10 mL/min
Chloramphenicol	
Clarithromycin	
Clindamycin	
Darunavir	Other tetracyclines should not be used in renal failure
Doxycycline	
Efavirenz	It has been proposed that the risk of toxicity should increase in patients with renal failure
Erythromycin	
Ethambutol	Limited data
Fosamprenavir	No data but minimal renal excretion
Indinavir	
Itraconazole	
Ketoconazole	
Linezolid	
Lopinavir	Exposure to two main metabolites increases 10 times at a glomerular filtration rate of <30 mL/min
Mebendazole	Limited data for anuric patients
Mefloquine

Zanamivir	

and between patients. The main reason for this is that, with time, a person undergoing CAPD is likely to develop fibrin adherence, which limits the peritoneal surface area available for dialysis. The efficacy of the dialysis may also vary with the position of the patient and the amount of dialysis fluid administered during a specified time. Other factors limiting elimination of drugs with CAPD are protein binding and molecular size. There is often limited information about rate of elimination of an antimicrobial agent in patients using CAPD. For renally eliminated antibiotics, the most common recommendation is to give the dose normally administered to a patient with a GFR <10 mL/min. When aminoglycosides are given to patients on CAPD, about 50% of the dose given is found in the dialysate fluid but regular serum concentration assays are recommended (*see below*).

In patients undergoing CAPD, antibiotics are also frequently used as additives to peritoneal dialysate fluid to treat peritonitis, a common complication in these patients. Since the most common agent causing these infections is coagulase-negative staphylococci that are often methicillin resistant, vancomycin is most frequently used. In such treatment varying

but generally quite high plasma concentrations are achieved as a result of passage of the antibiotic from the dialysate fluid to plasma. This is especially important to note if the patient is also on systemic antibiotic treatment.

HEMODIALYSIS

In hemodialysis toxic substances are cleared from blood through passive diffusion across a membrane. Drug elimination via hemodialysis depends on molecular size of the drug, protein binding and volume of distribution (drugs with a molecular weight <500 Da normally pass through the dialysis filter easily if they are not protein bound). Factors of the dialysis technique that influence drug elimination are dialysis time, blood and dialysate flow rates, and dialysis membrane permeability, pore size and surface area. Elimination of molecules of 500–5000 Da will depend largely on the type of filter used; some of the modern filters also allow passage of relatively large molecules.

For most antibiotics, the effect of hemodialysis on elimination is known, although information is more limited on antifungal, antiparasitic and antiviral drugs (Tables 5.2 and 5.3). With drugs that are readily eliminated during hemodialysis it is necessary to give a new dose directly after hemodialysis; no dose corrections are needed for those that are not significantly eliminated.

Table 5.2 Antimicrobial drugs which are removed during hemodialysis

Drug	Dose recommendation
Abacavir	The manufacturer does not recommend the use of abacavir in patients with severe renal insufficiency
Aцикловир	Maximal oral dose 800 mg every 12 h. New parenteral dose after dialysis and then half normal dose every 24 h
Аdefovir dipivoxil	One dose weekly
Amikacin	Two-thirds of normal dose after dialysis. Monitor serum concentrations
Amoxicillin	New dose after dialysis
Amoxicillin-clavulanic acid	New dose after dialysis
Ampicillin	New dose after dialysis
Aztreonam	Half normal dose after dialysis and one-quarter of normal dose between dialyses
Cefaclor	New dose after dialysis
Cefadroxil	New dose after dialysis
Cefalexin	New dose after dialysis
Cefamandole	New dose after dialysis
Cefapirin	New dose after dialysis
Cefazolin	New dose (maximum 1 g) after dialysis
Cefdinir	New dose after dialysis
Cefepime	0.5 g per day. New dose (maximum 1 g) after dialysis
Cefixime	New dose after dialysis
Cefoperazone	New dose after dialysis
Cefotaxime	New dose (maximum 1 g) after dialysis
Cefotetan	New dose (maximum 1 g) after dialysis
Cefpodoxime	New dose after dialysis
Cefprozil	250 mg after dialysis
Cefradine	New dose after dialysis
Ceftazidime	New dose (maximum 1 g) after dialysis
Cefuroxime	New dose after dialysis
Clarithromycin	New dose after dialysis
Daptomycin	Insufficient data to allow dosage recommendations

Didanosine	New dose after dialysis and then once daily
Doripenem	Insufficient data to allow dosage recommendations
Emtricitabine	New dose every 96 h
Entecavir	0.1 mg every 24 h or 0.5 mg every 72 h
Ertapenem	Insufficient data to allow dosage recommendations
Famciclovir	New dose after dialysis and then every 48 h
Fluconazole	New dose after dialysis
Flucytosine	New dose after dialysis. Monitor serum concentrations
Ganciclovir	Half dose after dialysis and then 0.625 mg/kg three times/week
Gentamicin	Two-thirds normal dose after dialysis. Monitor serum concentrations
Imipenem-cilastatin	New dose after dialysis and then 0.5 g every 12 h
Lamivudine	25 mg once daily
Levofloxacin	125 mg per day
Mecillinam	New dose after dialysis
Meropenem	New dose after dialysis
Metronidazole	New dose after dialysis
Netilmicin	Two-thirds normal dose after dialysis. Monitor serum concentrations
Oflloxacin	100 mg every 12 h
Paludrine	50 mg every week
Penicillin V and G	New dose after dialysis
Piperacillin	1 g after dialysis and then 2 g every 8 h
Piperacillin-tazobactam	2 g (of piperacillin) after dialysis and then 4 g (of piperacillin) every 12 h
Stavudine	New dose after dialysis and then once daily
Sulfamethoxazole	New dose after dialysis
Sulfisoxazole	New dose after dialysis
Tecoplanin	Dose for GFR <10 mL/min. Monitor serum concentrations
Telbivudine	New dose every 96 h
Tenofovir disoproxil	New dose once weekly
Ticarcillin	New dose after dialysis
Tobramycin	Two-thirds normal dose after dialysis. Monitor serum concentrations
Trimethoprim	New dose after dialysis
Valaciclovir	Maximal dose 1 g once daily
Valganciclovir	Insufficient data to allow dosage recommendations
Vancomycin	Dose for GFR <10 mL/min. Monitor serum concentrations

Doses, when specified, are for adults. GFR, glomerular filtration rate.
Data are partly taken from Livornese et al.⁴

No information has been found on elimination of the following in patients on hemodialysis: abacavir, artemether plus lumefantrine, daptomycin, doripenem, ertapenem, foscarnet, indinavir, itraconazole, ketoconazole, mefloquine, moxifloxacin, polymyxin B (colistin), ritonavir, saquinavir, sparfloxacin, trovafloxacin, zalcitabine and zidovudine. The manufacturer of isoniazid states that it is eliminated during hemodialysis but gives no dosage recommendations. The combination of atovaquone and proguanil (Malarone) for malaria prophylaxis should not be used in patients with severe renal dysfunction.

HEMOFILTRATION AND HEMODIAFILTRATION

There is far less information on elimination of drugs in patients on hemofiltration than there is for those on hemodialysis. The principle of removal of compounds by hemofiltration is convection of the compound in solution in plasma water over a filter, while hemodialysis involves diffusion against a dialysis fluid. In hemofiltration the drug is removed by drag of plasma

Table 5.3 Antimicrobial drugs that are not removed by hemodialysis

Drug	Comments
Amphotericin B	Large molecular weight
Azithromycin	Large molecule; very large volume of distribution
Ceftriaxone	High protein binding; alternative biliary excretion
Chloramphenicol	Large volume of distribution
Chloroquine	Large volume of distribution
Ciprofloxacin	Large volume of distribution
Clindamycin	Large volume of distribution; high protein binding
Cloxacillin	High protein binding
Dicloxacillin	High protein binding
Doxycycline	High protein binding; large volume of distribution
Erythromycin	Large molecule; large volume of distribution
Fusidic acid	High protein binding
Mefloquine	High protein binding
Minocycline	High protein binding; large volume of distribution
Nafcillin	High protein binding
Quinine	Large volume of distribution
Quinupristin-dalfopristin	Large volumes of distribution; large molecules
Rifabutin	Large volume of distribution; high protein binding
Rifampicin	Large volume of distribution
Spectinomycin	Always single dose
Tetracycline	High protein binding; large volume of distribution

water. Only free drug can be removed by this process and protein binding is a major factor restricting elimination. Large molecular size is also a restrictive factor. The efficiency with which a drug is removed is measured as the *sieving coefficient*; a drug with a sieving coefficient of 1 will cross the filter freely; one with a coefficient of 0 is unable to cross. Amikacin has a sieving coefficient of 0.9, amphotericin B (which has a high molecular weight) 0.3 and oxacillin (which has a very high protein binding) 0.02.

Hemofiltration is generally less efficient than hemodialysis in eliminating drugs from plasma. The most common recommendation for drugs which are normally given in a full dose after each intermittent hemodialysis is to give the dose used in patients with moderate renal failure (GFR 10–50 mL/min) during CVVHF or CAVHF. In patients treated with aminoglycosides or glycopeptides, serum concentrations should be monitored to avoid toxic reactions.

Another way of treating patients with acute renal failure is to use continuous venovenous hemodiafiltration (CVVHDF), which combines hemofiltration and hemodialysis. This technique is more efficient in eliminating filterable and dialyzable drugs. Table 5.4 gives a comparison of CVVHF and CVVHDF when used in patients treated with meropenem.

NEPHROTOXICITY OF ANTIMICROBIAL DRUGS

Some antimicrobial drugs – such as the aminoglycosides, vancomycin and amphotericin B – are also nephrotoxic when dosed correctly in relation to the renal function of the patients. Others (e.g. cefaloridine; no longer available) are nephrotoxic

Table 5.4 Comparison of meropenem pharmacokinetics in patients treated with continuous venovenous hemofiltration (CVVHF) or hemodiafiltration (CVVHDF)

Parameter (mean \pm pL SD)	CVVHF	CVVHDF (1 L/h)	CVVHDF (2 L/h)
Meropenem half-life (h)	7.5 \pm pL 2.0	5.6 \pm pL 1.4 ^a	4.8 \pm pL 1.2 ^{a,b}
Meropenem clearance (L/h)	3.3 \pm pL 2.3	4.7 \pm pL 2.7 ^a	5.7 \pm pL 3.6 ^a

^a Significantly ($p < 0.05$) different from the CVHF.
^b Significantly ($p < 0.05$) different from the CVHDF (1 L/h) phase.
Data from Valtonen et al.⁵

if overdosed while a large number of drugs, especially the penicillins and rifampicin (rifampin), have been reported to cause interstitial nephritis in a very low frequency of patients treated. Some antimicrobial agents (e.g. older sulfonamides, quinolones and indinavir) may cause urolithiasis as a consequence of precipitation in the renal pelvis.

AMINOGLYCOSIDE NEPHROTOXICITY

This subject has been excellently reviewed by Mingeot-Leclercq and Tulkens.⁶ Following glomerular filtration, approximately 5% of an aminoglycoside dose is reabsorbed in the proximal tubular cells of the kidneys. This process is assumed to be, at least partially, the result of adsorptive endocytosis and most of the reabsorbed aminoglycoside is found in endosomal and lysosomal vacuoles. However, part of the reabsorbed drug is found in the Golgi complex. The tubular reabsorption of aminoglycosides results in accumulation of drug in the proximal tubular cells since the release from the cells is far slower than the rate of uptake. Important for the discussion below of optimal dosing of aminoglycosides is the fact that the uptake into the tubular cells seems to be saturable.

At normal aminoglycoside doses, signs of nephrotoxicity can be observed after a few days, manifest as release of brush border and lysosomal enzymes and increased excretion of potassium, magnesium, calcium, glucose and phospholipids. After prolonged treatment (>7 days) serum creatinine increases as a consequence of reduced GFR. At the subcellular level, accumulation of polar lipids into so-called ‘myeloid bodies’ is seen. There is some evidence that generation of toxic oxygen metabolites (hydrogen peroxide) plays an important role in this pathological process.⁷ If these early changes are overlooked and if the patient is overdosed, the end result will be tubular necrosis and renal failure.

The best way to reduce the effects of aminoglycoside nephrotoxicity is to adjust doses in order to avoid overdosing and subsequent risks for serious nephrotoxicity and for ototoxicity. This can be achieved by regular monitoring of serum concentrations of the aminoglycoside used (*see later*).

The pharmacodynamics of aminoglycosides are characterized by a direct correlation between antibacterial efficacy and the area under the serum concentration curve, i.e. the higher

Table 5.5 Results of a meta-analysis of single versus multiple daily dosing of aminoglycosides

Parameter	Mean difference ^a	95% confidence interval
Overall clinical response	3.06% ($p = 0.04$)	0.17–5.95%
Overall microbiological response	1.25% (not significant)	−0.40 to 2.89%
Nephrotoxicity	−0.18% (not significant)	−2.17 to 1.81%
Ototoxicity	1.38% (not significant)	−0.99 to 3.75%
Vestibular toxicity	−3.05% (not significant)	−10.7 to 4.59%

^aA positive result for response or a negative result for toxicity favors single daily dose regimens.

Data modified from Ali & Goetz.⁸

the individual dose the more bactericidal the aminoglycoside. This speaks in favor of using few doses per time unit. Fortunately, several studies show there to be no increase in toxicity of aminoglycosides when once-a-day regimens have been used rather than regimens with two or three daily doses. Table 5.5 shows the results of a meta-analysis of studies comparing single and multiple daily dosing of aminoglycosides. From the results of that study (and others) it seems clear that aminoglycosides should be administered once daily. This has been questioned for neutropenic patients in whom there may be a reduced post-antibiotic effect of the aminoglycoside. However, studies have indicated no reduction in efficacy or safety of aminoglycosides when single and multiple daily dosing have been compared in neutropenic patients.

GLYCOPEPTIDE NEPHROTOXICITY

Both vancomycin and teicoplanin are nephrotoxic but the latter appears to be less so.⁹ The mechanism by which these antibiotics are nephrotoxic is not completely known. It has been postulated that glycopeptides accumulate in proximal tubular cells as a result of passage from the blood rather than by tubular reabsorption.

The risk of developing nephrotoxicity seems to vary with certain risk factors. In one study cisplatin administration, high APACHE scores and administration of carboplatin, cyclophosphamide or non-steroidal anti-inflammatory drugs correlated to increased nephrotoxicity of vancomycin in cancer patients.¹⁰ High individual doses (high area under the serum concentration curve) and prolonged treatment seem to increase the risk of nephrotoxicity.¹¹

Nephrotoxicity of glycopeptides seems to be reversible in most cases. However, vancomycin therapy should be monitored with serum concentration assays (see below). Teicoplanin concentrations should also be monitored but this is more to achieve therapeutic levels (e.g. in a patient with endocarditis) than to prevent nephrotoxicity.

NEPHROTOXICITY OF β -LACTAM ANTIBIOTICS

Cefaloridine (no longer available for therapeutic use) was the first cephalosporin with marked dose-related nephrotoxicity. Cefaloridine accumulates in proximal renal tubular cell, probably by active anionic transport. Thus, probenecid, which blocks such transport, eliminates the nephrotoxicity of cefaloridine.

Nephrotoxicity of the cefaloridine type has been seen with imipenem given intravenously to rabbits. That toxicity is completely blocked if imipenem is administered as a 1:1 combination with cilastatin, an inhibitor of the brush border renal enzyme (dehydropeptidase-I) which metabolizes imipenem and which also has a probenecid-like effect.

Ceftazidime, which has a mode of elimination and renal handling very similar to that of cefaloridine, has shown slight nephrotoxicity in overdose.

Dicloxacillin, when used as prophylaxis in orthopedic surgery, increases serum creatinine. So far no explanation has been offered as to why single doses of dicloxacillin (with or without single dose of gentamicin) should result in increased serum creatinine.

NEPHROTOXICITY OF POLYMYXIN B (COLISTIN)

Colistin is an antibiotic which is being used more commonly now than when it was introduced because of its activity against multiresistant Gram-negative bacteria, especially *Acinetobacter baumanii* and Enterobacteriaceae producing extended spectrum β -lactamases. It had a bad reputation due to reports of neurotoxicity and nephrotoxicity. Recent studies have shown lower rates of nephrotoxicity than previously reported.^{12,13} However, in one of these reports,¹² 7/42 patients with high serum creatinine values prior to colistin treatment developed renal failure.

AMPHOTERICIN B NEPHROTOXICITY

Amphotericin B acts by binding to ergosterol in the cytoplasmic membrane of the fungal cell. It is fungicidal and, for systemic treatment of several clinically important mycoses, is often the only therapeutic choice. Unfortunately, amphotericin B also binds to ergosterol in the human cell and in particular the proximal tubular cells of the kidney. Thus, treatment of mycoses such as aspergillosis and disseminated candidiasis with normal doses of amphotericin B results in reduced renal function manifested by loss of potassium, loss of magnesium, signs of tubular necrosis and decreased GFR. Factors of importance for how long treatment can continue are total dose given and renal function at the start of treatment.

The nephrotoxicity of amphotericin B can be reduced considerably, but not eliminated, by administration of the drug as a lipid formulation. Several variants of such formulations (e.g. incorporation of amphotericin B in liposomes and complex binding to phospholipids) have been developed (see Ch. 32).

ACUTE INTERSTITIAL NEPHRITIS AND ANTIMICROBIAL DRUGS

The following antimicrobial drugs have been reported to cause acute nephritis: aciclovir, cephalosporins, chloramphenicol, erythromycin, ethambutol, fluoroquinolones (ciprofloxacin and norfloxacin), gentamicin, minocycline, penicillins, rifampicin, sulfonamides, trimethoprim and vancomycin.¹⁴ Typically, the patient develops hematuria and proteinuria after more than 10 days of treatment. Other common symptoms are fever and rash, often with eosinophilia. These conditions are normally rapidly reversible if treatment is stopped.

UROLITHIASIS CAUSED BY ANTIMICROBIAL DRUGS

Sometimes a drug may precipitate in the kidney as a result of poor solubility in urine. Important factors in the risk of formation of precipitates are urine volume, urine pH and drug solubility. Drugs with a high tendency to precipitate and cause symptoms of urolithiasis include the older sulfonamides and indinavir, an HIV protease inhibitor. For ciprofloxacin and some other fluoroquinolones, the solubility is very poor at alkaline pH. Thus, a patient with a renal infection caused by *Proteus* spp. may be at risk of clinically significant precipitation of the quinolone.

MONITORING OF SERUM CONCENTRATIONS OF ANTIMICROBIAL DRUGS

Serum concentration assays have two purposes: to avoid exceeding drug levels known to increase the risk of toxicity and to ensure that the dose given is sufficient to achieve therapeutic activity. For most antimicrobial drugs, serum concentration assays are not meaningful because there are no defined limits for toxicity or therapeutic efficacy. With some antibiotics (e.g. imipenem) concentration assays should be avoided because the drug is very unstable and transportation of the sample may lead to degradation of imipenem and falsely low concentrations in the assay. However, for some antimicrobial agents serum concentration assays are clinically indicated (Table 5.6).

Table 5.6 Antimicrobial drugs for which serum concentration monitoring is indicated

Drug	Comments
Aminoglycosides	High trough levels clearly related to nephrotoxicity and ototoxicity; low peak levels related to increased risk of therapeutic failure
Flucytosine	Concentrations <25 mg/L increase risk of emergence of resistance; concentrations >100 mg/L may result in toxicity
Glycopeptides	High trough levels related to nephrotoxicity and ototoxicity; low peak levels related to increased risk of therapeutic failure
Isoniazid	Concentration assay helps in identifying fast and slow acetylators; concentrations may be too low in the former and toxic in the latter

Drug interactions involving anti-infective agents

Keith A. Rodvold and Donna M. Kraus

The medical treatment of common causes of infectious diseases (e.g. HIV, fungi, tuberculosis, and resistant Gram-negative or Gram-positive bacteria) has continued to evolve. The standard of care for these infections often requires patients to receive combinations of anti-infective agents as well as other medications to treat other diseases or clinical conditions. The medication profiles of individual patients in the infectious diseases clinic or hospital services have become increasingly more complex and are associated with higher probabilities of drug–drug interactions and adverse drug reactions.

Recent regulatory actions by the US Food and Drug Administration (FDA) remind us that important drug–drug interactions with anti-infective agents can result in withdrawal of drugs from the marketplace, termination of clinical development and restrictive dosage recommendations. Examples of these consequences include the withdrawal of terfenadine, astemizole and cisapride in the 1990s after patients experienced serious cardiac toxicity when taking these anti-histamine or prokinetic drugs in combination with macrolide antibiotics or azole antifungals.¹ The antiviral agent, pleconaril, was not recommended for FDA approval for the treatment of the common cold in 2002 because of the potential for drug–drug interactions.² Pleconaril, a known cytochrome P₄₅₀ (CYP) inducer, can potentially lower the plasma drug concentrations of CYP3A substrates and reduce their effectiveness, including oral contraceptive steroids such as ethinyl estradiol. Finally, the product package insert of the CCR5 co-receptor antagonist, maraviroc, is an example of the FDA restricting the dosing recommendations (Table 6.1) because of potential drug–drug interactions with potent CYP3A inhibitors or inducers during combination therapy.³ Both the pharmaceutical industry and regulatory agencies have issued guidance papers on the methodologies of in-vitro and in-vivo pharmacokinetic drug–drug interaction studies because of the increasing concern about drug–drug interactions.⁴ In addition, labeling of product package inserts has recently been revised and various sections describe relevant information about metabolic enzymes, drug transporters and drug–drug interactions.

Drug–drug interactions in the field of infectious diseases continue to expand as old and new agents requiring metabolic enzymes and transporters are commonly used, treatment recommendations for co-infections are revised, and the use of multiple medications (e.g. polypharmacy) proliferates in an aging population.^{5–7} In addition, commonly

prescribed medications with known drug–drug interactions are more likely to cause serious adverse health outcomes in elderly patients admitted to the hospital. Juurlink et al. recently performed a case-control study to determine the odds ratio (OR) for association between hospital admission of elderly patients with digoxin toxicity and use of clarithromycin within the previous week.⁶ A total of 1051 patients admitted to the hospital for digoxin toxicity were compared to a control group ($n = 51\,896$) without toxicity. The patients with digoxin toxicity were 13 times more likely to have received prior clarithromycin therapy (OR, 13.6; confidence interval [CI] 8.8–20.8). In comparison, no significant association (OR, 2.0; CI, 0.6–6.4) was found between patients with digoxin toxicity and prior use of cefuroxime within 1 week of hospital admission. This evidence is further supported by a large retrospective study that demonstrated a five-fold increased in the rate of cardiac-related sudden death in patients who were co-administered CYP3A inhibitors and erythromycin compared to patients who did not receive a CYP3A inhibitor or anti-infective agent.⁷ These studies illustrate that many of the known drug–drug interactions are avoidable and that clinicians must consider alternative therapy when appropriate.

This chapter provides an overview of the principles and mechanisms of drug–drug interactions and uses extensive tables to summarize pharmacokinetic–pharmacodynamic interactions commonly associated with each anti-infective class. Physicochemical and in-vitro antimicrobial activity (e.g. additive, synergistic or antagonistic) interactions will not be discussed. This review was based on information available in the product package inserts, primary literature retrieval from PubMed, computer databases of Micromedex Drugdex® System, and current issues of the following textbooks: Piscitelli and Rodvold's *Drug Interactions in Infectious Diseases*,⁸ Hansten and Horn's *Drug Interactions Analysis and Management*,⁹ Tatro's *Drug Interaction Facts*,¹⁰ and Stockley's *Drug Interactions*.¹¹ In addition, Stockley's *Herbal Medicine Interactions*¹² is a recently published textbook that provides a comprehensive review of drug interactions with herbal medicines, dietary supplements and nutraceuticals. The reader is referred to these resources as well as to the primary literature and online websites for detailed information and reference lists about drug–drug interactions associated with a specific anti-infective agent. The reference list at the end of this chapter is mainly limited to secondary literature because of the publication space restrictions.

Table 6.1 Dosing recommendations for maraviroc associated with drug–drug interactions

Maraviroc dosage	Dosing recommendation for interacting drugs
300 mg every 12 h	Standard dose of maraviroc with no concomitant administration of cytochrome P ₄₅₀ (CYP) 3A inhibitors or inducers; recommended dosage of maraviroc with concomitant administration of tipranavir–ritonavir or nevirapine
150 mg every 12 h	Reduced dose of maraviroc with concomitant administration of CYP3A4 inhibitors (with or without a CYP3A inducer) including protease inhibitors (exception: tipranavir–ritonavir [see above dosage recommendation]), delavirdine, ketoconazole, itraconazole, clarithromycin (including with etravirine plus ritonavir-boosted protease inhibitors or with efavirenz plus either lopinavir–ritonavir or saquinavir–ritonavir), and other strong CYP3A inhibitors (e.g. nefazadone, telithromycin)
600 mg every 12 h	Increased dose of maraviroc with CYP3A inducers (without a CYP3A inhibitor) including rifampicin, carbamazepine, phenytoin, phenobarbital, efavirenz and etravirine

PHARMACOKINETIC AND PHARMACODYNAMIC DRUG-DRUG INTERACTIONS

A drug–drug interaction is defined as the change in efficacy or toxicity of one drug by prior or concomitant administration of a second drug. In general, drug–drug interactions involve two drugs: the interacting drug (e.g. precipitant, perpetrator) is the agent that causes a change to occur upon another drug (e.g. substrate, object, victim). Alterations in the pharmacokinetic or pharmacodynamic characteristics of the object drug are the two commonly used mechanisms for categorizing drug–drug interactions.¹³

Pharmacokinetic interactions are those associated with alterations in the processes of absorption, distribution, metabolism or elimination of a medication. The consequences of this type of drug–drug interaction include increased or decreased concentrations of a drug in the blood, body fluids and/or tissues, which may in turn alter the efficacy or toxicity of the object drug. The most commonly measured pharmacokinetic parameters used to describe and assess these changes include maximum drug concentration (C_{\max}), area under the concentration–time curve (AUC), apparent drug clearance (CL), half-life ($t_{1/2}$) or total amount of drug excreted in the urine (Ae).

Absorption interactions generally involve orally administered drugs and occur in the mucous membranes of the gastrointestinal (GI) tract. Common causes for drug–drug interactions involving absorption include: (1) alterations in GI pH; (2) adsorption, chelation or other complexing mechanisms; (3) changes in GI motility; (4) induction or inhibition of drug transporter proteins or intestinal CYP isoenzymes; (5) malabsorption caused by drugs; and (6) alteration to the normal GI flora.¹¹ Oral anti-infective agents such cefpodoxime

proxetil, ketoconazole, itraconazole, delavirdine and atazanavir have dissolution and absorption that is pH dependent and can be affected by antacids, proton pump inhibitors and histamine₂ (H₂) antagonists.^{11,14} Antacids, vitamin/mineral supplements or other therapeutic agents containing divalent and trivalent cations, such as aluminum, magnesium, calcium or iron, chelate tetracycline and fluoroquinolones, resulting in markedly reduced oral GI absorption, lower systemic drug concentrations and lower anti-infective efficacy.¹⁵

The oral bioavailability of digoxin can be increased or decreased by agents such as clarithromycin and rifampicin (rifampin), respectively. These effects are most likely explained by alterations to P-glycoprotein (P-gp).¹⁶ This efflux transporter can reduce drug absorption from the GI tract, as well as promote drug removal or decrease drug entry at various sites of distribution and elimination. Rifampicin is an inducer of P-gp which leads to decreased oral absorption of medications while macrolides such as erythromycin and clarithromycin are inhibitors of intestinal and renal P-gp of digoxin. Oral neomycin can impair the absorption of digoxin by causing a malabsorption syndrome similar to non-tropical sprue.¹¹ Antibiotics can also alter the normal GI flora and thus affect the metabolism and absorption of medications such as warfarin and estrogen-containing products (e.g. oral contraceptive agents).

Pharmacokinetic drug–drug interactions can be related to protein binding and distribution characteristics of medications. Drug–drug interactions associated with protein binding could be clinically significant if the drug being displaced has a narrow therapeutic index, small volume of distribution, high extraction ratio, and is highly protein bound (>90%) at therapeutic concentrations. Displacement interactions have often been associated with drugs that are highly protein bound (e.g. warfarin, phenytoin). However, these agents have a low extraction ratio and drug concentrations are independent of protein binding changes since they can effectively clear any increase in the unbound fraction of the drug. The significance of drug–drug interactions involving protein binding and drug displacement is less than what was once thought since steady-state unbound (free) drug concentrations often redistribute and remain unaltered.¹⁷ In addition, some drug–drug interactions once thought to be associated with protein binding and drug displacement have been shown to be associated with other interaction mechanisms. For example, the increased anticoagulant activity associated with warfarin when administered with trimethoprim–sulfamethoxazole is more likely caused by the inhibition of S-warfarin metabolism (e.g. CYP2C9) than from warfarin being displaced from its protein-binding sites.¹⁵

There are several transport proteins which play a role in mediating tissue-specific distribution as well as absorption and excretion of drugs.^{18–21} The two major gene superfamilies responsible for the transport of drugs are ABC (ATP binding cassette) and SLC (solute carrier). P-glycoprotein (P-gp, also termed MDR1) is one of the most studied transporters from the ABC superfamily. P-gp and other transport proteins are

located throughout the body in tissues and can control exposure of drugs at target organs. It has also been shown P-gp and organic anion transporting polypeptide (OATP) and organic anion transporter (OAT) families are involved with efflux transport in the blood–brain barrier and blood–cerebrospinal fluid (CSF) barrier. The organic transport systems are particularly important in the distribution of β -lactam agents. Membrane transporters and drug response is a growing field of research and should further clarify drug–drug interactions associated with the distribution of anti-infective agents.

Drug metabolism serves as the major mechanism of many pharmacokinetic drug–drug interactions.^{13,22} Drugs are mainly metabolized by enzymes in the liver, GI tract, skin, lungs and blood. Drug-metabolizing enzymes are found in the endoplasmic reticulum of these sites and are classified as microsomal enzymes. There are two major types of drug metabolizing reaction: phase I, which increases the polarity of drugs predominantly through oxidation, reduction or hydrolysis; and phase II, which catalyzes drugs and/or metabolites to inactive products by glucuronidation, sulfation or acetylation. Phase II reactions are most commonly mediated by sulfotransferase (SULT), uridine diphosphate glucuronosyltransferase (UGT), glutathione-S-transferase (GST), N-acetyltransferase (NAT) and thiopurine methyltransferase (TPMT) (Figure 6.1). Many of the enzymes involved in phase II are still being further defined, and drug–drug interactions are being further investigated.

The majority of phase I reactions are catalyzed by cytochrome P₄₅₀ enzymes in the liver and small intestine, which are heme-containing, membrane-bound proteins. Cytochrome P₄₅₀ is a superfamily of enzymes divided into families (designated by CYP followed by a number, e.g. CYP2), subfamilies (designated by a capital letter, e.g. CYP2C), and individual members (designated by a number, e.g. CYP2C19) based on amino acid sequence homology. The most common individual members of enzyme subfamilies responsible for the majority of phase I metabolic reactions are CYP3A4, CYP2D6, CYP1A2, CYP2C9 and CYP2C19 (Figure 6.2).^{13,22}

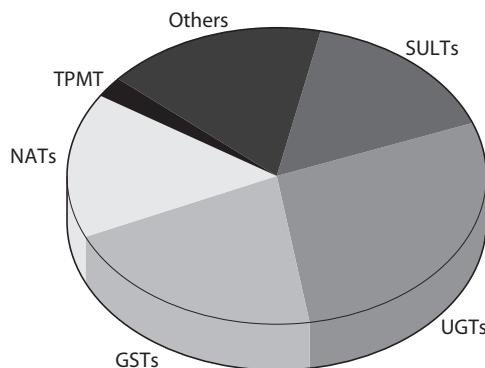

Fig. 6.1 The relative proportions of clinically used drugs metabolized by phase II enzymes. GST, glutathione-S-transferase; NAT, N-acetyltransferase; TPMT, thiopurine methyltransferase; SULT, sulfotransferase; UGT, uridine diphosphate glucuronosyltransferase.

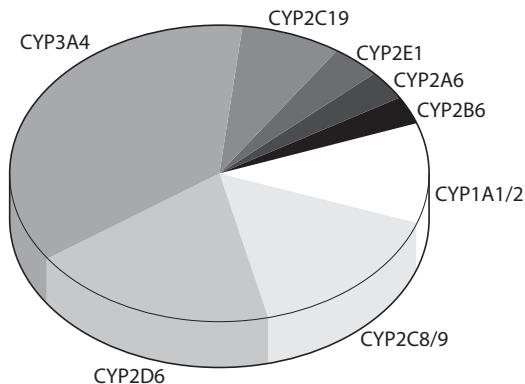

Fig. 6.2 The relative proportions of clinically used drugs metabolized by phase I (cytochrome P₄₅₀ [CYP]) enzymes.

More than 50% of all drugs on the market are metabolized by CYP3A4.^{13,22} CYP3A4 is the major CYP isoform found in the adult liver and accounts for 28% of total hepatic CYP enzymes. In addition, CYP3A4 is also found in the GI tract and has effects on bioavailability. There is significant overlapping activity between P-gp and CYP3A4 at both of these sites, and a drug causing an effect on P-gp will also have the same effect on CYP3A4. Many drug–drug interactions previously thought to be due to only CYP3A4 may actually involve the additive effects of both P-gp and CYP3A4. Phase I reactions can also involve other CYP-independent enzymes such as monoamine oxidases and epoxide hydrolases.

Drug–drug interactions involving CYP isoenzymes are often the result of either enzyme inhibition or induction.¹³ A drug that is an inhibitor of a specific drug-metabolizing enzyme will decrease the rate of metabolism and increase plasma concentrations of an object drug. Increased drug accumulation can result in enhanced therapeutic effects or adverse effects, especially if the object drug has a narrow therapeutic range or index. A greater increase in the AUC or C_{max} of the object drug would be predicted to occur when the specific drug-metabolizing enzyme is the primary elimination pathway compared to substrates with multiple elimination pathways of which the enzyme plays only a minor role. Inhibition of metabolic pathways can also lead to decreased formation of an active metabolite of the object drug and this may result in decreased therapeutic efficacy of the drug.

Inhibition of CYP3A4 is a common cause of drug–drug interactions with anti-infective agents. Table 6.2 provides examples of some of the serious and/or life-threatening drug–drug interactions known to occur between substrates of CYP3A4 and anti-infective agents known to be potent inhibitors of CYP3A4. The co-administration any CYP3A4 inhibitors should be avoided or only undertaken with extreme precautions (e.g. dosage adjustments or use of less potent inhibitors) with the listed substrates due to the serious clinical consequences. Anti-infective agents that are moderate to strong inhibitors of CYP3A4 include protease inhibitors, delavirdine, azole antifungal agents, clarithromycin, erythromycin and telithromycin.

Table 6.2 Substrates of CYP3A4 with major or life-threatening interactions when co-administered with a CYP3A inhibitor¹

CYP3A4 substrate	Pharmacological effect	Management recommendation
Astemizole, ² terfenadine, ² cisapride, ² bepridil, ² pimozide	QTc interval prolongation, arrhythmias, sudden death, torsade de pointes	Contraindicated
Ciclosporin, sirolimus, tacrolimus	Increased serum concentrations and immunosuppression	Monitor immunosuppressive agent serum concentrations; adjust dose as needed
Ergot alkaloids	Ergotism, peripheral ischemia	Contraindicated
Lovastatin, simvastatin	Risk of rhabdomyolysis	Use other HMG-CoA reductase inhibitors such as pravastatin or fluvastatin
Midazolam, triazolam	Excessive sedation	Use other benzodiazepines such as lorazepam, oxazepam or temazepam
Rifabutin	Uveitis, neutropenia, flu-like syndrome	Reduce dose of rifabutin
Sildenafil, tadalafil, vardenafil	Hypotension, priapism	Reduce dose or avoid use entirely
Vincristine, vinblastine	Neurotoxicity	Reduce dose and monitor for vinca toxicity

¹Examples of anti-infective agents that are potent cytochrome P₄₅₀ (CYP) 3A4 inhibitors include clarithromycin, erythromycin, telithromycin, protease inhibitors, delavirdine, ketoconazole, itraconazole and voriconazole.

²Drugs no longer commercially available in the USA.

HMG-CoA, hydroxymethylglutaryl-coenzyme A.

Inhibition of a specific drug-metabolizing enzyme can be either competitive or non-competitive. Competitive inhibition occurs when two drugs are substrates for the same drug-metabolizing enzyme. Binding of one agent to the enzyme prevents binding by the other, thereby decreasing the rate of metabolism and increasing systemic exposure and/or pharmacological effects of the drug with lower enzyme-binding affinity. In contrast, non-competitive inhibition occurs when one drug is an inhibitor of a specific drug-metabolizing enzyme (e.g. CYP3A4) and can substantially reduce the metabolism of an object drug of that enzyme. However, the inhibitor is metabolized by a different drug-metabolizing enzyme (e.g. CYP2D6) than the object drug being inhibited. The onset and dissipation of drug-drug interactions involving inhibition is rapid and occurs within the first few days after co-administration.

Phase I and II reactions can also be induced. Enzyme induction occurs when the precipitant drug induces the synthesis of the drug-metabolizing enzyme. Drugs that induce cytochrome P₄₅₀ isoforms cause increased drug clearance and decreased plasma concentrations of substrate drugs. Rifampicin is one of the most potent inducers and has effects on both CYP enzymes and P-gp.²²⁻²⁴ Rifampicin can also induce phase II enzymes such as UGT as well as other relevant transporter proteins. Because of this broad and potent range of induction activity, numerous drug-drug interactions have been reported between rifampicin and various therapeutic classes of drugs, including anti-infective agents (Table 6.3).²³ Because induction requires creation of new enzymes, the time course of the onset and dissipation of induction is slow and can take weeks to occur. When rifampicin induces the metabolism of an object drug, serum drug concentrations are gradually decreased and the full effect may not be seen for 2 weeks.

Many of the commonly used anti-infective agents are substrates, inhibitors and/or inducers of the clinically significant CYP isoforms, P-gp and UGT (Table 6.4). In addition, an updated list of drugs from various therapeutic classes and their designation as substrates, inhibitors or inducers of specific CYP isoforms can be found on the website <http://medicine.iupui.edu/clinpharm/ddis>. These tables can assist in the semi-quantitative prediction of potential drug-drug interactions, particularly when no published studies are available. It is important to appreciate that a drug can be a substrate of more than one CYP isoform and that the same drug may serve as an inhibitor or inducer of a different CYP isoform than the one being metabolized by it.

Factors that play an important role in determining the magnitude of changes in substrate metabolism include single or multiple substrate elimination pathways, existence of dominant elimination isoforms and the inhibitory-induction potency. Simultaneous therapy with both inducers and inhibitors of CYP isoforms may have unpredictable effects. There are no dosage guidelines that address these competing effects. It is suggested that close monitoring for toxicity or alternative agents that do not interact be used.

The clinical significance of the potential pharmacokinetic drug-drug interaction is supratherapeutic drug concentrations resulting in an exaggerated clinical response, toxicity, or both, or subtherapeutic drug concentrations resulting in loss of efficacy, the development of resistance, or both. For inhibition, the clinical consequences may be amplification of known adverse effects or the occurrence of a concentration-related toxicity. The therapeutic index, type of concentration-dependent toxicity and the dosage that the patient is receiving when the enzyme inhibitor is added to the treatment regimen are all important considerations.

Table 6.3 Drug–drug interactions of rifampicin (rifampin)

Interacting drug	Comments and management strategy
Anti-infective agents	
Atovaquone	Monitor clinical response; increase dose if needed; consider alternative agent
Caspofungin	Monitor clinical response; increase dose to 70 mg per day
Chloramphenicol	Monitor chloramphenicol serum concentrations; increase dose if needed
Clarithromycin	Monitor clinical and microbiological response; increase dose if needed
Dapsone	Monitor clinical response and hematological toxic effects
Delavirdine	Avoid rifampicin; use rifabutin or alternative agent and monitor viral response
Doxycycline	Monitor clinical and microbiological response; increase dose if needed
Efavirenz	Monitor viral response; increase dose if needed (e.g. 800 mg if >60 kg)
Etravirine	Avoid rifampicin; use rifabutin or alternative agent and monitor viral response
Fluconazole	Monitor clinical and microbiological response; increase dose if needed
Itraconazole, voriconazole	Avoid rifampicin; if used, increase dose of azole and monitor response
Maraviroc	Monitor viral response; appropriate dosing with inducers and inhibitors (see Table 6.1)
Mefloquine	Consider avoiding combination; larger study needed
Metronidazole	Monitor clinical and microbiological response; increase dose if needed
Nevirapine	Avoid rifampicin; use rifabutin or alternative agent and monitor viral response
Praziquantel	Consider alternative agent if possible; monitor clinical response
Protease inhibitors	Avoid rifampicin; use rifabutin or alternative agent and monitor viral response
Quinine	Monitor clinical response; consider alternative agent if possible
Raltegravir	Consider using rifabutin; if rifampicin is used, monitor viral response
TMP-SMX	Monitor clinical and microbiological response; increase dose if needed
Analgesics	
Codeine	Monitor pain control and clinical response
COX-2 inhibitors ¹	Monitor clinical response; increase dose if needed
Fentanyl	Monitor pain control; increase dose if needed
Methadone	Increase methadone dose; monitor and control withdrawal symptoms
Morphine	Monitor pain control and clinical response
Anticonvulsants	
Phenytoin	Monitor phenytoin serum concentrations and seizure activity; increase dose if needed
Antidiabetic agents	
Sulfonylureas ²	Monitor blood glucose levels; adjust dose based on blood glucose control
Meglitinides ³	Monitor blood glucose levels; adjust dose based on blood glucose control
Thiazolidinediones ⁴	Monitor blood glucose levels; adjust dose based on blood glucose control
Anticoagulants (oral)	
	Monitor INR; increase anticoagulant dose as needed
Cardiovascular drugs	
Beta-blocking agents	Monitor clinical response; increase propranolol or metoprolol dose if needed
Digitoxin	Monitor clinical response and/or arrhythmia control, monitor digitoxin serum concentrations
Digoxin (oral)	Monitor clinical response and/or arrhythmia control, monitor digitoxin serum concentrations
Diltiazem	Use alternative agent; monitor patient for clinical response
Disopyramide	Monitor arrhythmia control; increase dose if needed
Losartan	Monitor clinical response; increase dose if needed
Nifedipine	Consider alternative agents; if used, monitor clinical response; increase dose if needed
Nilvadipine	Monitor clinical response; increase dose if needed
Propafenone	Monitor clinical response; increase dose if needed; consider alternative agent
Quinidine	Monitor quinidine serum concentrations and arrhythmia control; increase dose if needed
Tocainide	Monitor arrhythmia control; increase dose if needed
Verapamil	Use alternative agent; monitor patient for clinical response
Contraceptives (oral)	
	Use alternative form(s) of birth control; counsel patient and document
Glucocorticoids	
	Increase dose of glucocorticoid two- to three-fold
HMG-CoA reductase inhibitors ⁵	Monitor lipid panel; increase dose if needed (likely for simvastatin)
Immunosuppressants	
Cyclosporin	Monitor cyclosporin serum concentrations; increased dose if needed
Tacrolimus	Monitor tacrolimus serum concentrations; increase dose if needed
Everolimus	Monitor everolimus serum concentrations; increase dose if needed
Psychotropic agents	
Buspirone	Monitor clinical response; increased dose likely needed; use alternative agent if possible

(Continued)

Table 6.3 Drug-drug interactions of rifampicin (rifampin)—cont'd

Interacting drug	Comments and management strategy
Clozapine	Monitor clinical response; increase dose if needed or use alternative agent if possible
Haloperidol	Monitor clinical response; increase dose if needed
Nortriptyline	Monitor clinical response and nortriptyline serum concentrations
Sertraline	Monitor clinical response; increase dose if needed
Others	
5-HT ₃ antiemetics ⁶	Monitor clinical response; increase dose if needed; use alternative agent if needed
Diazepam	Monitor clinical response; increase dose if needed
Gefitinib	Avoid combination; if must use, increase dose
Imatinib	Avoid combination; if must use, increase dose
Levothyroxine	Monitor thyroid stimulating hormone; increased dose likely needed
Lorazepam	Monitor clinical response; increase dose if needed
Midazolam	Avoid combination; use alternative agent if possible
Tamoxifen, toremifene	Monitor clinical response; increased dose likely needed
Theophylline	Monitor theophylline serum concentrations; increase dose if needed
Triazolam	Avoid combination; use alternative agent if possible
Zolpidem	Monitor clinical response; increase dose if needed or use alternative agent if possible

¹Examples include celecoxib and rofecoxib (no longer available).

²Examples include tolbutamide, chlorpropamide, gliclazide and glimepiride.

³Examples include repaglinide and nateglinide.

⁴Examples include rosiglitazone and pioglitazone.

⁵Examples include simvastatin, atorvastatin and pravastatin.

⁶Examples include ondansetron and dolasetron.

5-HT₃, 5-hydroxytryptamine 3; HMG-CoA, hydroxymethylglutaryl-coenzyme A; TMP-SMX, trimethoprim-sulfamethoxazole.

With this knowledge, one can decide whether the drug-drug interaction makes co-administration potentially hazardous. For induction, a hypothetical clinical consequence may be loss of anti-infective activity or possible development of resistance. In both of these examples, co-administration would not be advisable. Alternatively, these interactions may be overcome with higher doses. However, higher doses have often not been studied in most cases and unless recommended in the product monograph this is not advisable. Suggested dosage adjustment recommendations are based on mean changes in substrate clearance, and in most in-vivo dosage interaction trials, doses used were less than currently

recommended. It is often unknown whether product monograph dosage adjustment recommendations will result in safe and therapeutic substrate concentrations.

Regulatory agencies such as the FDA have placed greater emphasis on in-vitro and in-vivo drug-drug interaction assessment.^{1,21} Information on the likely potential of drug-drug interactions involving CYP enzymes and drug transporter proteins is included in the product package inserts of recently approved medications. For example, the product insert for daptomycin states that metabolic drug-drug interactions are unlikely since in-vitro studies have shown that daptomycin neither induces nor inhibits CYP isoforms 1A2, 2A6, 2C9, 2C19, 2D6, 2E1 and 3A4.²⁵ Similar to CYP isoforms, further information about metabolism and potential drug-drug interactions of phase II reactions are being included in product package information. The product insert for raltegravir states that this agent is mainly eliminated by metabolism via a UGT1A1-mediated glucuronidation pathway and is not a substrate of CYP enzymes.²⁶ Drugs known to inhibit (e.g. atazanavir) and induce (e.g. rifampicin) UGT1A1 have been shown in vivo to increase and decrease plasma concentrations of raltegravir, respectively.

There is significant interindividual variability in the outcomes of drug-drug interactions. This variability is often associated with patient-specific factors such as disease states, other concomitant medications and genetics. Genetic polymorphism has been identified with CYP2D6, CYP2C9 and CYP2C19, as well as many of the phase II enzymes. Clinically significant polymorphisms can contribute to ethnic differences in metabolism as well as drug safety and efficacy.²⁷ For CYP2D6, the prevalence of poor metabolizers is 5–8% in Caucasians and <1% in Asians. In comparison, the incidence of CYP2C19 poor metabolizers is 2–6% of Caucasians and 18–20% of Asians. The magnitude that drug-drug interactions will have is dependent in part on whether the initial enzyme activity is at a high or a low level. Inhibition of a drug-metabolizing enzyme in extensive or rapid metabolizers may result in more significant effects than in slow metabolizers. Thus, drug-drug interactions involving polymorphisms must be assessed for clinical relevance to an individual patient.

Pharmacokinetic drug-drug interactions can also occur during renal excretion. These interactions are rapid and occur competitively. The mechanisms for drug-drug interactions of renal elimination involve glomerular filtration, tubular secretion, tubular reabsorption, and drug transporter proteins (e.g. P-gp and OATs).^{13,18,19} Tubular secretion is the most common site of renal interactions since drugs often compete with each other for the same active transport system in the renal tubules. The classic anti-infective example is probenecid reducing the renal excretion of penicillin to increase anti-infective serum concentrations for therapeutic benefit. It has more recently been appreciated that organic anion transport (OAT) proteins are primarily located in the kidneys and facilitate the active renal secretion of several anti-infective agents including cidofovir, adefovir, aciclovir (acyclovir), ganciclovir, zidovudine and β-lactam antibiotics.^{18,19} Probenecid,

Table 6.4 Examples of anti-infective agents as substrates, inhibitors and inducers of CYP enzymes, UGT and P-gp

Enzymes or transporter	Substrates	Inhibitors	Inducers
CYP1A2	Ritonavir	Erythromycin, clarithromycin, ciprofloxacin, norfloxacin, ritonavir	Ritonavir, rifampicin
CYP2C9	Nelfinavir, ritonavir, fluconazole, voriconazole, dapsone	Erythromycin, metronidazole, sulfamethoxazole, trimethoprim-sulfamethoxazole, fluconazole, miconazole, voriconazole, isoniazid	Rifampicin, rifapentine
CYP2C19	Chloramphenicol, nelfinavir, ritonavir, fluconazole, voriconazole	Chloramphenicol, ritonavir, fluconazole, ketoconazole, voriconazole	Rifampicin
CYP2D6	Ritonavir	Primaquine, ritonavir	Rifampicin
CYP2E1	Ritonavir, isoniazid, dapsone	Ritonavir, isoniazid	Isoniazid
CYP3A4	Erythromycin, clarithromycin, telithromycin, clindamycin, protease inhibitors, delavirdine, nevirapine, NNRTIs, maraviroc, miconazole, ketoconazole, itraconazole, fluconazole, voriconazole, posaconazole, dapsone, quinine	Chloramphenicol, erythromycin, clarithromycin, telithromycin, norfloxacin, ciprofloxacin, amprrenavir, nelfinavir, lopinavir-ritonavir, ritonavir, saquinavir, indinavir, delavirdine, efavirenz, quinupristin-dalfopristin, clotrimazole, miconazole, itraconazole, ketoconazole, fluconazole, voriconazole, posaconazole	Efavirenz, nevirapine, rifampicin, rifabutin, rifapentine, ritonavir
UGT	Posaconazole, zidovudine, raltegravir	Ketoconazole, fluconazole, atazanavir	Rifampicin
P-gp	Clarithromycin, erythromycin, indinavir, nelfinavir, ritonavir, saquinavir, maraviroc, ketoconazole, itraconazole, fluconazole, posaconazole,	Clarithromycin, erythromycin, ketoconazole, itraconazole, indinavir, nelfinavir, ritonavir, saquinavir	Rifampicin, ritonavir

CYP, cytochrome P₄₅₀; NNRTIs, non-nucleoside reverse transcriptase inhibitors; P-gp, P-glycoprotein; UGT, uridine diphosphate glucuronosyltransferase.

a known OAT1 inhibitor, blocks the tubular transport of the nucleotide cidofovir and reduces its renal clearance to the rate of glomerular filtration. Concomitant use of probenecid decreases the risk of nephrotoxicity associated with cidofovir and is considered a beneficial drug–drug interaction. Although cidofovir does not affect the disposition of other agents, the concurrent administration of probenecid can inhibit renal tubular secretion of other commonly administered agents such as reverse transcriptase inhibitors (e.g. zidovudine, zalcitabine), β-lactams, methotrexate and non-steroidal anti-inflammatory drugs (NSAIDs). Various anti-infective agents (e.g. clarithromycin, itraconazole), as well as probenecid, have been shown to inhibit P-gp in the kidney. As with liver metabolism, significant overlapping activity exists between P-gp and other transport mechanisms involved with renal excretion.

In addition to pharmacokinetic drug–drug interactions, pharmacodynamic interactions can also occur.^{13,15} Pharmacodynamic drug–drug interactions are associated with a change in the pharmacological response (e.g. efficacy or toxicity) of the object drug, with or without changes in pharmacokinetics. Pharmacodynamic interactions can be categorized as:

- *additive*: two agents leads to enhanced pharmacological effect (e.g. increased bone marrow suppression with concurrent use of zidovudine and ganciclovir);
- *synergistic*: use of two or more agents results in drug effect greater than (e.g. exponential vs additive) the addition of all of the drugs together (e.g. combined effect with

concurrent use of indinavir, lamivudine, and zidovudine than the sum of their individual effects); or

- *antagonistic*: the pharmacological effect of one agent is reduced due to concurrent therapy with another agent (e.g. concurrent use of zidovudine and stavudine reduces antiviral effect).

Some of the common additive or overlapping adverse effects associated with anti-infective agents include ototoxicity, nephrotoxicity, bone marrow suppression and prolongation of the QTc interval. Concurrent administration of aminoglycoside antibiotics and other nephrotoxic agents such as amphotericin B, cisplatin, cyclosporin or vancomycin would be examples of additive risk for developing nephrotoxicity.¹⁵ Pharmacodynamic drug–drug interactions are less predictive a priori than pharmacokinetic interactions, and fewer reports exist in the literature.

IDENTIFICATION OF CLINICALLY SIGNIFICANT DRUG-DRUG INTERACTIONS

The prescribing of safe and effective anti-infective therapy has become increasingly important as issues of resistance and treatment failure constantly challenge our anti-infective armamentarium. In addition, anti-infective drug regimens have become more complex because of the expansion of different drug classes; increased number of agents per anti-infective class; the availability of more agents as substrates,

inhibitors and/or inducers of metabolism or transporter systems; and multiple different drug therapies being required to prevent or treat acute and chronic conditions or diseases due to both infectious and non-infectious causes. Awareness of clinically significant drug-drug interactions and appropriate inventions to minimize their occurrence are essential as anti-infective regimens become more complex.

Strategies for avoiding drug-drug interactions when selecting agents for use include:²⁸

- obtaining a detailed medication history before prescribing anti-infective agents;
- avoiding adding a drug with high drug-drug interaction potential;
- delaying initiation of an interacting drug until anti-infective therapy is completed;
- reviewing and considering concomitant diseases states that influence drug disposition and interactions;
- selecting specific agents with the least potential for known drug-drug interactions;
- avoiding agents associated with serious adverse effects or toxicities;
- avoiding concurrent administration of drugs with overlapping or additive adverse effects;
- using the lowest effective drug doses; and
- not underestimating the ability of patients to adhere to the recommended drug dosage regimens.

Many of the drug-drug interactions involving absorption can be simply avoided by separating or spacing the times of concurrent drug administration. While not all drug-drug interactions are avoidable, many can be better managed with dosage adjustments, selection of alternative agents with lower interaction probabilities, and therapeutic drug monitoring.

Infectious disease clinicians are often forced to assess of the possibility of a potential drug-drug interaction in patients already receiving multiple medications from different drug classes. Clues that should prompt careful evaluation of pre-existing drug regimens for potential drug-drug interactions include:²⁸

- drugs with well-documented drug-drug interaction potential;
- drugs with known, relatively narrow therapeutic ranges or indices;
- drugs with well-described pharmacodynamic determinants of efficacy or toxicity;
- drugs associated with serious adverse effects or toxicities; and
- the presence of extensive medication profiles in patients who cannot be easily monitored for drug efficacy and toxicity.

In addition, the drug interaction probability scale (DIPS) is a new tool that may be of assistance in providing a guide to evaluating drug-drug interaction causation in a specific patient.²⁹ Consultation with other infectious diseases physicians, pharmacists or drug-information specialists may also be valuable when multiple interactions are encountered.³⁰

Computer programs are a practical and potentially effective method for detecting drug-drug interactions.^{5,30} The intention of most of these programs is to alert the prescriber or dispensing pharmacist of a potential drug-drug interaction based on the information available in the patient medication profile. However, the level of concordance, specificity and sensitivity varies between programs, including those used in the community and hospital setting. In addition, many software programs and/or order entry systems have differing limitations such as accuracy in the classification or the lack of evidence for specific drug-drug interactions. Most programs do not provide timely updates as new information becomes available. Several studies have shown that users often override many of the different types of alerts and warnings being flagged. This often results in ‘alert fatigue’, which causes clinicians to ignore critical drug-drug interaction warnings which may require further information to determine the clinical relevance of the interaction and the individual patient being treated.

ANTIBACTERIAL AGENTS (Table 6.5)

Nearly all mechanisms of drug-drug interactions are represented by antibacterial agents.^{15,31-33} Several different types of absorption drug-drug interaction occur with different antibacterial agents:

- alterations in gastric pH caused by antacids, H₂-receptor antagonists or proton pump inhibitors (e.g. oral cephalosporins);
- inhibition of a transport pump such as intestinal P-gp (e.g. effect of clarithromycin on plasma digoxin concentrations);
- alterations of gut flora (e.g. decreased effectiveness of oral contraceptives or augmentation of effects of warfarin); and
- chelation of drug (e.g. tetracyclines or fluoroquinolones) by co-administration of divalent or trivalent cations such as calcium, magnesium, aluminum or iron. Common products containing multivalent cations include antacids, laxatives, antidiarrheals, multivitamins, sucralfate, didanosine tablets or powder, molindone, and quinapril tablets.

Sulfonamides can potentially displace sulfonylurea hypoglycemics and methotrexate from plasma protein binding sites, resulting in hypoglycemia and severe bone marrow depression, respectively.

Significant drug-drug interactions involving CYP3A4 and P-gp have been well documented for macrolide and ketolide agents (e.g. erythromycin, clarithromycin, telithromycin) since many of these drug-drug interactions are associated with serious or life-threatening adverse events (see Table 6.2).^{15,33} In addition, several classes of antibacterial agent are selective inhibitors of CYP2C8 and CYP2C9 (trimethoprim and sulfamethoxazole, respectively) and CYP3A4 (e.g. quinupristin-dalfopristin). Carbapenems can significantly decrease (e.g. by 40–80%) the serum concentrations of valproic acid by inhibiting the

Table 6.5 Drug–drug interactions of antibacterial agents

Antibacterial agent	Interacting drug	Interaction and management strategy
Oral cephalosporin prodrugs ¹	H ₂ antagonists or antacids	Decreased absorption of cephalosporin; space administration by at least 2 h
Penicillins, cephalosporins and carbapenems ²	Probenecid	Increased serum concentrations of β-lactam agent; avoid concomitant use when higher concentrations are not desirable or increased risk in toxicity (e.g. CNS) may occur
Ampicillin or amoxicillin	Allopurinol	Increased risk (three-fold higher) for rash; monitor for rash; consider alternative agent if possible
Carbapenems ³	Valproic acid	Decreased serum concentrations of valproic acid; monitor serum valproic acid concentrations and seizure activity; increase dose of valproic acid if needed or avoid concomitant use
Imipenem	Ganciclovir or ciclosporin	Increased risk for CNS toxicity; concomitant use of these agents is not recommended
Erythromycin, clarithromycin or telithromycin	Substrates of CYP3A4	See Table 6.2
	Antiarrhythmic agents ⁴	Increased serum concentrations of antiarrhythmic agents leading to the risk of QTc prolongation, torsades de pointes and death; alternative agents should be considered
	Calcium channel blockers ⁵	Increased serum concentrations of calcium channel blocker; monitor for hypotension, tachycardia, edema, flushing and dizziness; increased risk of sudden cardiac death (diltiazem, verapamil); consider alternative agent if possible
	Colchicine	Increased toxicity and mortality; avoid concurrent administration
	Digoxin	Increased digoxin serum concentrations and risk of toxicity; monitor serum digoxin concentrations and toxicity; decrease dose of digoxin as needed
	Theophylline	Increased theophylline serum concentrations and risk of toxicity; monitor serum theophylline concentrations and toxicity; decrease dose of theophylline as needed
	Tricyclic antidepressants and antipsychotic agents ⁶	Increased serum concentrations of antidepressant or antipsychotic agent; risk of QTc prolongation and torsades de pointes; alternative agents should be considered
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately
Fluoroquinolones ⁷	Multivalent cations ⁸	Decreased absorption of fluoroquinolone; space administration by at least 2–4 h
	Class Ia and IIIa antiarrhythmic agents	Increased risk of QTc prolongation and torsades de pointes; alternative agents should be considered in patients who at risk (e.g. history QTc prolongation or uncorrected electrolyte abnormalities)
	Theophylline	Ciprofloxacin or norfloxacin can increase theophylline serum concentrations and risk of toxicity; monitor serum theophylline concentrations and toxicity; decrease dose of theophylline as needed
	Tizanidine	Ciprofloxacin can increase tizanidine serum concentrations and risk of hypotensive effects; use alternative agents such as fluoroquinolones without CYP1A2 inhibition (e.g. levofloxacin or moxifloxacin)
Aminoglycosides, ⁹ polymyxin, colistin	Nephrotoxic agents ¹⁰	Direct or additive injury to the renal tubule; concomitant therapy should be avoided or used with caution and includes monitoring of renal function and dosage adjustment based on body weight, creatinine clearance estimation and/or serum aminoglycoside concentrations
	Ototoxic agents ¹¹	Increased risk of ototoxicity; concomitant therapy should be avoided or used with caution at the lowest possible dose; consider alternative agent if possible
	Neuromuscular blocking agents ¹²	Increased respiratory suppression produced by neuromuscular agent; concomitant therapy should be avoided or used with caution and includes monitoring for respiratory depression
Vancomycin	Aminoglycosides	Direct or additive injury to the renal tubule; concomitant therapy should be used with caution and includes monitoring of renal function and dosage adjustment based on body weight, creatinine clearance estimation and/or serum aminoglycoside and vancomycin concentrations
Daptomycin	HMG-CoA reductase inhibitors ¹³	May increase creatinine phosphokinase concentrations or cause rhabdomyolysis; monitor for signs and symptoms and consider temporarily discontinuation of HMG-CoA reductase inhibitor during daptomycin therapy
Linezolid	Selective serotonin reuptake inhibitors (SSRIs) ¹⁴	Increased serotonin concentrations and development of serotonin syndrome (hyperpyrexia, cognitive dysfunction); concomitant therapy should be avoided or used with caution and includes monitoring for serotonin syndrome
	Sympathomimetic agents ¹⁵	Enhance pharmacological (e.g. enhanced vasopressor effect); concomitant therapy should be avoided or used with caution; counsel patients regarding choice of OTC products

(Continued)

Table 6.5 Drug-drug interactions of antibacterial agents—cont'd

Antibacterial agent	Interacting drug	Interaction and management strategy
Quinupristin-dalfopristin	Substrates of CYP3A4	See Table 6.2
Tigecycline	Warfarin	Potential decreased clearance of warfarin; monitor PT/INR and adjust warfarin dose appropriately
Tetracyclines	Multivalent cations, ⁸ colestipol, kaolin-pectin, activated charcoal, and sodium bicarbonate	Decreased absorption of tetracyclines; space administration by at least 2 h
	Atovaquone	Decreased atovaquone concentrations; parasitemia should be closely monitored; consider alternative agent if possible
	Digoxin	Increased digoxin serum concentrations and toxicity; monitor digoxin serum concentrations and adjust dose appropriately
	Ergotamine tartrate	Increased ergotism; monitor for ergotism and use alternative therapy when possible
	Isotretinoin, acitretin	Additive effects of pseudotumor cerebri (benign intracranial hypertension); avoid concurrent use
	Lithium	Increased lithium serum concentrations and toxicity; monitor lithium serum concentrations and adjust dose appropriately
	Methotrexate	Increased methotrexate serum concentrations and toxicity; monitor methotrexate serum concentrations and use leucovorin rescue as needed
	Quinine	Increased quinine serum concentrations; monitor for quinine toxicity
	Theophylline	Increased theophylline serum concentrations; monitor toxicity and theophylline serum concentrations, and adjust dose appropriately
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately
Doxycycline	Barbiturates, chronic ethanol ingestion, carbamazepine, phenytoin, fosphenytoin, rifampicin, rifabutin	Decreased doxycycline serum concentrations; use other tetracycline product or alternative agent if possible
Metronidazole	Ethanol, OTC and prescription products containing ethanol or propylene glycol ¹⁶	Produces a disulfiram-like reaction (e.g. flushing, palpitation, tachycardia, nausea, vomiting); avoid concomitant therapy within 2 or 3 days of taking metronidazole; counsel patients about these potential side effects
	5-Fluorouracil	Increased toxicity; avoid concomitant use
	Lithium, busulfan, cyclosporin, tacrolimus, phenytoin, carbamazepine	Increased serum concentrations of interacting drugs; monitor toxicity and serum drug concentrations; adjust dose appropriately
	Phenobarbital, phenytoin, rifampicin, prednisone	Decreased metronidazole serum concentrations; monitor efficacy; doses of metronidazole may need to be increased
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately
Chloramphenicol	Paracetamol	Equivocal changes to chloramphenicol serum concentrations; monitor chloramphenicol serum concentrations and adjust dose appropriately; use other analgesic or antipyretic agents
	Cyclophosphamide	Decreased effectiveness of cyclophosphamide; avoid concomitant use
	Cimetidine	Bone marrow suppression and increased risk for aplastic anemia; avoid concomitant use and consider use of other antiulcer medications
	Folic acid, iron, cyanocobalamin	Delayed response of anemias; avoid concomitant use
	Cyclosporin, tacrolimus, phenobarbital, phenytoin	Increased serum drug concentrations of the interacting drug; monitor toxicity and serum drug concentrations; adjust dose appropriately
	Phenobarbital, phenytoin, rifampicin	Decreased chloramphenicol serum concentrations; monitor efficacy and chloramphenicol serum concentrations; adjust dose appropriately
	Sulfonylurea hypoglycemic ¹⁷	Enhanced hypoglycemia; monitor efficacy and blood glucose concentrations
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately

(Continued)

Table 6.5 Drug–drug interactions of antibacterial agents—cont'd

Antibacterial agent	Interacting drug	Interaction and management strategy
Trimethoprim-sulfamethoxazole	Amantadine, dapsone, digoxin, dofetilide, lamivudine, methotrexate, phenytoin, fosphenytoin, procainamide, zidovudine	Increased serum drug concentrations of the interacting drug; monitor for toxicity, drug concentrations (e.g. digoxin, procainamide and its metabolite, NAPA) or appropriate laboratory test (dapsone: methemoglobin level; zidovudine: CBC) and adjust dose appropriately; avoid concomitant use (e.g. dofetilide, methotrexate) if possible
	Azathioprine	Increased leucopenia; monitor CBC
	Ciclosporin	Decreased ciclosporin serum concentrations and azotemia; monitor ciclosporin serum concentrations and renal function; adjust dose appropriately
	Enalapril (ACE inhibitors), potassium, potassium-sparing diuretics	Hyperkalemia; monitor serum potassium level
	Methenamine	Crystallization of sulfonamides in urine; avoid concomitant use
	Metronidazole	Disulfiram reaction (ethanol in intravenous TMP-SMX product); use alternative therapy when possible
	Procaine, tetracaine	Decreased effect of sulfonamides; use alternative therapy when possible
	Pyrimethamine	Megaloblastic anemia and pancytopenia; monitor CBC and consider adding leucovorin rescue; avoid concomitant use
	Repaglinide, rosiglitazone, sulfonylurea hypoglycemic ¹⁷	Increased serum concentrations of interacting drug and increased hypoglycemic effect; monitor serum glucose concentrations and adverse effects
	Rifabutin	Increased sulfamethoxazole hydroxylamine concentrations; monitor for SMX toxicity
	Rifampicin	Increased rifampicin concentrations and decreased TMP-SMX concentrations; monitor TMP-SMX efficacy
	Thiazide diuretics	Hyponatremia; monitor serum sodium level
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately

¹Oral cephalosporin prodrugs such as cefpodoxime proxetil, cefuroxime axetil and cefditoren pivoxil.

²Inhibition of tubular secretion of most renally eliminated β -lactam agents.

³Imipenem, meropenem, ertapenem and doripenem.

⁴Examples include quinidine, ibutilide, sotalol, dofetilide, amiodarone and bretylium.

⁵Examples include nifedipine, felodipine, diltiazem and verapamil.

⁶Examples include amitriptyline, haloperidol, risperidone and quetiapine.

⁷Norfloxacin, ciprofloxacin, levofloxacin and moxifloxacin.

⁸Examples include antacids (containing aluminum or magnesium or calcium), iron, zinc, bismuth subsalicylate, multivitamin products, laxatives, sucralfate, didanosine, sevelamer and quinapril.

⁹Gentamicin, tobramycin, amikacin.

¹⁰Examples include amphotericin B, cisplatin, cyclosporin, vancomycin, foscarnet, intravenous pentamidine, cidofovir, polymyxin B, colistin, radio contrast and aminoglycosides.

¹¹Examples include ethacrynic acid, furosemide, urea, mannitol and cisplatin.¹¹

¹²Examples include succinylcholine, d-tubocurarine, vecuronium, pancuronium and atracurium.

¹³Hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (or the 'statins'), such as simvastatin, lovastatin, pravastatin and fluvastatin.

¹⁴Examples include sertraline, paroxetine, citalopram and fluoxetine.

¹⁵Examples include dopamine, epinephrine, and OTC cough and cold preparations that contain pseudoephedrine or phenylpropanolamine.

¹⁶Examples include oral (cough and cold OTC preparations, ritonavir solution) and intravenous products (diazepam, nitroglycerin, phenytoin, TMP-SMX). Amprenavir oral solution has a high content of propylene glycol.

¹⁷Examples include tolbutamide, chlorpropamide, glipizide and glibenclamide (glyburide).

ACE, angiotensin converting enzyme; CBC, complete blood count; CNS, central nervous system; CYP, cytochrome P₄₅₀; OTC, over-the-counter; PT/INR, prothrombin time/international normalized ratio; TMP-SMX, trimethoprim-sulfamethoxazole.

hydrolysis process between the glucuronide metabolite and valproic acid.^{31,34} Chloramphenicol has recently been shown to be a potent inhibitor of CYP2C19 and CYP3A4 and a weak inhibitor of CYP2D6 in human liver microsomes. In contrast, newer agents such as daptomycin, linezolid and tigecycline do not have significant activity to inhibit common human CYP isoforms (1A2, 2C9, 2C19, 2D6 and 3A4).^{15,25,33}

Probenecid inhibits OAT1 and renal tubular secretion of most β -lactams eliminated by the kidney.^{18,19} The product

package insert states that doripenem and probenecid should not be co-administered.³⁴ Other agents with the potential to inhibit tubular secretion of β -lactams include methotrexate, aspirin and indometacin. Trimethoprim is a potent inhibitor of renal tubular secretion and can increase plasma concentrations of amantadine, dapsone, digoxin, dofetilide, lamivudine, methotrexate, procainamide and zidovudine. Trimethoprim can also inhibit sodium channels of the renal distal tubules and can potentially cause hyperkalemia with

angiotensin converting enzyme (ACE) inhibitors, potassium supplements and potassium-sparing diuretics. In addition, hyponatremia has been associated with thiazide diuretics and trimethoprim therapy.

Several classes of antibacterial agent are associated with pharmacodynamic drug-drug interactions involving overlapping and/or additive toxicity.^{15,33} Numerous reports have documented the increased risk of developing nephrotoxicity with the concurrent administration of aminoglycosides with amphotericin B, cisplatin, ciclosporin (cyclosporine), vancomycin or indometacin (in neonates with patent ductus arteriosus). In addition, aminoglycosides should be avoided or used with caution with the above agents as well as other known nephrotoxic agents such as foscarnet, intravenous pentamidine, cidofovir, polymyxin B and colistin. An increased risk of ototoxicity has been reported with the co-administration of aminoglycosides and loop diuretics. Ethacrynic acid has been reported to cause hearing loss when administered alone and in conjunction with aminoglycosides such as kanamycin and streptomycin. Furosemide has also been identified as an additive risk factor for increased rates of nephrotoxicity and ototoxicity with aminoglycosides. Ethacrynic acid, furosemide, urea and mannitol should be used cautiously at the lowest possible doses in patients receiving concurrent aminoglycoside therapy. Aminoglycosides and clindamycin may enhance the effects of neuromuscular blocking agents (e.g. d-tubocurarine, pancuronium, vecuronium) and result in a prolonged duration of neuromuscular blockade.

Additive inhibition of dihydrofolate reductase to azathioprine, methotrexate or pyrimethamine contributes, in part, to the increased risk of myelotoxicity, pancytopenia and/or megaloblastic anemia when these agents are combined with trimethoprim and/or sulfamethoxazole.^{15,33,35} The combining of cimetidine with chloramphenicol has been associated with additive bone marrow suppression and increased risk for aplastic anemia. Tetracycline may potentiate the toxicities of lithium, methotrexate, methoxyflurane and ergotamine tartrate. The combination of tetracyclines or tigecycline with retinoids (e.g. acitretin, isotretinoin) is not recommended due to the potential additive effects of pseudotumor cerebri (benign intracranial hypertension).

Metronidazole produces a disulfiram-like reaction (e.g. flushing, palpitations, tachycardia, nausea, vomiting) in some patients who drink ethanol while taking the drug.¹⁵ Careful selection of over-the-counter and prescription medication is necessary since several oral (e.g. cough and cold preparations, ritonavir solution) and intravenous (e.g. diazepam, nitroglycerin, phenytoin, trimethoprim-sulfamethoxazole) products contain ethanol. Metronidazole and medications with a high content of propylene glycol should also be avoided or used with caution since metronidazole inhibits the alcohol and aldehyde dehydrogenase pathway that metabolizes propylene glycol.

Several case reports have been published regarding the temporal drug-drug interaction relationship between linezolid and selective serotonin reuptake inhibitors (SSRIs) such as

sertraline, paroxetine, citalopram and fluoxetine.^{15,33} The reversible monoamine oxidase inhibitor (MAOI) activity of linezolid also has the potential for drug-drug interactions involving over-the-counter cough and cold preparations containing adrenergic agents such as pseudoephedrine and phenylpropanolamine.

ANTIFUNGAL AGENTS (Table 6.6)

Amphotericin B and flucytosine are eliminated by renal excretion and are associated with significant adverse effects. Drug-drug interactions of amphotericin B and flucytosine involve overlapping or additive pharmacodynamic adverse effects (e.g. increased risks for myelosuppression or nephrotoxicity).³⁶ Amphotericin B-associated nephrotoxicity can cause fluid and electrolyte imbalances (e.g. hypokalemia) and these changes result in additive effects with diuretics, aminoglycosides or corticosteroids, or enhanced pharmacological effects with digoxin. However, combination therapy of amphotericin B and flucytosine may have synergistic antifungal effects and can be beneficial in the treatment of cryptococcal meningitis.

Azole antifungal agents are associated with numerous pharmacokinetic drug-drug interactions involving both induction and inhibition of CYP isoenzymes.³⁶⁻³⁹

- Ketoconazole is a substrate and strong inhibitor of CYP3A4.
- Fluconazole is an inhibitor of CYP3A4, CYP2C9 and CYP2C19. It is also a substrate of P-gp and inhibitor of UGT. Fluconazole is a much less potent inhibitor of CYP3A4 than itraconazole and ketoconazole; however, it is a stronger inhibitor of CYP2C9 than voriconazole. Unlike other azole agents, fluconazole is mainly renally eliminated (e.g. 80%) and only 11% is metabolized to two inactive metabolites.
- Itraconazole is a substrate and potent inhibitor of CYP3A4 (hepatic and intestinal) and P-gp.
- Voriconazole is a substrate and an inhibitor of CYP2C19, CYP3A4 and CYP2C9.
- Posaconazole is metabolized by phase II biotransformation using UGT and is an inhibitor of CYP3A4.
- Miconazole is a potent inhibitor of CYP2C9 and has been associated with drug-drug interactions (e.g. warfarin), even though miconazole is most commonly administered as a topical or oral gel.

Examples of clinically significant pharmacokinetic azole-drug interactions include induction (e.g. reduced plasma concentration of the azole by rifamycins), inhibition of CYP2C9 (e.g. warfarin and voriconazole), inhibition of CYP and breast cancer resistance protein (e.g. lovastatin and itraconazole), inhibition of CYP and P-gp (e.g. quinidine and itraconazole), inhibition of P-gp (e.g. digoxin and itraconazole), inhibition of UGT (e.g. zidovudine and fluconazole), and two-way interactions (e.g. induction of CYP or UGT by phenytoin and inhibition of CYP3A4 by azole). In addition, ketoconazole and itraconazole may have altered gastric absorption because

Table 6.6 Drug–drug interactions of antifungal agents

Antifungal agent	Interacting drug	Interaction and management strategy
Amphotericin B	Flucytosine	May increase myelosuppression; monitor CBC, renal function and flucytosine serum concentrations; initiate flucytosine at a low dosage (e.g. 75–100 mg/kg) and adjust dose as needed
	Nephrotoxic agents ¹	Direct or additive injury to the renal tubule; concomitant therapy should be avoided or used with caution and includes monitoring of renal function and dosage adjustment based on toxicity, body weight and creatinine clearance estimation
	Zidovudine, ganciclovir	May increase bone marrow toxicity; monitor CBC weekly
Flucytosine	Amphotericin B	May increase myelosuppression; monitor CBC, renal function and flucytosine serum concentrations; initiate flucytosine at a low dosage (e.g. 75–100 mg/kg) and adjust dose as needed
	Cytarabine	Antagonizes the antifungal activity of flucytosine; avoid concomitant use
	Zidovudine, ganciclovir	May increase bone marrow toxicity; monitor CBC weekly
Fluconazole	Substrates of CYP3A4	See Table 6.2; fluconazole is contraindicated for concomitant use with ergot alkaloids and drugs (e.g. astemizole, terfenadine, cisapride, quinidine, pimozide, mesoridazine, bepridil, thioridazine, levomethadyl, ziprasidone) that are CYP3A4 substrates and prolong the QTc interval
	Ciclosporin, tacrolimus, sirolimus, everolimus	Increased ciclosporin, tacrolimus, sirolimus or everolimus serum concentrations; monitor toxicity and serum drug concentrations, adjust dose as needed
	Phenytoin, fosphenytoin	Increased phenytoin serum concentrations and phenytoin toxicity; monitor toxicity and phenytoin serum concentrations and adjust dose as needed
	Rifampicin, rifapentine	Decreased fluconazole serum concentrations; monitor efficacy and increase dose as needed
	Sulfonylurea hypoglycemic ²	Enhanced hypoglycemia; monitor efficacy and blood glucose concentrations
	Theophylline	Increased theophylline serum concentrations and risk of toxicity; monitor serum theophylline concentrations and toxicity; decrease dose of theophylline as needed
	Warfarin	Enhanced anticoagulation; monitor prothrombin time/international normalized ratio (PT/INR) and adjust warfarin dose appropriately
Itraconazole	Zidovudine	Increased zidovudine serum concentrations; monitor for toxicity and adjust dose as needed
	Substrates of CYP3A4	See Table 6.2; itraconazole is contraindicated for concomitant use with ergot alkaloids, HMG-CoA reductase inhibitors metabolize by CYP3A4 (lovastatin, simvastatin), oral midazolam, triazolam, alprazolam, astemizole, terfenadine, cisapride, quinidine, pimozide, dofetilide, levomethadyl, silodosin, eplerenone, nisoldipine, ranolazine, alfuzosin or conivaptan
	Antacids, H ₂ antagonist (e.g. famotidine), proton pump inhibitor (e.g. omeprazole), didanosine (buffered formulation)	Decreased itraconazole absorption and serum concentrations; loss of antimycotic efficacy; alternative antifungal agent or interacting drug should be considerate; space antacid administration by at least 2 h; administer itraconazole with a cola beverage if receiving H ₂ antagonist; use new didanosine formulation with buffer
Itraconazole	Buspirone, haloperidol, risperidone, diazepam	Increased serum concentrations of interacting agents; monitor toxicity and adjust dose as needed
	Busulfan, docetaxel	Increased serum concentrations of interacting drugs and toxicity; monitor toxicity and complete blood count; adjust dose appropriately
	Calcium channel blockers ³	Increased serum concentrations of calcium channel blocking agents; monitor toxicity and adjust dose as needed
	Ciclosporin, tacrolimus, sirolimus, everolimus	Increased ciclosporin, tacrolimus, sirolimus or everolimus serum concentrations; monitor toxicity and serum drug concentrations; adjust dose as needed
	Digoxin	Increased digoxin serum concentrations and toxicity; monitor digoxin serum concentrations and adjust dose appropriately
	Loperamide	Increased loperamide serum concentrations; monitor for increased loperamide toxicity (e.g. nausea, vomiting, dry mouth, dizziness or drowsiness)
	Protease inhibitors (indinavir, ritonavir, saquinavir)	Increased serum concentrations of protease inhibitors and/or itraconazole; monitor toxicity and adjust dose as needed
Rifampicin, rifabutin, isoniazid, carbamazepine, phenobarbital, efavirenz, nevirapine, St John's wort	Rifampicin, rifabutin, isoniazid, carbamazepine, phenobarbital, efavirenz, nevirapine, St John's wort	Decreased itraconazole serum concentrations and loss of antimycotic efficacy; alternative antifungal agent or interacting drug should be considerate
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately

(Continued)

Table 6.6 Drug–drug interactions of antifungal agents—cont'd

Antifungal agent	Interacting drug	Interaction and management strategy
Posaconazole	Substrates of CYP3A4	See Table 6.2; posaconazole is contraindicated for concomitant use with ergot alkaloids, sirolimus and drugs (e.g. astemizole, terfenadine, cisapride, quinidine, pimozide, halofantrine) that are CYP3A4 substrates and prolong the QTc interval
	Cimetidine	Decreased posaconazole serum concentrations; avoid concomitant use and consider use of other antiulcer medications
	Ciclosporin, tacrolimus	Increased ciclosporin or tacrolimus serum concentrations; reduce dose of ciclosporin (by 25%) or tacrolimus (by 66%), monitor toxicity and ciclosporin or tacrolimus serum concentrations, and adjust dose as needed
	Phenytoin, fosphenytoin	Decreased posaconazole serum concentrations and increased phenytoin serum concentrations; avoid concomitant use; if concomitant use required, monitor efficacy, toxicity and phenytoin serum concentrations, and adjust dose as needed
Voriconazole	Substrates of CYP3A4	See Table 6.2; voriconazole is contraindicated for concomitant use with ergot alkaloids, ritonavir (400 mg every 12 h), sirolimus and drugs (e.g. astemizole, terfenadine, cisapride, quinidine, pimozide, ranolazine) that are CYP3A4 substrates and prolong the QTc interval
	Ciclosporin, tacrolimus	Increased ciclosporin or tacrolimus serum concentrations; reduce dose of ciclosporin or tacrolimus by 33–50%, monitor toxicity and ciclosporin or tacrolimus serum concentrations, and adjust dose as needed
	Methadone	Increased R-methadone concentrations and risk of toxicity (e.g. QTc prolongation, respiratory depression); monitor for toxicity and adjust dose as needed
	Omeprazole	Increased omeprazole serum concentrations; reduce omeprazole dose in half
	Phenytoin, fosphenytoin	Decreased voriconazole serum concentrations and increased phenytoin serum concentrations; increase voriconazole dose to 400 mg every 12 h (oral) or 5 mg/kg every 12 h (intravenous), monitor efficacy, toxicity and phenytoin serum concentrations and adjust dose as needed
	Rifampicin, rifabutin, carbamazepine, phenobarbital, mephobarbital, efavirenz, St John's wort	Decreased voriconazole serum concentrations; voriconazole is contraindicated for concomitant use with these interacting drugs
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately
	Anidulafungin	Slight increase in anidulafungin serum concentrations; no dose adjustment required
Caspofungin	Ciclosporin	Increased caspofungin serum concentrations and transient elevations in liver enzymes (e.g. ALT and AST); monitor for toxicity and liver enzymes
	Rifampicin (and potentially other potent inducers)	Decreased serum concentrations of caspofungin; monitor clinical response and increase caspofungin maintenance dose to 70 mg per day if needed
	Tacrolimus	Increased tacrolimus blood concentrations; monitor tacrolimus blood concentrations and adjust as needed
Micafungin	Ciclosporin	Decreased oral clearance and increased half-life of ciclosporin; monitor ciclosporin serum concentrations and adjust dose as needed
	Nifedipine	Increased nifedipine serum concentrations; monitor for nifedipine toxicity and reduce dose if needed

¹Examples include amphotericin B, cisplatin, ciclosporin, vancomycin, foscarnet, intravenous pentamidine, cidofovir, polymyxin B, colistin, radio contrast and aminoglycosides.

²Examples include tolbutamide, chlorpropamide, glipizide and glibenclamide (glyburide).

³Examples include nifedipine, felodipine, diltiazem and verapamil.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CYP, cytochrome P₄₅₀; HMG-CoA, hydroxymethylglutaryl-coenzyme A; PT/INR, prothrombin time/international normalized ratio.

of alteration in gastric pH or binding drug–drug interactions. Fluconazole, ketoconazole and voriconazole can also be associated with pharmacodynamic drug–drug interactions involving QTc prolongation.

Echinocandin antifungal agents are not commonly associated with drug–drug interactions.³⁶ Anidulafungin and micafungin are not clinically important substrates, inducers

or inhibitors of CYP isoenzymes or P-gp. Caspofungin is a poor substrate for CYP isoenzymes and is not a substrate for P-gp. Co-administration of rifampicin decreases serum concentrations of caspofungin. Caution is recommended when other potent drug inducers (e.g. carbamazepine, phenytoin, efavirenz, nevirapine, dexamethasone) are administered with caspofungin.

ANTIRETROVIRAL AGENTS

Some of the most challenging drug–drug interactions are associated with antiretroviral agents, particularly with non-nucleoside reverse transcriptase inhibitors, protease inhibitors and chemokine receptor antagonists.^{35,40,41} The increased knowledge about how these agents are metabolized and eliminated from the body has been helpful in predicting and managing many of the clinically significant drug–drug interactions. The reader should refer to the most recent report by the Panel on Antiretroviral Guidelines for Adults and Adolescents: A Working Group of the Office of AIDS Research Advisory Council (<http://www.aidsinfo.nih.gov>) for up-to-date guidelines on prescribing and monitoring antiretroviral agents, including important drug–drug interactions. In addition, there are several websites (e.g. <http://hivinsite.ucsf.edu>; <http://www.hiv-druginteractions.org>) that are readily available and contain updated information about drug–drug, drug–food and drug–herbal interactions with antiretroviral agents.

Table 6.7 Drug–drug interactions of nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs)

Antiviral agent	Interacting drug	Interaction and management strategy
Abacavir	Methadone	Decreased methadone serum concentrations; monitor for methadone withdrawal and titrate methadone dose as needed
	Tipranavir–ritonavir	Decreased abacavir serum concentrations; monitor for abacavir efficacy; appropriate dose for this combination is not established
Didanosine	Ganciclovir, valganciclovir (oral)	Increased didanosine serum concentrations and decreased ganciclovir serum concentrations after oral administration; monitor ganciclovir efficacy and didanosine toxicity
	Ribavirin	Increased didanosine intracellular concentrations; contraindicated for co-administration
Stavudine	Hydroxyurea	Peripheral neuropathy, lactic acidosis and pancreatitis have been seen with this combination (with or without stavudine); avoid co-administration if possible
	Tenovofir	Peripheral neuropathy, lactic acidosis and pancreatitis have been seen with this combination (with or without hydroxyurea); avoid co-administration if possible
Allopurinol		Increased didanosine serum concentrations and increased risk for toxicity (pancreatitis, neuropathy); contraindicated for co-administration
	Atazanavir	Decreased didanosine serum concentrations with simultaneous co-administration; space administration by 2 h before or 1 h after didanosine
Tipranavir–ritonavir		Decreased didanosine and tipranavir serum concentrations; space administration by at least 2 h
	Indinavir	Decreased indinavir serum concentrations after pediatric solution; space administration by at least 1 h
Delavirdine		Decreased delavirdine serum concentrations after didanosine pediatric solution; space administration by at least 1 h
	Tenofovir	Increased didanosine serum concentrations; decrease didanosine dose (e.g. delayed-release capsules: if $\text{CL}_{\text{cr}} > 60 \text{ mL/min}$: 250 mg per day if patient weighs >60 kg; 200 mg if patient weighs <60 kg)
Methadone		Decreased didanosine serum concentrations with didanosine pediatric solution; monitor didanosine efficacy
	Fluoroquinolones	Decreased fluoroquinolone serum concentrations with simultaneous co-administration of didanosine pediatric solution but not delayed-release capsules; space administration by at least 2–6 h
Tetracyclines		Decreased tetracycline serum concentrations with simultaneous co-administration of didanosine pediatric solution; space administration by at least 1–2 h
	Itraconazole	Decreased itraconazole serum concentrations with concurrent administration of didanosine pediatric solution; space administration by at least 2 h

NUCLEOSIDE AND NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTIs) (Table 6.7)

Nucleoside and nucleotide reverse transcriptase inhibitors do not undergo metabolism or inhibition by common human CYP isoforms.^{35,40} The majority of drug–drug interactions associated with NRTIs involve drug absorption (e.g. didanosine), antagonism of intracellular phosphorylation (e.g. stavudine and zidovudine) or increased/additive toxicity. Mechanisms of many of these drug–drug interactions of NRTIs remain unclear.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIs) (Table 6.8)

The possibility of drug–drug interactions should be carefully considered and monitored in all patients prescribed NNRTIs.^{35,40} All NNRTIs are metabolized in the liver by

(Continued)

Table 6.7 Drug–drug interactions of nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs)—cont'd

Antiviral agent	Interacting drug	Interaction and management strategy
Emtricitabine	No major interactions	–
Lamivudine	Trimethoprim-sulfamethoxazole	Increased lamivudine serum concentrations; monitor lamivudine toxicities
Stavudine	Zidovudine	Antagonism may occur; competitive inhibition of intracellular phosphorylation of stavudine by zidovudine; avoid concomitant administration
	Methadone	Decreased stavudine serum concentrations; monitor stavudine efficacy
	Didanosine	Peripheral neuropathy, lactic acidosis and pancreatitis have been seen with this combination (with or without hydroxyurea); avoid co-administration if possible
Tenofovir	Didanosine	Increased didanosine serum concentrations; decrease didanosine dose (e.g. delayed-release capsules: if $\text{CL}_{\text{CR}} > 60 \text{ mL/min}$: 250 mg per day if patient weighs $> 60 \text{ kg}$; 200 mg if patient weighs $< 60 \text{ kg}$)
	Atazanavir–ritonavir	Decreased atazanavir serum concentrations and increased tenofovir serum concentrations; recommended dosage regimen: atazanavir 300 mg, ritonavir 100 mg, tenofovir 300 mg given once daily with food; monitor for tenofovir toxicities; avoid concomitant administration without ritonavir
	Darunavir–ritonavir	Increased tenofovir serum concentrations; monitor tenofovir toxicities
	Lopinavir–ritonavir	Increased tenofovir serum concentrations; monitor tenofovir toxicities
	Tipranavir–ritonavir	Decreased tenofovir serum concentrations; monitor tenofovir efficacy
Zidovudine	Stavudine	Antagonism may occur; competitive inhibition of intracellular phosphorylation of stavudine by zidovudine; avoid concomitant administration
	Ganciclovir, valganciclovir	Increased risk of hematological toxicity (e.g. anemia, neutropenia, pancytopenia) and GI toxicity; concomitant therapy should be avoided or used with caution with careful monitoring of hematological function and at the lowest possible dose; consider alternative antiretroviral agent
	Aciclovir	Increased risk of neurotoxicity (e.g. drowsiness, lethargy); monitor for adverse events
	Ribavirin	Ribavirin inhibits intracellular phosphorylation of zidovudine; avoid concomitant administration; if administered together, monitor virological efficacy and hematological toxicities
	Methadone	Increased zidovudine serum concentrations; monitor zidovudine toxicities
	Atazanavir	Decreased zidovudine serum concentrations; monitor zidovudine efficacy
	Tipranavir–ritonavir	Decreased zidovudine and tipranavir serum concentrations; monitor virological efficacy
	Atovaquone	Increased zidovudine serum concentrations; monitor zidovudine toxicities
	Probenecid	Increased zidovudine serum concentrations; monitor zidovudine toxicities
	Cidofovir	Manufacturer recommends that on days of cidofovir plus probenecid (see Table 6-10) co-administration, zidovudine should be temporarily discontinued or given at a 50% reduced dose
Efavirenz	Fluconazole	Increased zidovudine serum concentrations; monitor zidovudine toxicities
	Valproic acid	Decreased zidovudine serum concentrations; monitor virological efficacy

CL_{CR} , creatinine clearance; GI, gastrointestinal.

the cytochrome P₄₅₀ system. Delavirdine is a substrate and a potent inhibitor of CYP3A4. Delavirdine is also a weak inhibitor of CYP2C9, CYP2D6 and CYP2C19 in vitro. The concurrent administration of drugs outlined in Table 6.2 should be avoided or used with extreme caution in patients receiving delavirdine. In addition, strong inducers and inhibitors of CYP3A4 will significantly decrease and increase plasma concentrations of delavirdine, respectively.

Nevirapine is metabolized by CYP3A4 and CYP2B6. Nevirapine is a moderate inducer of CYP3A4 and will lower the plasma concentrations of CYP3A4 substrates.

The metabolism of efavirenz is mainly by CYP2B6 but also to a lesser extent by CYP3A4. Efavirenz is a moderate inducer of CYP3A4 but also an inhibitor of CYP3A4, CYP2C9 and CYP2C19. The impact that nevirapine and efavirenz may have on substrates of CYP3A4 by lowering plasma concentrations must be carefully considered. In addition, potent inducers of CYP3A4 (e.g. rifampicin, anticonvulsants, St John's wort) can lower the plasma concentrations of nevirapine and efavirenz, and appropriate dosing guidelines or alternative agents (e.g. rifabutin) need to be considered.

Etravirine is the newest NNRTI and is metabolized by CYP3A4, CYP2C9, CYP2C19 as well as glucuronidation (minor).⁴¹ Etravirine is a moderate inducer of CYP3A4 and acyl glucuronides, and an inhibitor of CYP2C9 and CYP2C19. It is recommended that other inducers such as nevirapine, efavirenz and rifampicin not be given in combination with

etravirine. In addition, clarithromycin, unboosted protease inhibitors, tipranavir–ritonavir, fosamprenavir–ritonavir and atazanavir–ritonavir should not be co-administered with etravirine. It is recommended that the dose of phosphodiesterase 5 inhibitors (e.g. sildenafil) be increased and titrated to the desired effect when administered with etravirine.

Table 6.8 Drug–drug interactions of non-nucleoside reverse transcriptase inhibitors (NNRTIs)

NNRTI	Interacting drug	Interaction and management strategy
Delavirdine	Substrates of CYP3A4	See Table 6.2; delavirdine is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide, bepridil) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, rifabutin, alprazolam, oral midazolam, triazolam, St John's wort, fosamprenavir, carbamazepine, phenobarbital and phenytoin
	Antacids–didanosine	Decreased delavirdine concentrations; space administration by at least 1 h
	Clarithromycin	Increased clarithromycin and delavirdine concentrations; reduce clarithromycin dose by 50% if CL_{CR} 30–60 mL/min and by 75% if $\text{CL}_{\text{CR}} < 30$ mL/min
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam)
	Hormonal contraceptives	Consider using additional methods
	Atorvastatin	Use lowest possible dose; use alternative lipid-lowering agent
	Protease inhibitors	See Table 6.9
	Maraviroc	Increased maraviroc serum concentrations; use lower maraviroc dose (e.g. 150 mg every 12 h)
	Methadone	Monitor for methadone toxicity; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed
Efavirenz	Itraconazole, posaconazole	Decreased itraconazole, OH-itraconazole and posaconazole serum concentrations; adjust dose as needed
	Voriconazole	Contraindicated at standard dose; use voriconazole 400 mg every 12 h and efavirenz 300 mg per day
	Carbamazepine, phenobarbital, phenytoin	Decreased carbamazepine concentrations; monitor anticonvulsant serum concentrations; adjust dose as needed or use alternative anticonvulsant
	Clarithromycin	Decreased clarithromycin serum concentrations; monitor efficacy or use alternative agent
	Rifabutin	Decreased rifabutin serum concentrations; increase dose
	Rifampicin	Decreased rifampicin serum concentrations; increase dose
	Oral midazolam	Do not administer with oral midazolam
	St John's wort	Avoid combination
	Hormonal contraceptives	Use alternative or additional methods
	Atorvastatin	Adjust atorvastatin dose according to lipid response
Protease inhibitors	Lovastatin, simvastatin	Adjust statin dose according to lipid response
	Pravastatin, rosuvastatin	Adjust statin dose according to lipid response
	Protease inhibitors	See Table 6.9
	Methadone	Decreased methadone serum concentrations; adjust dose as needed; monitor for withdrawal
	Warfarin	Monitor PT/INR; adjust dose as needed

(Continued)

Table 6.8 Drug–drug interactions of non-nucleoside reverse transcriptase inhibitors (NNRTIs)—cont'd

NNRTI	Interacting drug	Interaction and management strategy
Etravirine	Antiarrhythmic agents	Decreased antiarrhythmic serum concentrations; use with caution, monitor antiarrhythmic serum concentrations and adjust dose as needed
	Dexamethasone	Decreased etravirine serum concentrations; use with caution or consider alternative corticosteroid for long-term use
	Itraconazole	Decreased itraconazole and increased etravirine serum concentrations; adjust dose as needed
	Voriconazole	Decreased itraconazole and etravirine serum concentrations; adjust voriconazole dose as needed
	Carbamazepine, phenobarbital, phenytoin	Do not co-administer; consider alternative anticonvulsant
	Clarithromycin	Decreased clarithromycin and increased OH-clarithromycin serum concentrations; increased etravirine serum concentrations; consider alternative agent
	Rifabutin	Use alternative agent or adjust dose appropriately
	Rifampicin	Do not co-administer
	Diazepam	Increased diazepam serum concentrations; decrease dose
	St John's wort	Avoid combination
Nevirapine	Hormonal contraceptives	Increased ethinyl estradiol serum concentrations; no dosage adjustment needed
	Atorvastatin, fluvastatin	Increased atorvastatin serum concentrations; standard dose; adjust dose according to response
	Lovastatin, simvastatin	Decreased statin serum concentrations; adjust dose according to response
	Sildenafil	Decreased sildenafil serum concentrations; may need to increase sildenafil dose based on clinical effect
	Protease inhibitors	See Table 6.9
	Warfarin	Monitor PT/INR; adjust dose as needed
	Fluconazole	Increased nevirapine serum concentrations and hepatotoxicity; monitor hepatotoxicity
	Carbamazepine, phenytoin, phenobarbital	Decreased nevirapine serum concentrations; contraindicated; do not co-administer
	Clarithromycin	Increased nevirapine and decreased clarithromycin serum concentrations; monitor efficacy or use alternative agent
	Rifampicin	Decreased nevirapine concentrations; do not co-administer
	St John's wort	Avoid combination
	Protease inhibitors	See Table 6.9
	Methadone	Decreased methadone serum concentrations; monitor for opiate withdrawal and increased methadone dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed
	CL _{CR} , creatinine clearance; CYP, cytochrome P ₄₅₀ ; PT/INR, prothrombin time/international normalized ratio.	

PROTEASE INHIBITORS (Table 6.9)

Protease inhibitors are major substrates of CYP3A4.^{40,41} The only exception is nelfinavir which is a major substrate of CYP2C19 and only a minor substrate of CYP3A4. The active metabolite of nelfinavir (M8) is a major substrate of CYP3A4. Ritonavir is also a substrate of CYP2C9 and CYP2D6. Protease inhibitors can be affected by potent

inhibitors or inducers of these substrates and, in selected cases, co-administration should be avoided (e.g. rifampicin or St John's wort).

Protease inhibitors can cause significant drug–drug interactions with other antiretroviral agents, antibacterial agents, ergot derivatives, sedatives/hypnotics, phosphodiesterase inhibitors and HMG Co-A reductase inhibitors because of inhibition of CYP3A4 and/or P-gp (Tables 6.1, 6.2 and 6.9).^{40,41}

Table 6.9 Drug–drug interactions of protease inhibitors¹

Protease inhibitor	Interacting drug	Interaction and management strategy
Atazanavir	Substrates of CYP3A4	See Table 6.2; atazanavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide, bepridil) that are CYP3A4 substrates and prolong the QTc interval; simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam, St John's wort and fluticasone
	Antacids	Decreased atazanavir concentrations; space administration by 2 h before or 1 h after antacid
	Didanosine	Decreased didanosine serum concentrations with simultaneous co-administration; space administration by 2 h before or 1 h after didanosine
	H ₂ -receptor antagonist	Decreased atazanavir concentrations; three dosing recommendations: • H ₂ -receptor antagonist dose should not exceed a dose equivalent to famotidine 40 mg every 12 h in treatment-naïve patients or 20 mg every 12 h in treatment-experienced patients • Atazanavir 300 mg plus ritonavir 100 mg should be administered simultaneously with and/or ≥10 h after the H ₂ -receptor antagonist • In treatment-experienced patients, if tenofovir is used with H ₂ -receptor antagonists, atazanavir 400 mg plus ritonavir 100 mg should be used
	Proton pump inhibitors	Decreased atazanavir concentrations; proton pump inhibitors are not recommended in patients receiving unboosted atazanavir or in treatment-experienced patients For atazanavir plus ritonavir, proton pump inhibitors should not exceed a dose equivalent to omeprazole 20 mg per day in treatment-naïve patients; proton pump inhibitor should be administered ≥12 h prior to atazanavir plus ritonavir
	Itraconazole	Potential bi-directional inhibition between itraconazole and atazanavir plus ritonavir; high-dose itraconazole (>200 mg per day) is not recommended; monitor itraconazole serum concentrations if possible
	Voriconazole	Atazanavir plus ritonavir 100–200 mg; decreased voriconazole serum concentrations; concomitant administration is not recommended; atazanavir plus ritonavir 400 mg every 12 h or higher is contraindicated
	Carbamazepine, phenytoin, phenobarbital	Monitor anticonvulsant and atazanavir serum concentrations and virological response; consider alternative anticonvulsant and ritonavir-boosting regimen
	Clarithromycin	Increased clarithromycin serum concentrations may prolong QTc; reduce clarithromycin dose by 50%; consider alternative therapy
	Rifabutin	Increased rifabutin serum concentrations; rifabutin dose of 150 mg every other day or three times per week
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam, oxazepam or temazepam)
	Calcium channel blockers: dihydropyridine, diltiazem	Caution: dose titration with ECG monitoring. Increased diltiazem serum concentrations with atazanavir plus ritonavir; decrease diltiazem dose by 50%; ECG monitoring recommended
	Hormonal contraceptives	<i>Boosted regimen:</i> decreased ethinyl estradiol and increased progestin serum concentrations; oral contraceptive should contain at least 35 mcg of ethinyl estradiol; consider using alternative or additional methods <i>Unboosted regimen:</i> increased ethinyl estradiol serum concentrations; oral contraceptive should contain at least 30 mcg of ethinyl estradiol; consider using alternative or additional methods
	Atorvastatin, rosuvastatin	Use lowest possible dose with careful monitoring; use alternative lipid-lowering agent
	Indinavir	Co-administration is not recommended because of potential additive hyperbilirubinemia
	Efavirenz	Decreased atazanavir serum concentrations; in treatment-naïve patients: atazanavir 400 mg plus ritonavir 100 mg plus standard dose of efavirenz. Do not co-administer in treatment-experienced patients
	Etravirine	Decreased atazanavir and increased etravirine serum concentrations; do not co-administer with boosted or unboosted atazanavir regimens
	Maraviroc	Increased maraviroc serum concentrations; use lower maraviroc dose (e.g. 150 mg every 12 h)
	Methadone	<i>Boosted regimen:</i> decreased methadone serum concentrations; monitor for methadone withdrawal; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed

(Continued)

Table 6.9 Drug-drug interactions of protease inhibitors—cont'd

Protease inhibitor	Interacting drug	Interaction and management strategy
Darunavir	Substrates of CYP3A4	See Table 6.2; darunavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam, St John's wort, fluticasone, carbamazepine, phenytoin and phenobarbital
	Itraconazole	Potential bi-directional inhibition between itraconazole and darunavir plus ritonavir; high-dose itraconazole (>200 mg per day) is not recommended; monitor itraconazole serum concentrations if possible
	Voriconazole	Darunavir plus ritonavir 100–200 mg: decreased voriconazole serum concentrations; concomitant administration is not recommended; darunavir plus ritonavir 400 mg every 12 h or higher is contraindicated
	Clarithromycin	Increased clarithromycin serum concentrations; reduce clarithromycin dose by 50% if CL_{CR} 30–60 mL/min; reduce clarithromycin dose by 75% if CL_{CR} <30 mL/min; consider alternative therapy
	Rifabutin	Increased rifabutin serum concentrations; rifabutin dose of 150 mg every other day or three times per week
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam, oxazepam or temazepam)
	Hormonal contraceptives	Consider using alternative or additional methods
	Atorvastatin, pravastatin, rosuvastatin	Use lowest possible dose with careful monitoring; use alternative lipid-lowering agent
	Paroxetine, sertraline	Decreased paroxetine and sertraline serum concentrations; monitor efficacy and titrate dose as needed
	Lopinavir–ritonavir, saquinavir	Decreased darunavir and increased lopinavir serum concentrations; co-administration is not recommended because dosing is not established
	Efavirenz	Decreased darunavir and increased efavirenz serum concentrations; use standard doses and monitor virological response
	Etravirine	Decreased etravirine serum concentrations; use standard doses and monitor virological response
	Nevirapine	Increased nevirapine serum concentrations; use standard doses and monitor virological response
	Maraviroc	Increased maraviroc serum concentrations; use lower maraviroc dose (e.g. 150 mg every 12 h)
	Methadone	<i>Boosted regimen:</i> decreased methadone serum concentrations; monitor for methadone withdrawal; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed
Fosamprenavir	Substrates of CYP3A4	See Table 6.2; fosamprenavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide, bepridil) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam, St John's wort, fluticasone, delavirdine and oral contraceptives
	Antacids	Decreased amprenavir concentrations; space administration by 2 h before or 1 h after antacid
	Didanosine	Decreased didanosine serum concentrations with simultaneous co-administration; space administration by 2 h before or 1 h after didanosine
	H_2 -receptor antagonist	Decreased amprenavir serum concentrations in unboosted regimen; separate administration if co-administration is necessary; consider boosting with ritonavir
	Itraconazole	Potential bi-directional inhibition between itraconazole and fosamprenavir plus ritonavir; high-dose itraconazole (>200 mg per day) is not recommended; monitor itraconazole serum concentrations if possible
	Voriconazole	Fosamprenavir plus ritonavir 100–200 mg: decreased voriconazole serum concentrations; co-administration is not recommended; fosamprenavir plus ritonavir 400 mg every 12 h or higher is contraindicated
	Carbamazepine, phenytoin, phenobarbital	<i>Unboosted regimen:</i> potential bi-directional inhibition; monitor for toxicities <i>Boosted regimen:</i> decreased phenytoin and increased amprenavir serum concentrations; monitor anticonvulsant serum concentrations and adjust dose as needed
	Rifabutin	<i>Unboosted regimen:</i> increased amprenavir serum concentrations; no dosage adjustment <i>Boosted regimen:</i> increased rifabutin serum concentrations; rifabutin dose of 150 mg every other day or three times per week <i>Unboosted regimen:</i> increased rifabutin serum concentrations; rifabutin dose of 150 mg every other day or 300 mg three times per week
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam, oxazepam or temazepam)

(Continued)

Table 6.9 Drug-drug interactions of protease inhibitors—cont'd

Protease inhibitor	Interacting drug	Interaction and management strategy
	Hormonal contraceptives	<i>Boosted regimen:</i> decreased ethinyl estradiol and norethindrone serum concentrations; use alternative or additional methods <i>Unboosted regimen:</i> increased ethinyl estradiol, norethindrone and amprenavir serum concentrations; use alternative or additional methods
	Atorvastatin, rosuvastatin	Use lowest possible dose with careful monitoring; use alternative lipid-lowering agent
	Delavirdine	Increased amprenavir and delavirdine serum concentrations; avoid concomitant administration
	Efavirenz	Decreased amprenavir serum concentrations; fosamprenavir dose of 1400 mg plus ritonavir 300 mg per day, or fosamprenavir 700 mg plus ritonavir 100 mg every 12 h plus standard dose of efavirenz
	Etravirine	Increased amprenavir serum concentrations; do not co-administer with boosted or unboosted atazanavir regimens
	Maraviroc	Use lower maraviroc dose (e.g. 150 mg every 12 h)
	Methadone	Decreased methadone serum concentrations; monitor for methadone withdrawal; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed
Indinavir	Substrates of CYP3A4	See Table 6.2; indinavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide, amiodarone) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam, St John's wort and atazanavir
	Itraconazole	Potential bi-directional inhibition between itraconazole and indinavir plus ritonavir; high-dose itraconazole (>200 mg per day) is not recommended; monitor itraconazole serum concentrations if possible <i>Unboosted regimen:</i> indinavir 600 mg every 8 h; do not exceed 200 mg itraconazole every 12 h
	Voriconazole	Indinavir plus ritonavir 100–200 mg: decreased voriconazole serum concentrations; concomitant administration is not recommended; indinavir plus ritonavir 400 mg every 12 h or higher is contraindicated
	Carbamazepine, phenytoin, phenobarbital	Monitor anticonvulsant and indinavir serum concentrations and virological response; consider alternative anticonvulsant- and ritonavir-boosting regimen
	Clarithromycin	Increased clarithromycin serum concentrations; reduce clarithromycin dose by 50% if CL_{CR} 30–60 mL/min; reduce clarithromycin dose by 75% if $CL_{CR} < 30$ mL/min; consider alternative therapy
	Rifabutin	<i>Boosted regimen:</i> increased rifabutin serum concentrations; rifabutin dose of 150 mg every other day or three times per week <i>Unboosted regimen:</i> increased rifabutin and decreased indinavir serum concentrations; rifabutin 150 mg per day or 300 mg three time weekly plus indinavir 1000 mg every 8 h or consider ritonavir boosting
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam, oxazepam or temazepam)
	Calcium channel blockers: dihydropyridine	Caution: dose titration with ECG monitoring. Increased amlodipine serum concentrations with indinavir plus ritonavir
	Hormonal contraceptives	<i>Ritonavir-boosted regimen:</i> consider using alternative or additional methods <i>Unboosted regimen:</i> increased ethinyl estradiol and indinavir serum concentrations; no dose adjustments needed
	Atorvastatin, rosuvastatin	Use lowest possible dose with careful monitoring; use alternative lipid-lowering agent
	Atazanavir	Co-administration is not recommended because of potential additive hyperbilirubinemia
	Delavirdine	Increased indinavir serum concentrations; indinavir dose of 600 mg every 8 h; standard dose for delavirdine
	Efavirenz	Decreased indinavir serum concentrations; indinavir dose of 1000 mg every 8 h; consider boosting regimen; standard efavirenz dose
	Nevirapine	Decreased indinavir serum concentrations; indinavir dose of 1000 mg every 8 h; consider boosting regimen; standard nevirapine dose
	Maraviroc	Possibly increased maraviroc serum concentrations; use lower maraviroc dose (e.g. 150 mg every 12 h)
	Methadone	For ritonavir-boosted regimen: decreased methadone serum concentrations; monitor for methadone withdrawal; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed

(Continued)

Table 6.9 Drug-drug interactions of protease inhibitors—cont'd

Protease inhibitor	Interacting drug	Interaction and management strategy
Lopinavir-ritonavir	Substrates of CYP3A4	See Table 6.2; Lopinavir-ritonavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide, flecainide, propafenone) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam, St John's wort and fluticasone
	Itraconazole	Increased itraconazole serum concentrations; do not exceed 200 mg per day; monitor itraconazole serum concentrations if possible
	Voriconazole	Atazanavir plus ritonavir 100–200 mg: decreased voriconazole serum concentrations; concomitant administration is not recommended; atazanavir plus ritonavir 400 mg every 12 h or higher is contraindicated
	Carbamazepine, phenytoin, phenobarbital	Increased carbamazepine and decreased phenytoin, phenobarbital and lopinavir serum concentrations; monitor anticonvulsant and lopinavir serum concentrations and virological response; consider alternative anticonvulsant
	Clarithromycin	Increased clarithromycin serum concentrations; reduce clarithromycin dose by 50% if CL_{CR} 30–60 mL/min; reduce clarithromycin dose by 75% if $CL_{CR} < 30$ mL/min; consider alternative therapy
	Rifabutin	Increased rifabutin serum concentrations; rifabutin dose of 150 mg every other day or three times per week
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam, oxazepam or temazepam)
	Calcium channel blockers: dihydropyridine	Increased amlodipine serum concentrations; caution is warranted and clinical monitoring is required
	Hormonal contraceptives	Decreased ethinyl estradiol; use alternative or additional methods
	Atorvastatin, rosuvastatin	Use lowest possible dose with careful monitoring; use alternative lipid-lowering agent
Nelfinavir	Ritonavir	Additional ritonavir is not recommended
	Tipranavir	Decreased lopinavir serum concentrations; avoid co-administration
	Maraviroc	Increased maraviroc serum concentrations; use lower maraviroc dose (e.g. 150 mg every 12 h)
	Methadone	For ritonavir-boosted regimen: decreased methadone serum concentrations; monitor for methadone withdrawal; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed
	Substrates of CYP3A4	See Table 6.2; nelfinavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam and St John's wort
	Proton pump inhibitors	Decreased nelfinavir and metabolite (M8) concentrations; avoid concomitant administration of proton pump inhibitors and nelfinavir
	Itraconazole	Potential bi-directional inhibition between itraconazole and nelfinavir plus ritonavir; high-dose itraconazole (>200 mg per day) is not recommended; monitor itraconazole serum concentrations if possible
	Voriconazole	Nelfinavir plus ritonavir 100–200 mg: decreased voriconazole serum concentrations; concomitant administration is not recommended; nelfinavir plus ritonavir 400 mg every 12 h or higher is contraindicated
	Carbamazepine, phenytoin, phenobarbital	Monitor anticonvulsant and nelfinavir serum concentrations and virological response; consider alternative anticonvulsant and ritonavir-boosting regimen
Hormonal contraceptives	Rifabutin	Increased rifabutin and decreased nelfinavir concentrations; rifabutin dose of 150 mg per day or 300 mg three times per week
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam, oxazepam or temazepam)
	Atorvastatin, rosuvastatin	Use lowest possible dose with careful monitoring; use alternative lipid-lowering agent

(Continued)

Table 6.9 Drug–drug interactions of protease inhibitors—cont’d

Protease inhibitor	Interacting drug	Interaction and management strategy
	Delavirdine	Decreased delavirdine and increased nelfinavir serum concentrations; monitor delavirdine virological efficacy and nelfinavir toxicities
	Efavirenz	Increased nelfinavir serum concentrations; use standard doses of each agent
	Nevirapine	Increased nelfinavir serum concentrations; use standard doses of each agent
	Maraviroc	Use lower maraviroc dose (e.g. 150 mg every 12 h)
	Methadone	Decreased methadone serum concentrations; monitor for methadone withdrawal; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed
Ritonavir ²	Substrates of CYP3A4	See Table 6.2; ritonavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide, bepridil, amiodarone, flecainide, propafenone, quinidine) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam, St John’s wort, fluticasone, alfuzosin and voriconazole (with ritonavir ≥400 mg every 12 h)
	Desipramine	Increased desipramine serum concentrations; reduce desipramine dose and monitor toxicities
	Trazodone	Increased trazodone serum concentrations; use lowest dose of trazodone and monitor CNS and cardiovascular toxicities
	Theophylline	Decreased theophylline serum concentrations; monitor theophylline serum concentrations and adjust dose as needed
	Hormonal contraceptives	Use alternative or additional methods
	Delavirdine	Increased ritonavir serum concentrations; no data on dosing recommendations
	Efavirenz	Increased ritonavir and efavirenz serum concentrations; use standard doses
	Nevirapine	Decreased ritonavir serum concentrations; use standard doses
	Maraviroc	Increased maraviroc serum concentrations; use lower maraviroc dose (e.g. 150 mg every 12 h)
Saquinavir	Substrates of CYP3A4	See Table 6.2; saquinavir–ritonavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam, St John’s wort and fluticasone
	Proton pump inhibitors	<i>Boosted regimen</i> : increased saquinavir serum concentrations; monitor for toxicities
	Itraconazole	Potential bi-directional inhibition between itraconazole and saquinavir plus ritonavir; use lower doses of itraconazole; monitor itraconazole serum concentrations if possible
	Voriconazole	Saquinavir plus ritonavir 100–200 mg: decreased voriconazole serum concentrations; concomitant administration is not recommended; atazanavir plus ritonavir 400 mg every 12 h or higher is contraindicated
	Carbamazepine, phenytoin, phenobarbital	Monitor anticonvulsant and saquinavir serum concentrations and virological response; consider alternative anticonvulsant and ritonavir-boosting regimen
	Clarithromycin	Increased clarithromycin serum concentrations; reduce clarithromycin dose by 50% if CL_{CR} 30–60 mL/min; reduce clarithromycin dose by 75% if $\text{CL}_{\text{CR}} < 30$ mL/min; consider alternative therapy
	Rifabutin	Increased rifabutin serum concentrations; rifabutin dose of 150 mg every other day or three times per week
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam, oxazepam or temazepam)
	Calcium channel blockers: dihydropyridine, diltiazem	Caution: dose titration with ECG monitoring. Increased diltiazem serum concentrations with atazanavir plus ritonavir; decrease diltiazem dose by 50%; ECG monitoring recommended
	Hormonal contraceptives	<i>Boosted regimen</i> : decreased ethinyl estradiol serum concentrations; use alternative or additional methods
	Atorvastatin, rosuvastatin	Use lowest possible dose with careful monitoring; use alternative lipid-lowering agent
	Delavirdine	Increased saquinavir serum concentrations; recommended dose: saquinavir–ritonavir 1000 mg/100 mg every 12 h

(Continued)

Table 6.9 Drug–drug interactions of protease inhibitors—cont’d

Protease inhibitor	Interacting drug	Interaction and management strategy
	Efavirenz	Decreased saquinavir and efavirenz serum concentrations; recommended dose: saquinavir–ritonavir 1000 mg/100 mg every 12 h
	Etravirine	Decreased saquinavir and etravirine serum concentrations; recommended dose: saquinavir–ritonavir 1000 mg/100 mg every 12 h
	Maraviroc	Increased maraviroc serum concentrations; use lower maraviroc dose (e.g. 150 mg every 12 h)
	Methadone	For ritonavir-boosted regimen: decreased methadone serum concentrations; monitor for methadone withdrawal; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed
Tipranavir–ritonavir	Substrates of CYP3A4	See Table 6.2; tipranavir–ritonavir is contraindicated for concomitant use with ergot alkaloids, drugs (e.g. astemizole, terfenadine, cisapride, pimozide, bepridil, amiodarone, flecainide, propafenone, quinidine) that are CYP3A4 substrates and prolong the QTc interval, simvastatin, lovastatin, rifampicin, rifapentine, oral midazolam, triazolam, St John’s wort and fluticasone
	Antacids	Decreased tipranavir concentrations; space administration by 2 h before or 1 h after antacid
	Proton pump inhibitors	Decreased omeprazole serum concentrations; may need to increase the dose of omeprazole
	Itraconazole	Potential bi-directional inhibition between itraconazole and tipranavir plus ritonavir; high-dose itraconazole (>200 mg per day) is not recommended; monitor itraconazole serum concentrations if possible
	Voriconazole	Tipranavir plus ritonavir 100–200 mg: decreased voriconazole serum concentrations; concomitant administration is not recommended; atazanavir plus ritonavir 400 mg every 12 h or higher is contraindicated
	Carbamazepine, phenytoin, phenobarbital	Monitor anticonvulsant and tipranavir serum concentrations and virological response; consider alternative anticonvulsant and ritonavir-boosting regimen
	Clarithromycin	Increased clarithromycin serum concentrations; reduce clarithromycin dose by 50% if CL_{CR} 30–60 mL/min; reduce clarithromycin dose by 75% if CL_{CR} <30 mL/min; consider alternative therapy
	Rifabutin	Increased rifabutin serum concentrations; rifabutin dose of 150 mg every other day or three times per week
	Benzodiazepines: alprazolam, diazepam	Avoid concomitant use; consider alternative agent (e.g. lorazepam, oxazepam or temazepam)
	Hormonal contraceptives	<i>Boosted regimen:</i> decreased ethinyl estradiol serum concentrations; use alternative or additional methods
	Atorvastatin, rosuvastatin	Use lowest possible dose with careful monitoring; use alternative lipid-lowering agent
	Efavirenz	Decreased or no change in tipranavir serum concentrations; use standard doses
	Etravirine	Decreased etravirine and increased tipranavir serum concentrations; avoid co-administration
	Maraviroc	Use standard doses of maraviroc (e.g. 300 mg every 12 h)
	Methadone	For ritonavir-boosted regimen: decreased methadone serum concentrations; monitor for methadone withdrawal; adjust dose as needed
	Warfarin	Monitor PT/INR; adjust dose as needed

¹ Adapted from: Panel on Antiretroviral Guidelines for Adults and Adolescents: A Working Group of the Office of AIDS Research Advisory Council (OARAC), Department of Health and Human Services. Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents. November 3, 2008. (Please refer to the product package insert and literature for complete details and potential list of both studied and theoretical drug–drug interactions.)

² Ritonavir is used at low doses (e.g. 100–200 mg) to increase serum concentrations of most protease inhibitors so review other protease inhibitor recommendations; over 200 drugs used in HIV-infected patients have been investigated for potential drug–drug interactions; please review the product package insert and literature for complete details and potential list of both studied and theoretical drug–drug interactions.

CL_{CR} , creatinine clearance; CNS, central nervous system; CYP, cytochrome P₄₅₀; ECG, electrocardiograph; PT/INR, prothrombin time/international normalized ratio.

Several drugs are contraindicated while administering protease inhibitors because of the potential for serious or life-threatening adverse events. In addition, some protease inhibitors are also inducers (e.g. ritonavir, lopinavir, tipranavir, darunavir) of CYP3A4 and/or P-gp, resulting in decreased concentrations

and effectiveness of drugs such as oral contraceptives and SSRIs (e.g. sertraline). Drug–drug interactions are less predictable and quite variable when a protease inhibitor or the combination of two protease inhibitors (e.g. tipranavir–ritonavir) has both inhibition and induction properties to a CYP isoform.

Ritonavir and nelfinavir can also induce glucuronyl transferase, CYP2C9 and CYP2C19. Lopinavir induces glucuronidation and can lower plasma concentrations of NRTIs such as zidovudine and abacavir (see Table 6.7). In contrast, atazanavir inhibits the phase II glucuronidation enzyme, UGT1A1. Because of the magnitude of inhibition or induction differs among the protease inhibitors, careful evaluation of potential drug–drug interaction with protease inhibitors is critical.

The current use of ritonavir is commonly at low doses (e.g. 100 or 200 mg) for its inhibitory effect on the CYP3A4 metabolism of other protease inhibitors. The co-administration of ritonavir is recommended with saquinavir, lopinavir, tipranavir and darunavir. This beneficial drug–drug interaction is used to increase and sustain the plasma drug concentrations of other protease inhibitors (booster effect). Benefits from booster ritonavir dosing with other protease inhibitors includes higher minimum (trough) serum concentrations, reduced development of drug resistance by increasing drug exposure, less frequent dosing, and enhance adherence by reducing the pill burden and simplifying the dosing regimen. Current drug–drug interaction reports with protease inhibitors must be carefully reviewed with regard to whether or not boosted ritonavir dosing was used and what dose of each protease inhibitor was administered.

OTHER ANTIRETROVIRAL AGENTS

The CCR5 co-receptor antagonist, maraviroc, is a substrate of CYP3A4 enzymes and the P-gp transport system.^{3,41} Maraviroc is neither an inhibitor nor an inducer of CYP3A4 or P-gp. Plasma concentrations of maraviroc are significantly decreased by potent CYP3A inducers and increased by potent CYP3A inhibitors. Table 6.1 outlines the dosage guidelines of maraviroc when administered with and without inducers and inhibitors.

Raltegravir is an HIV-1 integrase strand transfer inhibitor and is neither an inhibitor nor an inducer of CYP enzymes or P-gp.^{26,41} Raltegravir is primarily eliminated by glucuronidation (e.g. UGT1A1). Strong inducers of UGT1A1 (e.g. rifampicin) can reduce the plasma concentrations of raltegravir and these combinations should be carefully monitored and used with caution. The recommended dosage of raltegravir is 800 mg every 12 h during co-administration with rifampicin. Other drug–drug interactions associated with reduced plasma concentrations of raltegravir include efavirenz, etravirine and tipranavir–ritonavir, whereas increased plasma concentrations of raltegravir were associated with co-administration of atazanavir, atazanavir–ritonavir and omeprazole. No adjustments to the dosage of raltegravir have been recommended with these drug–drug interactions.

Enfuvirtide is an infusion inhibitor that undergoes catabolism of its amino acid constituent. Enfuvirtide is not associated with clinically significant drug–drug interactions.

ANTIVIRAL AGENTS (NON-RETROVIRAL)

The following section will review the drug–drug interactions associated with antiviral agents that are systemically administered for non-human immunodeficiency virus (non-HIV) infections. The individual drugs have been grouped according to their most common clinical use as antiviral agents.¹⁵

ANTIHERPESVIRUS AGENTS (Table 6.10)

The majority of drug–drug interactions with aciclovir, ganciclovir and foscarnet involve the risk of overlapping and/or additive myelosuppressive, central nervous system (CNS) toxicity or nephrotoxicity.^{15,35} In addition, probenecid inhibits renal tubular secretion of the nucleoside analogs, resulting in an increased AUC and reduced renal clearance of each agent. Cautious use and close monitoring for blood dyscrasias are recommended when ganciclovir is combined with agents such as antineoplastics, amphotericin B, dapsone, flucytosine, intravenous pentamidine, primaquine, pyrimethamine, trimethoprim–sulfamethoxazole and trimetrexate. The combined use of ganciclovir and zidovudine should be avoided whenever possible. In a controlled trial of patients receiving zidovudine and ganciclovir, approximately 80% of patients required a dosage reduction because of hematological (anaemia or neutropenia) or gastrointestinal toxicity. Caution is also recommended in the use of ganciclovir, foscarnet or high-dose intravenous aciclovir with other nephrotoxic agents (e.g. aminoglycosides, amphotericin B, cidofovir, foscarnet, cyclosporin, intravenous pentamidine) because of the additive potential of nephrotoxicity. Case reports have suggested dosage adjustments may be needed for phenytoin, valproic acid or theophylline (e.g. agents with a narrow therapeutic index) when co-administered with aciclovir. However, no clinically significant drug–drug interactions and only minor alterations in pharmacokinetic parameter values have been observed with the co-administration of famciclovir with digoxin, cimetidine, allopurinol, theophylline or zidovudine. Severe symptomatic hypocalcemia can be increased when foscarnet is combined with intravenous pentamidine. Serum electrolyte, calcium and magnesium should be carefully monitored in all patients to minimize adverse effects.

Cidofovir-associated nephrotoxicity is a result of renal cellular uptake via OAT1 and drug accumulation in the renal proximal tubules.^{15,18,35} To minimize the risk of nephrotoxicity, intravenous cidofovir is administered with high-dose probenecid (2 g 3 h before, and 1 g 2 and 8 h after, cidofovir infusion). The use of other nephrotoxic agents (e.g. aminoglycosides, amphotericin B, foscarnet, intravenous pentamidine, NSAIDs, contrast dye) are contraindicated during cidofovir therapy, and the manufacturer recommends waiting at least 7 days between exposure of these agents and administration of cidofovir.

Table 6.10 Drug–drug interactions of antiherpesvirus agents

Antiviral agent	Interacting drug	Interaction and management strategy
Aciclovir, valaciclovir, famciclovir	Cimetidine	Increased serum concentrations of antiviral agents; avoid concomitant use when high-dose aciclovir or patients who require a dose adjustment because of renal impairment or current adverse effects; monitor for adverse events
	Mycophenolate	Increased serum concentrations of antiviral agent and glucuronide metabolite of mycophenolate; monitor for adverse events and CBC
	Probenecid	Increased serum concentrations of antiviral agents; avoid concomitant use when high-dose aciclovir or patients who require a dose adjustment because of renal impairment or current adverse effects; monitor for adverse events
Aciclovir	Phenytoin, fosphenytoin, valproic acid	Increased risk of seizures; monitor seizure activity and serum concentrations of the anticonvulsant agents; adjust dose as needed
	Theophylline	Increased theophylline serum concentrations and risk of toxicity; monitor theophylline serum concentrations and toxicity; decrease dose of theophylline as needed
	Tizanidine	Increased tizanidine serum concentrations and risk of toxicity (e.g. hypotension, sedation); concomitant therapy should be avoided; consider alternative agent for managing spasticity
	Zidovudine	Increased risk of neurotoxicity (e.g. drowsiness, lethargy); monitor for adverse events
Ganciclovir, valganciclovir	Didanosine	Increased didanosine and slightly decreased ganciclovir serum concentrations; monitor for didanosine toxicity
	Imipenem–cilastatin	Increased risk of seizures; monitor adverse events and consider alternative antibacterial agent
	Myelosuppressive agents ¹	Increased risk of blood dyscrasias; concomitant therapy should be avoided or used with caution at the lowest possible dose; consider alternative agent if possible
	Nephrotoxic agents ²	Additive injury to the renal tubule; concomitant therapy should be avoided or used with caution and includes monitoring of renal function and dosage adjustment based on creatinine clearance estimation
	Probenecid	Increased ganciclovir serum concentrations; monitor for ganciclovir toxicity
Zidovudine		
Foscarnet	Nephrotoxic agents ²	Direct or additive injury to the renal tubule; concomitant therapy should be avoided or used with caution and includes monitoring of renal function and dosage adjustment based on creatinine clearance estimation
	Pentamidine (intravenous)	Increased risk for severe symptomatic hypocalcemia; monitor electrolytes, calcium and magnesium to minimize adverse events
	Saquinavir and/or ritonavir	Increased risk of abnormal renal function; monitor renal function and consider alternative antiretroviral agents
Cidofovir	Nephrotoxic agents ²	Concomitant administration of cidofovir with potentially nephrotoxic drugs is contraindicated, and the manufacturer recommends waiting at least 7 days between exposure to these agents and administration of cidofovir
	Probenecid	Concomitant probenecid is used to decrease the risk of renal toxicity of cidofovir by decreasing its concentrations within proximal tubular cells; careful monitoring for other drug–drug interactions of probenecid and dose adjust as needed

¹Examples include antineoplastics, amphotericin B, flucytosine, dapsone, trimethoprim–sulfamethoxazole, intravenous pentamidine, primaquine and pyrimethamine.²Examples include amphotericin B, cisplatin, ciclosporin, vancomycin, foscarnet, intravenous pentamidine, cidofovir, polymyxin B, colistin, radio contrast and aminoglycosides. CBC, complete blood count; GI, gastrointestinal.**AGENTS FOR INFLUENZA (Table 6.11)**

Additive anticholinergic effects and/or increased CNS adverse effects of amantadine can potentially occur with the concomitant administration of anticholinergic agents (e.g. benzatropine, biperiden, trihexyphenidyl), sedating antihistamines

(e.g. chlorphenamine [chlorpheniramine], phenylpropanolamine) and bupropion.¹⁵ If any of above combinations is used, patients need to be monitored for CNS reactions and dosage adjustment may be required. Triamterene–hydrochlorothiazide, quinidine, quinine and trimethoprim (alone or in combination with sulfamethoxazole) can reduce

Table 6.11 Drug–drug interactions of anti-influenza agents

Antiviral agent	Interacting drug	Interaction and management strategy
Amantadine	Anticholinergic agents ¹ or antihistamines ²	Increased central nervous system (CNS) adverse effects (e.g. additive anticholinergic effects); avoid combination or use lowest possible dose or alternative agent
	Bupropion	Increased risk of neurotoxicity (e.g. restlessness, agitation, gait disturbances, dizziness); avoid combination or use alternative agent
	Triamterene–hydrochlorothiazide, quinidine, quinine or trimethoprim (alone or in combination with sulfamethoxazole)	Increased amantadine serum concentrations and CNS toxicities; avoid combination or use lowest possible dose or alternative agent
Rimantadine	No major interactions	–
Oseltamivir	Probenecid	Increased oseltamivir carboxylate metabolite serum concentrations; no dose adjustment or monitoring is recommended because of wide margin of safety
Zanamivir	No major interactions	–

¹Examples include benzatropine, biperiden and trihexyphenidyl.²Examples include chlorphenamine (chlorpheniramine) and phenylpropanolamine.

the renal tubular secretion of amantadine and may cause increased plasma drug concentrations and CNS toxicities. The reported drug–drug interactions for rimantadine have only been minor alterations in pharmacokinetic parameters which are unlikely to be clinically important.

In-vitro studies demonstrate that oseltamivir and zanamivir are not substrates and do not affect any of the common human CYP isoenzymes.¹⁵ No clinically significant metabolic drug–drug interactions have been reported with either agent. The co-administration of probenecid completely reduces the anionic tubular secretion of oseltamivir carboxylate and results in a 50% decrease in renal clearance, a 1.9-fold increase in C_{max} and a 2.5-fold increase in the AUC of oseltamivir carboxylate. Despite these changes, no dosage adjustment is recommended due to the wide margin of safety associated with the active metabolite.

AGENTS FOR TUBERCULOSIS (Table 6.12)

Rifampicin as well as other rifamycins such as rifabutin and rifapentine are potent inducers of oxidative metabolic systems such as the CYP isoenzyme system.^{23,24,42–44} In addition, rifampicin can induce transmembrane efflux pumps such as P-gp and conjugative enzyme systems such as UGT and sulfonyltransferases. Consequently, there exists an extensive drug–drug interaction profile with the use of rifampicin

(see Table 6.3). Substitution of rifabutin for rifampicin is often used clinically, especially when used concomitantly in patients with HIV receiving highly active antiretroviral therapy (HAART). Similarly, isoniazid inhibits CYP isoenzyme systems and monoamine oxidase and is associated with some drug–drug interactions. For example, inhibition of CYP2C9, CYP2C19 and CYP3A4 by isoniazid is considered the mechanism of interaction with phenytoin, carbamazepine, diazepam and warfarin.^{42,43} The potential for this interaction is greater in slow acetylators, which comprise 30–50% of Caucasians and African–Americans. In contrast, a limited number of drug–drug interactions have been reported for other first-line agents such as ethambutol and pyrazinamide, as well as second-line agents such as aminosalicylic acid, capreomycin, cycloserine and ethionamide.^{42,43} It is important to note that a few interaction studies have incorporated the effect of combination antituberculosis agents, for example the inhibitory effect of isoniazid on CYP may be negated or overinfluenced by the induction of this system by rifampicin. Consequently, therapeutic drug monitoring and thoughtful consideration of the adverse event profile of concomitantly used agents is critical.

ANTIMALARIAL AGENTS (Table 6.13)

Various drug classes are used as antimalarial agents.^{44–47} Most of the agents are metabolized in the liver and are substrates of CYP3A4 or CYP2C isoforms. The combination product artemether–lumefantrine has recently been approved for use by the FDA. A limited number of drug–drug interactions have been reported so far (Table 6.13) but in-vitro and/or clinical studies are desperately needed to assess the effects of co-administered CYP3A4 inducers or inhibitors as well as specific anti-infective classes (e.g. rifampicin, NNRTIs, protease inhibitors) that would likely be used concurrently in patients with malaria.^{44–48} Mefloquine, ketoconazole and lopinavir–ritonavir have been shown to alter the AUC of artemether and/or lumefantrine; however, the clinical significance of these changes is unknown.⁴⁸

The plasma AUC of atovaquone is decreased by potent inducers of CYP-mediated drug metabolism (e.g. rifampicin, rifabutin, ritonavir), as well as by tetracycline and metoclopramide.^{11,35,46} Concomitant administration of rifampicin and atovaquone is not recommended. The plasma AUC of didanosine and zidovudine can be decreased with concurrent administration of atovaquone, whereas the systemic exposure of rifampicin and etoposide is increased. Alteration in binding to plasma proteins has also been suggested as a mechanism of drug–drug interactions for atovaquone. Proguanil, which is combined with atovaquone, is mainly metabolized by CYP2C19 and CYP3A4 to an active metabolite, cycloguanil. Further studies are needed to identify and understand the clinical significance of drug–drug interactions with proguanil and/or cycloguanil, particularly in patients on combination therapy or with various genetic polymorphisms (slow versus fast metabolizers).

In-vitro studies have suggested that chloroquine is an inhibitor of CYP2D6, although less in-vivo evidence is available to

Table 6.12 Drug–drug interactions of antituberculosis agents

Antituberculosis agent	Interacting drug	Interaction and management strategy
Aminosalicylic acid	Probenecid	Increased aminosalicylic acid serum concentrations (transiently); monitor for toxicity
	Diphenhydramine	Decreased absorption of aminosalicylic acid; avoid concomitant use
	Digoxin	Increased digoxin serum concentrations and toxicity; monitor digoxin serum concentrations and adjust dose appropriately
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately
	Ammonium chloride	Increased probability of crystalluria; avoid concomitant use
Capreomycin	Nephrotoxic agents ¹	Direct or additive injury to the renal tubule; concomitant therapy should be avoided or used with caution and includes monitoring of renal function and dosage adjustment based on body weight and creatinine clearance estimation
	Ototoxic agents ²	Increased risk of ototoxicity; concomitant therapy should be avoided or used with caution at the lowest possible dose; consider alternative agent if possible
	Neuromuscular blocking agents ³	Increased respiratory suppression produced by neuromuscular blocking agent; concomitant therapy should be avoided or used with caution and includes monitoring for respiratory depression
Cycloserine	Isoniazid	Increased CNS adverse effects (e.g. dizziness, drowsiness) when both drugs are used concurrently; monitor toxicity
	Ethionamide	Increased CNS adverse effects (e.g. seizures) when both drugs are used concurrently; monitor toxicity
	Phenytoin, fosphenytoin	Increased phenytoin serum concentrations; monitor toxicity and phenytoin serum concentrations, and adjust dose as needed
Ethambutol	Antacids	Decreased ethambutol serum concentrations with aluminum-containing antacids; space administration by at least 4 h
	Ethionamide	Increased adverse effects (e.g. GI distress, headache, confusion, neuritis, hepatotoxicity) when both drugs are used concurrently; monitor toxicity and avoid concomitant use when possible
Ethionamide	Aminosalicylic acid, ethambutol, isoniazid, pyrazinamide, rifampicin	Potentiates the adverse effects of other antituberculosis agents (hepatotoxicity, peripheral neuritis, GI distress, headache, confusion, neuritis, seizures, encephalopathy); monitor toxicity
	Excessive alcohol	Increased psychotic reactions; avoid concomitant use
	Isoniazid	Increased isoniazid serum concentrations (temporarily); monitor for toxicity
Isoniazid	Cycloserine, ethionamide	Increased CNS adverse effects; monitor toxicity
	Carbamazepine	Increased carbamazepine serum concentrations and toxicity (e.g. ataxia, headache, blurred vision, drowsiness, confusion); monitor toxicity and carbamazepine serum concentrations; decrease dose if needed
	Phenytoin, fosphenytoin	Increased phenytoin serum concentrations and toxicity; monitor toxicity and phenytoin serum concentrations; decrease dose if needed
	Primidone	Increased primidone serum concentrations; monitor toxicity and primidone serum concentrations; adjust dose if needed
	Meperidine	Increased toxicity (e.g. serotonin syndrome); monitor toxicity and adjust dose if needed
	Itraconazole	Decreased itraconazole serum concentrations and loss of antimycotic efficacy; alternative antifungal agent or interacting drug should be considered
	Warfarin	Enhanced anticoagulation; monitor PT/INR and adjust warfarin dose appropriately
	Disulfiram	Increased CNS changes (e.g. coordination difficulties, mood or behavioral changes); monitor toxicity and consider dose reduction or discontinuation of disulfiram
	Paracetamol	Increased risk for hepatotoxicity; avoid concomitant use or limit use of paracetamol
	Diazepam	Increased diazepam serum concentrations; monitor toxicity and adjust dose if needed
Levodopa		Increased toxicity (e.g. flushing, palpitations, hypertension); monitor toxicity and adjust dose if needed
	Aluminum hydroxide	Decreased isoniazid serum concentrations; space administration by at least 1 h

(Continued)

Table 6.12 Drug-drug interactions of antituberculosis agents—cont'd

Antituberculosis agent	Interacting drug	Interaction and management strategy
Pyrazinamide	Ethionamide or rifampicin	Increased hepatotoxicity; monitor liver enzymes and toxicity
	Ciclosporin	Decreased ciclosporin serum concentrations; monitor clinical response and ciclosporin serum concentrations; adjust dose as needed
	Zidovudine	Decreased pyrazinamide serum concentrations and efficacy; consider alternative antituberculosis agent if possible
	Probenecid	Decreased efficacy of probenecid (e.g. increased serum uric acid levels, worsening symptoms of gout); monitor serum uric acid levels and adjust probenecid dose as needed
Rifabutin	Ritonavir-boosted protease inhibitors (ATV/r, FPV/r, DRV/r, IDV/r, LPV/r, SQV/r, TPV/r)	Increased rifabutin serum concentrations; rifabutin dosing to 150 mg every other day or three times weekly; monitor viral response and CBC
	Fosamprenavir	Increased rifabutin serum concentrations; rifabutin dosing to 150 mg per day or 300 mg three times weekly; monitor viral response and CBC
	Indinavir	Increased rifabutin and decreased indinavir serum concentrations; rifabutin dosing to 150 mg per day or 300 mg three times weekly; indinavir 1000 mg every 8 h or consider ritonavir boosting; monitor viral response and CBC
	Nelfinavir	Increased rifabutin and decreased nelfinavir serum concentrations; rifabutin dosing to 150 mg per day or 300 mg three times weekly; monitor viral response and CBC
	Delavirdine	Increased rifabutin and decreased delavirdine serum concentrations; co-administration is not recommended
	Efavirenz	Decreased rifabutin serum concentrations; dose rifabutin 450–600 mg per day or 600 mg three times weekly if efavirenz is not co-administered with a protease inhibitor; monitor viral response and CBC
	Etravirine	Decreased rifabutin and metabolite serum concentrations and decreased etravirine serum concentrations; dose rifabutin 300 mg per day if not co-administered with a ritonavir-boosted protease inhibitor; if co-administered with lopinavir plus ritonavir, dose rifabutin 150 mg per day or three times weekly
	Nevirapine	Increased rifabutin and decreased nevirapine serum concentrations; dosage adjustment is not recommended; monitor viral response and CBC
	Maraviroc	Maraviroc dose of 300 mg every 12 h if used without a strong CYP3A inducer or inhibitor; maraviroc dose of 150 mg every 12 h if used with a strong CYP3A inhibitor; monitor viral response
	Fluconazole	Increased rifabutin serum concentrations and potential rifabutin toxicity (uveitis, ocular pain, photophobia, visual disturbances); monitor toxicity and CBC
Rifampicin	Itraconazole, voriconazole, posaconazole	Increased rifabutin serum concentrations and potential rifabutin toxicity (uveitis, ocular pain, photophobia, visual disturbances); decreased azole serum concentrations and/or loss of antimycotic efficacy; alternative antifungal agent should be considered
	Clarithromycin	Decreased clarithromycin serum concentrations and increased risk of rifabutin toxicity (rash, GI disturbances, hematological abnormalities); monitor efficacy, toxicity and CBC
	Ciclosporin	Decreased ciclosporin serum concentrations; monitor clinical response and ciclosporin serum concentrations; adjust dose as needed
	Warfarin	Decreased anticoagulation; monitor PT/INR and adjust warfarin dose appropriately
	Oral contraceptives	Use alternative form(s) of birth control; counsel patient and document
	Rifampicin	See Table 6.3

CBC, complete blood count; CNS, central nervous system; GI, gastrointestinal; PT/INR, prothrombin time/international normalized ratio.

Table 6.13 Drug–drug interactions involving antimalarial agents

Antimalarial drug	Interacting drug	Mechanism/effects	Management recommendations
Artemether-lumefantrine (co-artemether)	Ketoconazole	↑ artemether AUC by 132%, ↑ dihydroartemisinin AUC by 51%, and ↑ lumefantrine AUC by 61%	Clinical significance unknown; no dosage adjustment recommended
	Lopinavir-ritonavir	↓ artemether AUC by 34%, ↓ dihydroartemisinin AUC by 45%, and ↑ lumefantrine AUC by 230%	Clinical significance unknown; no dosage adjustment recommended
	Mefloquine	↓ lumefantrine AUC by 30–41% and C_{max} by 29%	Clinical significance unknown
	Quinine	Increased risk for QTc prolongation; ↓ quinine AUC by 46%	Monitor for toxicity and clinically significant lengthening of the QTc interval
Atovaquone	Didanosine	↓ didanosine AUC by 24%	Not clinically significant; administer didanosine without food and atovaquone with food
	Etoposide	↑ etoposide AUC by 8.6% and ↑ catechol metabolite AUC by 28.4%	Separate administration by 1–2 days and use caution with concurrent substrates of CYP3A4 or P-glycoprotein
	Indinavir	↑ atovaquone AUC by 13% and ↓ indinavir AUC by 5–9%	Clinical significance unknown; monitor effectiveness of indinavir
	Metoclopramide	↓ atovaquone concentrations	Caution in concomitant administration; if used, monitor effectiveness of atovaquone
	Rifabutin	↓ atovaquone AUC by 34% and ↓ rifabutin AUC by 19%	Caution in concomitant administration; if used, monitor effectiveness of atovaquone
	Rifampicin	↓ atovaquone AUC by 50% and ↑ rifampicin AUC by 30%	Avoid concomitant administration; if used, monitor effectiveness of atovaquone
	Ritonavir	↓ atovaquone concentrations (predicted)	Monitor effectiveness of atovaquone; may need to increase atovaquone dose
	Tetracycline	↓ atovaquone concentrations by 40%	Monitor effectiveness of atovaquone
	Zidovudine	↑ zidovudine AUC by 30% and ↓ CL by 25%; inhibition of zidovudine glucuronidation	Clinical significance unknown; monitor for zidovudine toxicity
Chloroquine	Ampicillin	↓ ampicillin absorption from 29% to 19%	Separate administration by at least 2 h; use other antibacterial agent
	Antacid (magnesium trisilicate)	↓ chloroquine AUC by 18%	Separate administration by 2–3 h
	Chlorpromazine	↑ chlorpromazine concentrations by 1.7- to 4.3-fold; increased sedation	Monitor toxicity; decrease dose of chlorpromazine
	Colestyramine	↓ chloroquine AUC by 30%	Separate administration either 1 h before or 4–6 after chloroquine
	Cimetidine	↓ chloroquine CL by 50%; prolonged $t_{1/2\beta}$ from 3.1 to 4.6 h	Use other H ₂ -receptor antagonists (e.g. ranitidine) that do not have this drug–drug interaction
	Ciprofloxacin	↓ ciprofloxacin AUC by 43% and C_{max} by 18%	Monitor efficacy; increase ciprofloxacin dose for systemic infections
	Ciclosporin	↑ ciclosporin serum concentrations and nephrotoxicity	Monitor ciclosporin concentrations and renal function; adjust dose as needed
	Digoxin	↑ digoxin serum concentrations by 70%	Monitor digoxin concentrations; adjust dose as needed
	Halofantrine	Warning: the combination may cause prolongation of the QTc interval	Avoid concurrent administration; if used, monitor for toxicity and clinically significant lengthening of the QTc interval
Insulin			
		↓ insulin requirement by 25%	Monitor blood glucose and adjust insulin dose as needed
Kaolin			
		↓ chloroquine AUC by 28%	Separate administration by 2–3 h

(Continued)

Table 6.13 Drug–drug interactions involving antimalarial agents—cont'd

Antimalarial drug	Interacting drug	Mechanism/effects	Management recommendations
	Methotrexate	↓ methotrexate AUC by 28% and C_{max} by 17–20%; ↑ methotrexate AUC by 52% with hydroxychloroquine	Monitor for efficacy and methotrexate serum concentrations; adjust methotrexate dose as needed
	Methylthioninium chloride (methylene blue)	↓ chloroquine AUC by 20% and desethylchloroquine (metabolite) AUC by 35%	Clinical significance unknown
	Metoprolol	Hydroxychloroquine ↑ metoprolol AUC by 65% and C_{max} by 72% in extensive CYP2D6 metabolizers	Not clinically significant; monitor for toxicity
	Penicillamine	↑ penicillamine AUC by 34% and C_{max} by 55%	Monitor toxicity (e.g. serious hematological effects)
	Praziquantel	↓ praziquantel AUC by 65% and C_{max} by 59%	Monitor for efficacy; ↑ dose of praziquantel for systemic infection
	Proguanil	1.5-fold ↑ in mouth ulcers and 1.33-fold ↑ in diarrhea	Monitor toxicity and treat as needed
	Promethazine	↑ chloroquine AUC and metabolite by 85%	Monitor toxicity; consider other agents
Mefloquine	Ampicillin	↑ mefloquine AUC by 34% and C_{max} by 49%	Clinical significance unknown
	Anticonvulsants	Increased risk of seizures	Avoid concurrent administration
	Artemether	↓ mefloquine AUC by 27%; cure rates similar	Clinical significance unknown
	Artesunate	↓ mefloquine AUC by 27% and ↑ CL by 2.6-fold; lower cure rates	Administer mefloquine 24 h after artesunate
	Cardioactive drugs ¹	Warning: mefloquine plus one of these agents contribute to the prolongation of the QTc interval, but do not contraindicate the use of mefloquine with these agents	Avoid concurrent administration (contraindicated with halofantrine); if used, monitor for toxicity and clinically significant lengthening of the QTc interval
	Cimetidine	↑ mefloquine AUC by 0–34% and C_{max} by 20–42% and ↓ CL by 40%; prolonged $t_{1/2\beta}$ from 9.6 to 14.4 days	Clinical significance unknown; use other H ₂ -receptor antagonists that do not have this drug–drug interaction
	Co-artemether	↓ lumefantrine AUC by 30–41% and C_{max} by 29%	Clinical significance unknown
	Hypoglycemic agents	Reduced blood glucose levels and hypoglycemia	Monitor blood glucose and adjust dose as needed
	Ketoconazole	↑ mefloquine AUC by 79%, C_{max} by 64% and $t_{1/2\beta}$ by 34%	Monitor toxicity
	Metoclopramide	↓ mefloquine absorption $t_{1/2}$ from 3.2 to 2.4 h and ↑ C_{max} by 31%; reduced GI adverse effects	Clinical significance unknown; however, less mefloquine toxicity
	Quinine (and related drugs [e.g. chloroquine])	Increased risk for QTc prolongation and seizures	Avoid concurrent administration; if used, delay mefloquine administration until at least 12 h after the last dose of quinine; monitor for toxicity and clinically significant lengthening of the QTc interval
	Quinolones	Increased risk for QTc prolongation and seizures	Avoid concurrent administration; if used, monitor for toxicity and clinically significant lengthening of the QTc interval
	Rifampicin	↓ mefloquine AUC by 68% and C_{max} by 19%	Avoid concurrent administration; if used, monitor for efficacy
	Ritonavir	↓ ritonavir AUC by 31% and C_{max} by 36% after multiple dosing	Clinical significance unknown
	Tetracycline	↑ mefloquine AUC by 30% and C_{max} by 38%, and ↓ $t_{1/2\beta}$ from 19.3 to 14.4 days	Not clinically significant
	Typhoid vaccine (oral)	Reduced efficacy of oral vaccine	Separate administration by 12 h (does not apply to capsular polysaccharide typhoid vaccine for injection)
Primaquine	Quinacrine	Increased toxicity	Avoid concomitant use (contraindicated)

(Continued)

Table 6.13 Drug-drug interactions involving antimalarial agents—cont'd

Antimalarial drug	Interacting drug	Mechanism/effects	Management recommendations
Proguanil	Antacid (magnesium trisilicate)	↓ proguanil AUC by 65%	Separate administration by 2–3 h
	Chloroquine	1.5-fold ↑ in mouth ulcers and 1.33-fold ↑ in diarrhea	Monitor toxicity and treat as needed
	Cimetidine	↑ proguanil AUC and $t_{1/2\beta}$; ↑ C_{max} by 89%; ↓ concentrations of active metabolite, cycloguanil	Clinical significance unknown; use other H ₂ -receptor antagonists that do not have this drug–drug interaction
	Cloxacillin	↓ cloxacillin bioavailability	Clinical significance unknown
	Ethinyl estradiol–levonorgestrel (hormonal contraceptives)	↓ concentrations of active metabolite, cycloguanil, by 34% in extensive metabolizer via CYP2C19	Clinical significance unknown
	Fluvoxamine	↓ CL of proguanil by 40%, cycloguanil by 85%, and 4-chlorophenylbiguanide by 89% in extensive metabolizer via CYP2C19	Clinical significance unknown; monitor efficacy
	Omeprazole	↓ AUC of active metabolite, cycloguanil, by 50% in extensive metabolizer via CYP2C19	Clinical significance unknown
Quinine sulfate	Amantadine	↓ renal CL of amantadine by 30% and ↑ plasma concentrations; ↓ CL of quinine by 50%	Clinical significance unknown
	Astemizole	↑ astemizole (and desmethyl metabolite) AUC and C_{max} by three-fold after a single 430 mg dose of quinine; increased risk for QTc prolongation and cardiac arrhythmias	Avoid concurrent administration (contraindicated by manufacturer); use a different antihistamine product
	Co-artemether	Increased risk for QTc prolongation; ↓ quinine AUC by 46%	Monitor for toxicity and clinically significant lengthening of the QTc interval
	Carbamazepine	↑ carbamazepine AUC by 104% and C_{max} by 81%	Monitor efficacy and carbamazepine plasma concentrations; adjust dose as needed
	Cimetidine	↑ quinine AUC by 42%, ↓ CL by 27%, and ↑ $t_{1/2\beta}$ from 7.6 to 11.3 h	Use other H ₂ -receptor antagonists (e.g. ranitidine) that do not have this drug–drug interaction
	Desipramine	↓ urinary excretion of 2-hydroxydesipramine by 56% in rapid hydroxylators	Monitor for toxicity (including QTc prolongation) and desipramine plasma concentrations; adjust dose as needed
	Digoxin	↑ digoxin plasma concentrations by 11–92%; ↓ CL by 26% and ↓ renal CL by 20%	Monitor for toxicity and digoxin plasma concentrations; adjust dose as needed
Flecainide	Flecainide	↑ flecainide AUC by 21% and ↓ CL by 16.5%; increased PR and QRS prolongation on electrocardiogram	Monitor for toxicity; adjust dose as needed
	Halofantrine	Warning: combination may cause prolongation of the QTc interval	Avoid concurrent administration; if used, monitor for toxicity and clinically significant lengthening of the QTc interval
	Ketoconazole	↓ quinine CL by 31% and AUC of 3-hydroxyquinine by 30%	Clinical significance unknown
	Mefloquine	Increased risk for QTc prolongation and seizures	Avoid concurrent administration; if used, delay mefloquine administration until at least 12 h after the last dose of quinine; monitor for toxicity and clinically significant lengthening of the QTc interval
	Phenobarbital	↑ phenobarbital AUC by 57% and C_{max} by 53%	Monitor efficacy and phenobarbital plasma concentrations; adjust dose as needed
	Phenytoin (fosphenytoin)	↓ quinine plasma concentrations	Limited data; monitor efficacy of quinine
	Rifampicin	↓ quinine plasma concentrations; ↑ quinine CL by six-fold and ↓ $t_{1/2\beta}$ from 11 to 5.5 h	Monitor efficacy of quinine and increase dose as needed
Tetracycline	Tetracycline	↑ quinine plasma concentrations by two-fold	Increased efficacy; no drug–drug interaction with doxycycline
	Urine alkalinizers ²	↓ excretion of unchanged quinine	Clinical significance unknown

(Continued)

Table 6.13 Drug–drug interactions involving antimalarial agents—cont'd

Antimalarial drug	Interacting drug	Mechanism/effects	Management recommendations
Sulfadoxine and pyrimethamine	Artemether	↑ pyrimethamine C_{max} by 44%	Clinical significance unknown
	Chlorpromazine	↑ chlorpromazine 3-h plasma concentrations by four-fold and ↑ hydroxyl metabolite plasma concentrations	Monitor toxicity; decrease dose of chlorpromazine
	Halofantrine	↑ halofantrine AUC_{0-6} and C_{max} by 60%	Monitor for toxicity and clinically significant lengthening of the QTc interval
Trimethoprim-sulfamethoxazole or sulfonamides		Increased risk of myelosuppression; serious pancytopenia and megaloblastic anemia when given with pyrimethamine	Monitor whole blood cell count and toxicity; avoid concomitant therapy with other folate antagonists; administer leucovorin as needed
Zidovudine		Increased risk of myelosuppression	Monitor whole blood cell count and toxicity; administer leucovorin as needed

¹Examples of cardioactive drugs include antiarrhythmics (e.g. class Ic and III), beta-blockers (e.g. propranolol), calcium channel blockers, antihistamines (e.g. astemizole and terfenadine), phenothiazines, related antimalarials (e.g. quinine), halofantrine and ziprasidone.

²Examples of urine alkalinizers include sodium bicarbonate and acetazolamide.

AUC, area under the plasma concentration–time curve; CL, clearance; C_{max} , maximum plasma drug concentration; CYP, cytochrome P₄₅₀; GI, gastrointestinal; $t_{1/2\beta}$, elimination half-life.

support this effect.^{11,46} A fair number of drug–drug interactions have been reported with chloroquine use and the great majority are easily managed.

Mefloquine is completely metabolized in the liver to a carboxy metabolite, probably by CYP3A4.^{11,46} Potent inhibitors (e.g. ketoconazole) and inducers (e.g. rifampicin) of CYP3A4 have increased and decreased the systemic exposure of mefloquine, respectively. Mefloquine has the potential to be associated with clinically significant pharmacodynamic drug–drug interactions and overlapping toxicities such as QTc prolongation, neuropsychiatric disturbances and seizures. Concurrent administration of quinine, quinidine, chloroquine and fluoroquinolones should be avoided. The administration of oral typhoid vaccine and mefloquine should be separated by 12 h to ensure adequate immunization from the vaccine.

Quinine is extensively metabolized in the liver to several metabolites, including biologically active 3-hydroxyquinine.^{11,46} The metabolism of quinine is a result of CYP3A (major) and CYP2C19 (minor). In contrast, quinidine is metabolized by intestinal and liver CYP3A4 and is a potent inhibitor of CYP2D6. Cimetidine, ketoconazole, tetracycline and urine alkalinizers can increase the systemic exposure or decrease the renal clearance of quinine or 3-hydroxyquinine. Both quinine and quinidine can increase the plasma concentrations of digoxin. Drugs that prolong the QTc interval should be avoided or used with caution and monitored for toxicity.

The antifolate agents such sulfadiazine and pyrimethamine are not associated with major pharmacokinetic drug–drug interactions.^{11,35} Overlapping adverse hematological toxicity (e.g. neutropenia, anemia, thrombocytopenia) may occur with concurrent use of trimethoprim–sulfamethoxazole or other sulfonamides, zidovudine or ganciclovir. Close monitoring and/or use of alternative therapies are recommended when possible.

ANTIPROTOZOAL AND ANTHELMINTIC AGENTS (Table 6.14)

A variety of different drug classes are used to treat protozoal and parasitic infections.^{11,35} Agents that can be used for these infections, as well as an antibacterial agent (e.g. metronidazole, clindamycin or trimethoprim–sulfamethoxazole), have been discussed in a previous section (e.g. Antibacterial agents; see Table 6.5) in this chapter.

Interactions involving antiprotozoal and anthelmintic agents may occur secondary to pharmacokinetic and/or pharmacodynamic mechanisms.¹¹ Drug–drug interactions involving albendazole, mebendazole and praziquantel mainly involve enzyme induction or inhibition. Agents reported in these drug–drug interactions have included anticonvulsants (e.g. phenytoin, carbamazepine, phenobarbital or valproic acid), rifampicin, dexamethasone and cimetidine. Tiabendazole (thiabendazole) appears to inhibit CYP1A2, and has significantly (e.g. >50%) increased the plasma concentrations of xanthine derivatives such as theophylline and caffeine. Renal excretion of diethylcarbamazine can be increased or decreased with concurrent administration of urinary acidifiers or alkalinizers, respectively.

Furazolidone is an MAOI and must be used with caution when other drugs (e.g. sympathomimetic amines) as well as food or drink containing tyramine are concurrently administered during or before therapy.¹¹ Disulfiram-like reactions have been associated with concurrent administration of alcohol and furazolidone or levamisole. The common adverse effects associated with pentamidine (e.g. bone marrow suppression, nephrotoxicity, pancreatitis or hypocalcemia) can result in additive toxicity when used in conjunction with antiviral and antiretroviral agents.

Table 6.14 Drug–drug interactions involving antiprotozoal and anthelmintic agents

Drug	Interacting drug	Mechanism/effects	Management recommendations
Albendazole	Carbamazepine, phenobarbital, phenytoin (fosphenytoin)	↓ (+)-albendazole sulfoxide AUC by 49% (carbamazepine), 61% (phenobarbital), and 66% (phenytoin) and ↓ (-)-albendazole sulfoxide C_{max} by 50–63%	Monitor efficacy of systemic infections and increase dose of albendazole as needed
	Cimetidine	↑ albendazole sulfoxide plasma concentrations and ↑ $t_{1/2\beta}$ from 7.4 to 19 h	Clinical significance unknown; increased efficacy observed
	Dexamethasone	↑ albendazole sulfoxide plasma concentrations by 50%	Clinical significance unknown
	Levamisole	↓ albendazole sulfoxide AUC by 75%	Caution with concomitant use; monitor efficacy of systemic infections
Atovaquone	See Table 6.13		
Diethylcarbamazepine	Ammonium chloride	Increased urinary excretion	Clinical significance unknown
	Sodium bicarbonate	Decreased urinary excretion	Clinical significance unknown
Furazolidone	Alcohol	Disulfiram-like reaction	Avoid alcohol during and shortly after therapy with furazolidone
	Omeprazole	↓ furazolidone AUC by 30%	Monitor efficacy; increase dose if needed
	Sympathomimetics ¹ (indirectly acting)	MAOI activity and pressor responses to tyramine, dextroamphetamine or pargyline	Avoid concomitant sympathomimetic drugs or tyramine-containing foods or drinks that may have non-selective MAOI effects; warn patients about prohibiting the use of these agents
Ivermectin	Alcohol	↑ ivermectin plasma concentrations by 51–66%	Monitor for toxicity (e.g. ataxia and postural hypotension)
	Levamisole	↑ ivermectin AUC by two-fold	Monitor for toxicity
Levamisole	Albendazole	↓ albendazole sulfoxide AUC by 75%	Caution with concomitant use; monitor efficacy of systemic infections
	Alcohol	Disulfiram-like reaction	Avoid alcohol during and shortly after therapy with levamisole
	Ivermectin	↑ ivermectin AUC by two-fold	Monitor for toxicity
Mebendazole	Carbamazepine, phenytoin (fosphenytoin)	↓ mebendazole serum concentrations	Monitor efficacy of systemic infections and increase dose of mebendazole as needed
	Cimetidine	↑ mebendazole C_{max} by 48%	Clinical significance unknown; increased efficacy observed
	Metronidazole	Increased risk of Stevens–Johnson syndrome/toxic epidermal necrolysis	Avoid concomitant administration
Pentamidine	Valproic acid	↑ mebendazole serum concentrations	Clinical significance unknown; monitor for toxicity
	Foscarnet	Additive hypocalcemia	Monitor serum calcium levels and toxicity
Piperazine	Nephrotoxic agents ²	Direct or additive injury to the renal tubule	Concomitant therapy should be avoided or used with caution and includes monitoring renal function and dosage adjustments based on toxicity, body weight and creatinine clearance estimation
	Zalcitabine, stavudine, didanosine	Additive pancreatic toxicity	Avoid concurrent administration; if used, zalcitabine therapy should be interrupted while receiving pentamidine
	Zidovudine	Additive bone marrow suppression	Monitor WBC and toxicity
Piperazine	Pyrantel	Piperazine opposes anthelmintic action of pyrantel	Avoid concomitant administration

(Continued)

Table 6.14 Drug–drug interactions involving antiprotozoal and anthelmintic agents—cont'd

Drug	Interacting drug	Mechanism/effects	Management recommendations
Praziquantel	Carbamazepine, phenobarbital, phenytoin (fosphenytoin)	↓ praziquantel AUC by 90% (carbamazepine) and 74% (phenytoin); ↓ praziquantel plasma concentrations with phenobarbital	Monitor efficacy of systemic infections and increase dose of praziquantel as needed
	Chloroquine	↓ praziquantel AUC by 65% and C_{max} by 59%	Monitor efficacy; ↑ dose of praziquantel for systemic infection
	Cimetidine	↑ praziquantel AUC and plasma concentrations by two-fold	May improve efficacy or reverse drug–drug interactions that ↓ praziquantel AUC (e.g. anticonvulsants, steroids)
	Dexamethasone	↓ praziquantel plasma steady-state concentrations by 50%	Monitor efficacy of systemic infections and increase dose of praziquantel as needed
	Rifampicin	↓ praziquantel plasma steady-state concentrations by 85–100%	Avoid concomitant administration
Pyrantel	Piperazine	Piperazine opposes anthelmintic action of pyrantel	Avoid concomitant administration
Tiabendazole	Aminophylline, theophylline	↑ theophylline plasma concentrations via inhibition of CYP1A2	Reduce theophylline dosage by 50% or stop theophylline while on tiabendazole; consider using albendazole or mebendazole (not associated with this drug interaction); if used concurrently, monitor toxicity and plasma theophylline concentrations, and adjust dose as needed
	Caffeine	↑ caffeine AUC by 57%, ↑ $t_{1/2\beta}$ by 140% and ↓ CL by 66%	Monitor and inform patient of adverse effects of caffeine

¹Examples of indirectly acting sympathomimetic amines include amphetamines, phenylpropanolamine and ephedrine.

²Examples include amphotericin B, cisplatin, ciclosporin, vancomycin, foscarnet, intravenous pentamidine, cidofovir, tenofovir, polymyxin B, colistin, radio contrast and aminoglycosides.

AUC, area under the plasma concentration–time curve; CL, clearance; C_{max} , maximum plasma drug concentration; MAOI, monoamine oxidase inhibitor; $t_{1/2\beta}$, elimination half-life; WBC, white blood cell count.

Antibiotics and the immune system

Arne Forsgren and Kristian Riesbeck

Numerous reports on the effect of antibacterial agents on the immune system have accumulated in recent years. However, immune capacity is difficult to examine, and different results, sometimes conflicting, will be obtained depending on the derivative, incubation time, cell type, analysis method or experimental animal used. In this chapter, selected current literature is reviewed.

Comprehensive reviews on the effects of antibiotics on the immune response have been published over the last three decades. Hauser and Remington in 1983 concluded that a potential for immunosuppression exists for several antibiotics,¹ although the clinical relevance of the experimental observations remained to be elucidated. Milatovic characterized the published results on phagocytosis to a large extent as controversial, thus rendering the evaluation rather difficult.² Labro's review of the therapeutic relevance of the observed effects on phagocyte functions and future research prospects raises more questions than answers.³ Extensive reviews on the immuno-modulatory effects of quinolones have been published by Riesbeck⁴ and Dalhoff and Shalit.⁵

During an infection, antibiotics interfere with both the infecting bacterium and the host in a complicated fashion (Figure 7.1). In addition to the conventional effects of an antibiotic, i.e. bacteristatic and bactericidal activity (A), some antibiotics act directly on important

components in the host defense such as granulocytes and lymphocytes (B). Antibiotics can alter the susceptibility of bacteria to host defenses and alter release of toxins and inflammatory products, with secondary effects on the host (C). Phagocytic or other host cells can also protect bacteria against antibiotics (D).

CHEMOTAXIS

Most studies on the direct effect of antibiotics on phagocytic cells concern chemotaxis. The effect of 20 different antibiotics on chemotaxis in vitro towards an *Escherichia coli* filtrate was studied by an agarose technique.⁶ Human leukocytes preincubated with clinically obtainable concentrations of rifampicin (rifampin) and sodium fusidate showed markedly depressed directional migration and, at concentrations slightly above those clinically achievable, doxycycline also inhibited chemotaxis. The clinical implications of these results must, however, be questioned as the experiments were performed in a low-protein tissue culture suspension, and fusidic acid particularly is heavily protein bound. In patients and healthy volunteers given doxycycline, leukocyte migration was studied ex vivo with the agarose technique and in vivo with a skin window technique. The very high dose 600 mg doxycycline administered intravenously had only an insignificant effect, while controls given non-steroidal anti-inflammatory drugs (NSAIDs) had significantly reduced values both ex and in vivo (A Scheja, A Forsgren, unpublished results). Aminoglycosides, β -lactams, macrolides, clindamycin, sulfamethoxazole, trimethoprim and also fluoroquinolones have shown no interactions with agarose chemotaxis. In contrast to those results, it has been reported that macrolides potentiate human neutrophil locomotion in vitro by inhibition of leukoattractant-activated superoxide generation and auto-oxidation. In addition, aminoglycosides have been reported to inhibit chemotaxis. The effects of macrolides and aminoglycosides have not been confirmed in in-vivo studies. The anti-inflammatory activities of quinolones were investigated with an in-vitro model of transendothelial migration

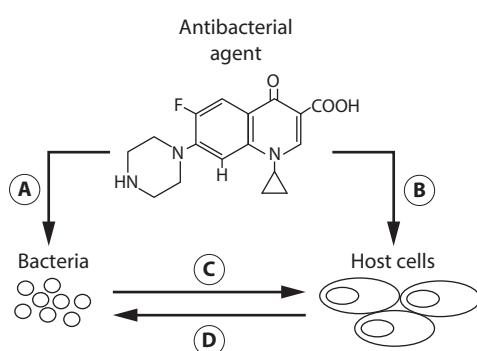

Fig. 7.1 Schematic drawing demonstrating host–cell interactions and different levels of intervention by antibacterial agents. See text for details.

(TEM). Human umbilical vein endothelial cells (HUVEC) infected with *Chlamydophila* (formerly *Chlamydia*) *pneumoniae* or stimulated with tumor neurosis factor alpha (TNF- α), as well as neutrophils and monocytes, were preincubated with quinolones. A significantly decreased neutrophil and monocyte migration and interleukin-8 (IL-8) production compared to antibiotic-free controls was detected. It was speculated that the decreased migration was due to decreased IL-8 levels.⁷

PHAGOCYTOSIS AND KILLING

Studies of the direct influence of antibiotics on other phagocytic cell functions such as engulfment, killing and metabolic responses are more scarce. In-vitro experiments by a number of investigators have shown that, at clinical concentrations slightly above those levels obtained *in vivo*, tetracyclines inhibit the uptake of different bacteria, yeast and particles. Furthermore, leukocytes harvested from healthy volunteers after ingestion of tetracycline also demonstrated decreased phagocytic capacity for yeasts, although results are conflicting. For aminoglycosides, decreased, increased or no effect on uptake has been reported. Other antibiotics have not been studied or have not shown effect on phagocyte engulfment or killing functions. At clinically achievable concentrations, for example, fluoroquinolones in general do not affect phagocyte functions.

INTRACELLULAR EFFECTS

Intracellular effects of antibiotics cannot be predicted on the simple basis of cellular drug accumulation and minimum inhibitory concentration (MIC) in broth. In most cases, intracellular activity is actually lower than extracellular activity, despite the fact that all antibiotics reach intracellular concentrations that are at least equal to, and more often higher than, the extracellular concentrations. This discrepancy may result from impairment of the expression of antibiotic activity or a change in bacterial responsiveness inside the cells. It therefore appears important to evaluate the intracellular activity of antibiotics in appropriate models.⁸

The penetration of antibiotics into human cells has been addressed by different methods, often including radiolabeled drugs. Again results vary with experimental conditions; for example, using different media with (or without) albumin considerably affects the outcome.⁹ Penicillins, cephalosporins and aminoglycosides have, in general, been shown to have limited access to the intracellular space with a cellular/extracellular ratio (C/E) less than 1, whereas quinolones, tetracyclines, ethambutol and rifampicin are enriched intracellularly. Azithromycin, clarithromycin, clindamycin, erythromycin, roxithromycin and telithromycin, as well as teicoplanin, demonstrate a C/E of 10:1 to 100:1 or higher. There are also large differences between host cells regarding their capacity to accumulate antibiotics intracellularly. Most

authors have reported a lack of intracellular accumulation of β -lactams in phagocytic cells. However, during longer incubations, β -lactam antibiotics diffuse through membranes into the cell cytosol. Macrophages and also fibroblasts incubated with aminoglycosides for several days accumulate these drugs to an apparent C/E of 2 to 4. Macrophages take up penicillins and aminoglycosides by pinocytosis, in contrast to granulocytes that lack this uptake mechanism. In macrophages actively ingesting bacteria and also in resting macrophages obtained from smokers, there is an increased rate of penetration of the drugs. The intracellular distribution of antibiotics will influence their ultimate biological activity. A prerequisite for a beneficial intracellular antibacterial effect is the localization of the antibiotic and the pathogen in the same intracellular compartment. Thus, intracellular bioactivity is not a common property among antibacterial agents, even though they are accumulated intracellularly.

Bacteria are internalized by both phagocytic and non-professional phagocytic cells in which they may not only survive but also multiply. The ability of bacteria to enter non-phagocytic host cells such as epithelial cells, endothelial cells and fibroblasts requires specific uptake mechanisms including invasins, which interact with specific host cell receptors or bacterial proteins, triggering membrane ruffling and concomitant bacterial uptake. Although the molecular details in the uptake mechanism of phagocytic cells differ among intracellular bacteria, the first event following the specific interaction between the bacterial cell and the phagocyte is always the formation of a primary phagosome. After being taken up, most extracellular bacteria are quickly or more slowly inactivated by the subsequent generation of reactive oxygen intermediates and nitrogen oxide, together with lytic enzymes supplied by the lysosomes. However, it is widely recognized that intracellular survival or even multiplication of many bacteria, traditionally referred to as extracellular parasites, play a significant role in the pathogenesis of the disease these organisms cause. This is evident in infections caused by *Staphylococcus aureus* but is also seen in the case of *Haemophilus influenzae*, pneumococci and streptococci. In order to escape these hostile conditions in the phagosome, intracellular bacteria have invented two different strategies either to modify the phagosomal compartment in a variety of ways to prevent the bactericidal attack or to escape from the primary phagosome into the cytosol of the host cell. The first strategy is used by *Salmonella* spp., *Mycobacterium tuberculosis*, *Legionella pneumophila* and *Chlamydia* spp. In contrast, *Listeria*, *Shigella* and *Rickettsia* spp. escape from the primary phagosome into the host cytosol, where they continue replicating.

The activity of antibiotics against intracellular bacteria was reviewed by van den Broek who commented on the difficulties in comparing data generated by different laboratories.¹⁰ Most antibiotics have not been tested *in vitro* for intracellular effect against microbes with different locations. Intracellular *Staph. aureus* have been shown to present a problem in antibiotic therapy and staphylococci phagocytosed by granulocytes have often been used as a model. Although there are

discrepancies in the literature on the ability of antibiotics to kill intracellular *Staph. aureus*, most studies have shown a good intraphagocytic activity for rifampicin. In contrast, studies on the intracellular accumulation and activity of ciprofloxacin, levofloxacin and moxifloxacin using different cellular models of *Staph. aureus*-infected phagocytes, have reported a bacteriostatic rather than a bactericidal effect of fluoroquinolones despite a many-fold accumulation of the drugs. These concordant data clearly indicate that as yet unknown factors must be at work to decrease the intracellular antibiotic efficiency of fluoroquinolones.¹¹ Macrolides, clindamycin, vancomycin and teicoplanin giving high intracellular levels have shown inability to kill intracellular *Staph. aureus*. This may be due to the fact that clindamycin (and also erythromycin) is mainly associated with the cytosol fraction and less with the lysosomal fraction where the staphylococci are found. In addition, macrolides and clindamycin are negatively affected by acidic pH in the lysosomal fraction. In most studies, β -lactam antibiotics and aminoglycosides have not shown reduction of *Staph. aureus* within neutrophils. However, in contrast, phenoxymethylpenicillin, cloxacillin, flucloxacillin and aminoglycosides have been shown to exert some activity against staphylococci within macrophages. It is widely believed that aminoglycosides only affect extracellular bacteria. However, as pointed out above, aminoglycosides enter macrophages and accumulate slowly. The activity of aminoglycosides against intracellular *M. tuberculosis* has been confirmed in classic macrophage studies. The activity of rifampicin against intracellular *Legionella pneumophila* and *M. tuberculosis* is well accepted. In addition, the intraphagocytic bactericidal effects of erythromycin on *Legionella* and *Chlamydia* spp. seem well established. This may, however, vary due to the cell type in question, as infection with *C. pneumoniae* in circulating human monocytes is refractory to antibiotic treatment with azithromycin and rifampicin.¹²

Extracellular respiratory tract pathogens such as *H. influenzae*, pneumococci and streptococci can enter epithelial cells and macrophages and survive intracellularly. When the activity of azithromycin, gentamicin, levofloxacin, moxifloxacin, penicillin G, rifampicin, telithromycin and trovafloxacin were tested against intracellular pneumococci, moxifloxacin, trovafloxacin and telithromycin were most active. Telithromycin killed all intracellular organisms.¹³

STRUCTURAL CHANGES IN BACTERIA EXPOSED TO ANTIBIOTICS

Altered uptake and killing of bacteria exposed to antibiotics has been clearly documented as reviewed by Gemmel and Lorian.^{14,15} Bacteria exposed to various antibiotics including β -lactam antibiotics, vancomycin, macrolides and quinolones have been reported to be more easily phagocytosed and killed. In contrast to those drugs, tetracycline and gentamicin have been reported to decrease phagocytosis. The reason for the improved killing varies but some bacteria exposed to low

concentrations of antibiotics, i.e. below MIC (sub-MIC), often show increased killing. Structural changes can be one reason for changed uptake and killing. β -Lactam antibiotics produce the most dramatic alteration of the bacterial morphology. The functional role of penicillin binding proteins (PBPs) in bacterial growth and morphological integrity provides the biochemical base for most of the alterations occurring in the presence of β -lactam antibiotics. Each β -lactam antibiotic has a characteristic binding activity for each PBP and at sub-MIC the antibiotic binds to that PBP for which it has the highest affinity, resulting in antibiotic-dependent specific changes (e.g. filaments or oval cells). However, all β -lactam antibiotics have similar morphological effects on staphylococci and other Gram-positive cocci due to little variation in PBP affinity in these bacteria. Fosfomycin and vancomycin, which inhibit earlier stages of cell wall synthesis, produce similar morphological alterations in Gram-positive cocci. Sub-MICs of antibiotics with targets other than cell-wall synthesis induce different morphological changes. Exposure of staphylococci to chloramphenicol, tetracycline, rifampicin and also synergic results in bacteria with multiple layers of cell wall. In Gram-negative bacteria, ciprofloxacin and trimethoprim leads to production of filaments.

Antibiotics may also inhibit the synthesis of key surface molecules. The enhanced phagocytosis and killing of clindamycin-exposed *Bacteroides* spp. appear to be due to the disappearance of capsule from the bacterial surface. Similarly, clindamycin and linezolid reduce the amount of protein A on the surface of *Staph. aureus* and M protein on group A streptococci; consequently these bacteria become more susceptible to phagocytic uptake and killing. In addition, these two antibiotics impair coagulase and hemolysin production of *Staph. aureus* as well as streptolysin and DNase of group A streptococci. Ceftriaxone and monobactams reduce the antiphagocytic antigen of *Esch. coli*. In parallel, ampicillin and chloramphenicol alter the antiphagocytic capsule of *H. influenzae* type b, resulting in increased uptake.

ENDOTOXIN AND EXOTOXIN RELEASE

As early as 1960, Hinton and Orr observed that α -hemolysin production by *Staph. aureus* is inhibited by streptomycin or bacitracin at concentrations below those interfering with bacterial growth. Confirmation of these findings was performed using other antibiotics (tetracyclines, clindamycin, chloramphenicol and erythromycin). Specific inhibition of, for example, toxic shock syndrome toxin is possible with sub-MIC levels of clindamycin. Treatment of several other species (e.g. *Clostridium difficile*, *Pseudomonas aeruginosa*, group A streptococci and *Esch. coli*) with mainly protein synthesis inhibitors reduces both toxin synthesis and the production of other virulence factors.¹⁴ Clindamycin has recently been used as an important supplement to, for example, benzylpenicillin to lower exotoxin levels in the treatment of patients suffering from infections with β -hemolytic group A streptococci.

An effect of great importance of antibacterial agents would be their potential ability to limit release of endotoxin (lipopolysaccharide; LPS), the major constituent of the outer membrane of Gram-negative bacteria, in the critically ill patient.

In-vitro and animal experiments as well as some clinical studies have shown that endotoxin concentrations increase after antibiotic treatment of Gram-negative infections. Antibiotics differ in their capacity to cause endotoxin release depending on their mode of action. β -Lactam antibiotics, acting on the cell wall, lead to a higher endotoxin release than aminoglycosides and other groups of antibiotics, affecting bacterial protein synthesis. Among the β -lactam antibiotics, there are also differences in capacity to liberate endotoxin depending on their affinities for the various PBPs. Furthermore, affinities for PBPs have been shown to be dose dependent. Ceftazidime has been demonstrated to bind to PBP 3 at low doses, leading to the formation of long filamentous structures with an increased endotoxin production before lysis. With increasing doses, ceftazidime also has a high affinity for PBP 1, leading to rapid lysis without elongation and with less endotoxin release.

In a randomized, multicenter, double-blind study, no differences in the levels of proinflammatory cytokines were detected in patients with Gram-negative urosepsis treated with either imipenem or ceftazidime.¹⁶ Thus, well-controlled clinical investigations are required to shed light on complicated biological phenomena. Reduced endotoxin shedding has been reported when β -lactam antibiotics have been combined with clindamycin and tobramycin.¹⁷

CELL PROLIFERATION AND CYTOKINE PRODUCTION

Effects of antibiotics on lymphoid cells or cells of other origins have been described for most antibiotics that accumulate intracellularly. Fluoroquinolones reach concentrations in human leukocytes 3–20 times the extracellular concentration.^{4,5} Importantly, these drugs are not associated with any specific cellular organelle and do not require cell viability for accumulation. At concentrations slightly above those clinically achievable, the effects of fluoroquinolones on the immune system have been thoroughly investigated by us and others. We have used ciprofloxacin as a model drug for this large group of derivatives. Ciprofloxacin (range 5–80 μ g/mL), and to a lower degree other fluoroquinolones, superinduces IL-2 synthesis by mitogen-activated peripheral blood lymphocytes.^{18–20} Experiments with T-cell lines and primary T lymphocytes transiently transfected with a plasmid containing the IL-2 promoter region, show ciprofloxacin to enhance IL-2 gene activation. In parallel with these observations, under certain in-vitro conditions, ciprofloxacin (20–80 μ g/mL) counteracts the effect of the immunosuppressive agent cyclosporin (cyclosporine) that normally inhibits the phosphatase activity of calcineurin inhibiting NFAT-1 activity. Ciprofloxacin thus interferes with a regulatory pathway common to several cytokines.

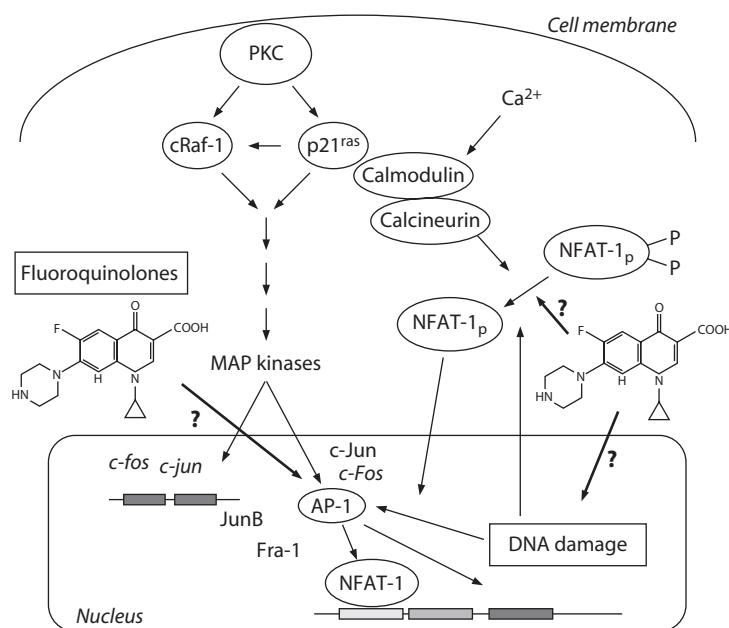

Indeed, analysis of cytokine mRNAs in ciprofloxacin-treated peripheral blood lymphocytes revealed that not only is IL-2 mRNA enhanced, but also an array of other cytokine mRNAs including interferon gamma (IFN- γ) and IL-4 (Figure 7.2A). An earlier and stronger ciprofloxacin-dependent activation of the transcriptional regulation factors NFAT-1 and activator protein-1 (AP-1) has been observed in T-cells explaining the upregulated mRNA transcription (Figure 7.2B). These data suggest a program commonly observed in mammalian stress responses. In fact, when microarray analysis was done on ciprofloxacin-treated T lymphocytes, several gene transcripts ($n = 104$) were upregulated in cells treated with ciprofloxacin, whereas 98 transcripts were downregulated out of 847 total genes included on the microarray.²¹ The increased mRNAs were distributed between major gene programs, including interleukins (36.5%), signal-transduction molecules (13.5%), adhesion molecules (10.6%), tumor necrosis factor and transforming growth factor superfamilies (10.6%), cell-cycle regulators (9.6%) and apoptosis-related molecules (8.7%). In parallel with this hypothesis, ciprofloxacin and trovafloxacin at experimental concentrations potentiate IL-8 and E-selectin (CD62E) synthesis in stimulated endothelial cells.²² However, the fluoroquinolone moxifloxacin (MXF) inhibits nuclear factor kappa B (NF- κ B) activation, mitogen-activated protein kinase activation and synthesis of the proinflammatory cytokines IL-8, TNF- α and IL-1 β in activated human monocytic cells.²³ It also had a protective anti-inflammatory effect in vivo in a model of *Candida albicans* pneumonia in immune suppressed animals, resulting in enhanced survival and reduction in IL-8 and TNF- α in lung homogenates.

Several reports exist on ciprofloxacin-dependent immunomodulation in vivo, strongly indicating that the observed cytokine upregulation is not an in-vitro artefact.^{4,5} It is thus clear that the fluoroquinolone ciprofloxacin stimulates bone marrow regeneration in both transplanted and sublethally irradiated mice by interfering with IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF) synthesis. The treated mice demonstrated a higher number of white blood cells and myeloid progenitor cells in bone marrow and spleen on days 4 and 8 post-irradiation as compared to saline-treated animals. Despite brilliant results in mouse models, only one successful study exists on this phenomenon in human subjects. In contrast to specific effects on the bacteria, fluoroquinolones (7% and 50% for trovafloxacin and tosufloxacin, respectively) protected mice from LPS-dependent mortality when animals were injected with lethal doses.²⁴ IL-6 and TNF- α serum concentrations were significantly reduced in fluoroquinolone-treated animals compared to drug-free controls. In parallel, numerous studies have shown that fluoroquinolones inhibit monokine production by LPS-activated monocytic cell, albeit at drug concentrations higher than the ones achieved in serum.

Macrolides including erythromycin, clarithromycin and roxithromycin have been analyzed in several cell systems using various stimulatory compounds such as cytokines and

Cytokine	Effects of fluoroquinolones	
	mRNA	Protein
IL-1	↑	↓
TNF-α	↑	-↓
LT	↑	-↓
IL-2	↑↑	↑↑
IL-2R	↑	↑↓
IFN-γ	↑↑	↑
IL-3	↑	↑
GM-CSF	↑	↑↓
IL-4	↑	not analysed
IL-8	not analysed	↑

(A)

(B)

Fig. 7.2 Immunomodulatory effects of the representative fluoroquinolone ciprofloxacin and its putative site(s) of action in a schematically drawn T lymphocyte. (A) Fluoroquinolones upregulate virtually all examined mRNA transcripts in mitogen-activated peripheral blood lymphocytes (4,5,21) or monocytes (IL-8) (23), whereas mainly T helper 1 and 2 cytokines are paralleled by an increased protein synthesis. (B) delineates the signaling events in a T lymphocyte stimulated through the T-cell receptor/CD3 complex resulting in protein kinase C (PKC) activation followed by triggering of the MAP kinase cascade on one hand and the increased Ca^{2+} mobilization on the other causing, dephosphorylation of the pre-existing nuclear factor of activated T cells-1 (NFAT-1p). It is not completely clear, however, whether ciprofloxacin directly interferes with the transcriptional regulation factors activator protein-1 (AP-1) or NFAT-1, or inhibits the DNA topoisomerase II resulting in DNA damage and genotoxic stress, leading to a secondary activation of the transcription factors (as indicated by the question marks).

endotoxins. Since macrolides are strongly accumulated intracellularly (>10- to 200-fold), this group of antibiotics consequently has the prerequisite to interfere with eukaryotic cell activities. The molecular target for macrolides as tested with erythromycin seems to be the nuclear transcription factor NF-κB or a target upstream.²⁵ A common feature of the macrolides in in-vitro experimental systems is to inhibit production of proinflammatory cytokines, such as IL-6, TNF-α and IL-8. The effects by the macrolides are similar on epithelial and monocytic cells. Macrolides also interfere directly with eosinophils (i.e. inhibited IL-8 synthesis) and neutrophils (decreased superoxide anion production) suggesting that, together with available data on inhibitory effects on proinflammatory cytokines, macrolides may inhibit the inflammatory response on different levels.²⁶

Tetracycline derivatives, and in particular doxycycline, have repeatedly been reported to interfere with the components of the immune system. For example, doxycycline inhibits proliferation of mitogen-activated peripheral blood lymphocytes,⁶ and minocycline has been shown to decrease T-helper cell cytokines such as IL-2 and IFN-γ. The primary target for tetracyclines may be mitochondria as tetracyclines inhibit mitochondrial protein synthesis, leading to a reduced mitochondrial mass and consequently a decreased oxidative phosphorylation and energy supply.²⁷

Fusidic acid at clinically achievable concentrations in low protein tissue culture suspension significantly inhibits mitogen-activated peripheral blood lymphocytes.⁵ Nitrofurantoin also interferes with lymphocyte proliferation, whereas penicillins, cephalosporins, aminoglycosides and trimethoprim do not appear to exert any specific effects on lymphocyte immune functions.

Rifampicin modifies several aspects of the immune response;¹ it interferes with lymphocyte proliferation as demonstrated by a decreased thymidine incorporation,⁶ and significantly prolongs graft survival up to 40% when examined in a split-heart allograft transplantation model. The mechanism responsible for this has not yet been thoroughly elucidated, but it is most likely that the drug inhibits the cellular immune response to the transplanted tissue. Interestingly, cytokine-activated monocytes incubated with rifampicin show an increased CD1b expression,³ a phenomenon that might be beneficial in tuberculosis patients on rifampicin therapy since CD1b plays a role in presentation of non-peptide antigens.

Cephalosporins do not in general potentiate or modify the immune system. The results obtained in several studies on cefodizime are contradictory and the precise mechanisms have not yet been defined, although the effects of cefodizime have been summarized by Bergeron et al.²⁸ The drug has been reported to exert negative, neutral or positive

effects on polymorphonuclear chemotaxis; to have no effect or positive effects on phagocytosis; to downregulate TNF- α , IL-1 and IL-6 released by stimulated human monocytes; to have no effect on IL-1 release; and to upregulate IL-8 release and GM-CSF from monocytes and bronchial epithelial cells, respectively. Ex vivo, cefodizime shows either neutral or positive effects on chemotaxis and phagocytosis. In vivo, cefodizime restores IL-1 and interferon production in immunocompromised hosts, and enhances phagocytosis and survival of mice infected with cefodizime-resistant pathogens. The drug decreases TNF- α synthesis and inflammation in mice infected by *Streptococcus pneumoniae*, whereas TNF- α production is increased in cefodizime-treated mice administered heat-killed *Klebsiella pneumoniae*.

CONCLUSION

Since the field of immunology expanded in the early 1980s, many studies have been performed in order to elucidate the effects of clinically useful antibiotics on different immune functions. Several antibiotics (e.g. certain fluoroquinolones, macrolides, tetracyclines and rifampicin) significantly interfere with the immune response; however, despite much effort, only a few of the precise mechanisms behind the immunomodulatory capacities have been elucidated. The term *biological response modifiers* has been coined for some drugs, but an antibiotic that is solely chosen for its immunomodulatory activity in lieu of others is not yet available. We are still awaiting drug derivatives with defined antibacterial activities in addition to well-clarified chemical structures that superinduce or inhibit specific immune functions. The field is still in its infancy; structural chemistry followed by high-throughput screening and modern molecular immunology should point us towards new drugs.

General principles of antimicrobial chemotherapy

Roger G. Finch

Antimicrobial agents have had a major impact on the practice of medicine for almost three-quarters of a century. They remain life-saving for many severe infections, such as meningitis, pneumonia and bloodstream infections. However, their use has also controlled many non-life-threatening infections, for example, those affecting the skin, respiratory and urinary tracts, thereby alleviating suffering and controlling the social and economic impact of infectious disease.

Their widespread use in surgical prophylaxis (see Ch. 10) has greatly reduced the infectious complications of surgical operations and made possible transplant surgery and the treatment of malignant disease, notably those requiring profound immunosuppression and cytotoxic chemotherapy for their control.

The very success of antibiotics has led to their widespread use and, indeed, misuse through overprescribing, prolonged treatment courses and for unproven indications. This, in part, has been due to the general acceptance by the public and prescribing professionals of the benefits and relative safety of these agents. Indeed, in many countries, antibiotics may be purchased without prescription from pharmacy stores, thereby adding further to their use.

Among therapeutic agents, antimicrobial drugs have several unique properties. Their use is not directed at particular host-derived disease or pathological processes, but at an infecting micro-organism(s). In general, they are used for short periods (single dose to a few days) rather than for prolonged periods of time as with many other drugs. However, of greater importance is their vulnerability to antimicrobial resistance mechanisms as a result of genetic mutation among target pathogens. Such resistance mechanisms are not only diverse, complex and continuously increasing, but also are readily transmitted both vertically and horizontally among bacterial species and across genera.

This continuous erosion of efficacy through drug resistance has been of professional concern for many years. More recently it has entered the public domain and given rise to political concern. Many countries have introduced a variety of initiatives which are attempting to stem the tide of drug resistance and encourage the development of new agents.

The clinical impact of drug resistance has been to steadily limit therapeutic choice and modify recommendations for managing many common infections (Table 8.1). More recently, multidrug-resistant pathogens have emerged and spread locally, nationally and, in some cases, globally. Reports of formerly sensitive, but now 'untreatable' pathogens are beginning to emerge.

Table 8.1 Impact of antibiotic resistance on prescribing choice

Target organisms	Agents formerly reliably active but for which sensitivity testing is now required
<i>Staphylococcus aureus</i>	Penicillin, methicillin, mupirocin
<i>Streptococcus pneumoniae</i>	Penicillin, tetracycline, erythromycin
<i>Streptococcus pyogenes</i>	Erythromycin, tetracycline
Enterococci	Ampicillin, teicoplanin, vancomycin
<i>Neisseria gonorrhoeae</i>	Penicillin, tetracycline, ciprofloxacin, cephalosporins
<i>Neisseria meningitidis</i>	Sulfonamides
<i>Haemophilus influenzae</i>	Ampicillin, chloramphenicol
Enterobacteriaceae	Ampicillin, cephalosporins, trimethoprim, ciprofloxacin
<i>Salmonella</i> spp.	Ampicillin, sulfonamides, chloramphenicol, ciprofloxacin
<i>Shigella</i> spp.	Ampicillin, tetracycline, sulfonamides
<i>Pseudomonas aeruginosa</i>	Gentamicin, ceftazidime

Drug resistance is by no means exclusive to bacteria. In the few years in which effective chemotherapy has become available to treat HIV infection, drug resistance (phenotypic as well as genotypic) has been the major reason for disease progression. Among fungi, primary and acquired resistance to azole antifungals is increasingly recognized, particularly among *Candida* spp. Worldwide resistance of *Plasmodium falciparum* to chloroquine and other drugs is a major cause of failure of therapeutic and prophylactic control of malaria.

For all the above reasons, a set of prescribing principles has evolved to guide prescribing practice of antimicrobial drugs in the management of infectious disease.¹ The basis for these principles is not only to ensure effective and safe management of infection, but also to reduce the risk of drug resistance emerging. Antibiotic prescribing can also have an ecological impact that may not only affect the recipient of the medication but also has the potential to spread either locally (within the hospital) or more widely in the community. International travel has added a global dimension to such dissemination.

THE PRINCIPLES OF ANTIMICROBIAL PRESCRIBING

DEFINING THE TARGET INFECTION

Fundamental to all antimicrobial prescribing is the need to establish the presence and nature of a particular target infection and to decide whether it is an antibiotic responsive or non-responsive condition. Ideally, such a diagnosis should be supported by microbiological evidence that confirms the nature of the infection. This is only possible where there is ready access to laboratory facilities as in hospital practice, or where reliable near-patient testing is available.

Very few infectious diseases present clinically in a manner that is pathognomonic and for which the microbiological diagnosis can be inferred. Examples include erysipelas caused by *Streptococcus pyogenes*, meningococcal septicemia with rash (*Neisseria meningitidis*) and varicella complicated by a primary pneumonia. The majority of infections do not permit such accurate diagnosis. Syndromes such as pneumonia, meningitis and pyelonephritis are the result of infection by diverse organisms. Microbiological investigations are of limited value in defining a microbial etiology. Initial management, where early microbiological information is unavailable or laboratory facilities do not exist, must therefore be based on a clinical assessment and a presumptive consideration of the likely or possible causal organisms. Such empirical prescribing governs the majority of infections managed in primary care and also reflects the initial management of infectious conditions admitted to hospital, especially where these are life-threatening.

ANTIBIOTIC SELECTION

Knowledge of the likely pathogens responsible for a particular target disease (e.g. urinary tract infection, meningitis, community-acquired pneumonia) is important in making an appropriate choice of agent. This can be greatly enhanced when it is based on local knowledge of the usual repertoire of pathogens and their current susceptibility to therapeutic agents.

Dosage regimens for specific indications are based on clinical trial data, accumulated experience and appropriate dose modification for the patient's age and, where relevant, excretory organ dysfunction, in order to reduce the risk from toxic effects. Dose adjustment may be necessary for pathogens causing 'site protected infections', such as pneumococcal meningitis for which much higher doses of penicillin G are required to produce therapeutic concentrations in the cerebrospinal fluid in comparison with the dosage regimen to treat pneumococcal pneumonia.

Antimicrobial agents, like other drugs, are bound to circulating plasma proteins, mostly albumen. Although microbiologically inactive in the bound state, there is rapid dissociation to the unbound state at the site of infection. The degree of protein binding varies widely, being high for flucloxacillin

(95%) and less marked for ciprofloxacin (30%) and amoxicillin (20%). Highly protein bound agents can perform less satisfactorily against pathogens of borderline susceptibility or in situations where drug concentrations at the site of infection are marginal. In general, the degree of protein binding has little impact on the treatment of infections.

PHARMACOKINETIC AND PHARMACODYNAMIC CONSIDERATIONS

In the past decade or so, pharmacokinetic/pharmacodynamic (PK/PD) modeling, which is derived from the pharmacokinetic behavior of a drug in comparison with the susceptibility of particular target pathogens, has had a major impact on dosage selection, dosage intervals and, more recently, in providing supporting evidence of clinical efficacy. This PK/PD approach plays a major part in new drug development and has been applied not only to antibacterial agents, but also to antiretroviral and antifungal drugs. In some instances, data from such PK/PD modeling have resulted in modification of dosage regimens post-licensing (see Ch. 4). PK/PD modeling has also been investigated for its ability to guide dosage regimens less likely to result in the emergence of drug resistance, by defining the 'mutant preventing concentration' of an agent.

ROUTE OF ADMINISTRATION

Antimicrobial agents can be administered systemically (parenterally or orally) or topically to the skin, eyes and external auditory meati. Other routes include aerosol administration to the lungs in the treatment of lower respiratory tract infections complicating cystic fibrosis and, very rarely, intrathecally or intraventricularly in the specialist management of central nervous system (CNS) infections. In the latter situation, the risk of drug toxicity is considerable and requires particular caution in dose selection and drug administration and, in general, is best avoided.

Drugs with high degrees of bioavailability, such as the fluoroquinolones, produce therapeutic blood and tissue concentrations following oral administration such that parenteral use can often be avoided. This approach is less costly, avoids the complications of vascular access and also supports early step-down therapy from intravenous to oral administration.

DURATION OF TREATMENT

The duration of therapy is poorly defined for many target diseases and is in general based on custom and practice and licensed data. For some diseases, the duration of treatment has been determined scientifically – for example, standard 6-month regimens of combination therapy in the treatment of pulmonary tuberculosis. Another example is the treatment

of streptococcal endocarditis, where the species and, more particularly, the in-vitro susceptibility of the target pathogen, permit short-course therapy (2–4 weeks) for highly sensitive viridans streptococci and prolonged courses (6 weeks) for less susceptible strains, notably enterococcal species.

For many common infections, the licensed duration of treatment has often been 1–2 weeks. In recent years and increasingly based on clinical trial data, 5–7 days is widely accepted for a variety of uncomplicated diseases, including lower respiratory tract infections. Likewise, uncomplicated urinary tract infections generally respond to 3 days' treatment. Many of the clinical features of infection are the result of the host inflammatory response, which often takes a few days to subside after the infecting micro-organism is eliminated. Short-course therapy has much to commend it in terms of compliance, lowered ecological impact, adverse drug effects and cost.

ADVERSE DRUG REACTIONS

No drug is free from side effects. Good prescribing practice must balance the potential benefits of treatment against the known repertoire of adverse effects and likelihood of these occurring in a particular patient. Some are predictable, while others are not. Drug hypersensitivity is particularly common with some agents, notably the β -lactams. Hence it is always important to enquire after any previous adverse reaction from past drug exposure. The known cross-hypersensitivity between the penicillins and cephalosporins precludes substitution of the latter, where an accelerated hypersensitivity reaction (anaphylaxis) has occurred. In contrast, the cautious use of a cephalosporin is often possible where the previous reaction to penicillin was that of delayed hypersensitivity.

Dose-related toxicity is a particular issue for agents dependent upon renal excretion. Where renal function is impaired, drug accumulation can arise. The most notable example is in the use of the aminoglycosides. Dose-related nephrotoxicity and ototoxicity are issues that require constant vigilance and careful monitoring. Therapeutic drug monitoring of gentamicin by timed assays has greatly increased safety in use by ensuring therapeutic, non-toxic serum concentrations linked to careful dose adjustment.

PLACE OF SINGLE AND COMBINED DRUG THERAPY

Whenever possible, single-agent therapy is preferred and is widely adopted in the management of community infections. It has the advantage of simplicity, cost, limits the risks of drug interactions and restricts the risk of adverse reactions to those of the single agent.

Combining agents has benefits in selected patients – for example, in the severely ill septic patient where prompt empirical treatment is necessary. This is usually in response to infections for which a range of pathogens may be responsible,

notably intra-abdominal or lower respiratory tract infections. Combined drug regimens ensure that the potential range of organisms is effectively covered whilst awaiting microbiological confirmation as to the nature of the infection. Once obtained, treatment can often be adjusted to a single agent. Recommendations and evidence-based guidelines now support the management of specific infections with combined drug therapy in the severely affected. The initial empirical management of severe community-acquired pneumonia is one such condition.

In the treatment of tuberculosis, HIV and malaria, combination therapy is now the standard approach but for another reason, namely to limit the risk of selecting drug-resistant strains. In the case of tuberculosis, low frequency primary drug resistance to isoniazid or rifampicin (rifampin) is an ever-present risk. By using combination treatment (e.g. isoniazid plus rifampicin plus ethambutol/pyrazinamide) as the initial regimen, the selection and emergence of drug-resistant disease is greatly limited.

BACTERICIDAL VERSUS BACTERISTATIC PROPERTIES

Another issue of importance in treating infection in severely immunocompromised patients is the need to select a bactericidal drug regimen. This is of particular importance in profoundly neutropenic patients, such as transplant recipients and those receiving cytotoxic chemotherapy for malignant disease. Regimens based on bactericidal agents such as the β -lactams and aminoglycosides are used in preference to bacteristatic agents, notably tetracyclines and antifolate drugs, which rely on an intact phagocytic cell system to eliminate the pathogens. Another example is the use of bactericidal regimens when treating bacterial endocarditis, since the target pathogens are embedded within the cardiac vegetations which is, in essence, an immunologically protected site into which phagocytic cells penetrate poorly.

PROPHYLACTIC USE

Antibiotics have been used extensively in surgical practice to prevent postoperative wound infections. Such prophylactic use has resulted in significant reductions in infectious morbidity and mortality complicating a range of operative procedures (see Ch. 10). For example, the infectious complications of colectomy have been reduced from approximately 40% to 5%. Implant surgery has also benefited, notably joint replacement and cardiac valve surgery.

The rationale for selection of a particular drug regimen for prophylactic use is based on the known risk of an infectious complication, predictable and normally susceptible target organism(s), and a regimen that has been shown to be safe and well tolerated. The latter is important in practice since prophylaxis will be administered to large numbers of patients,

for some of whom the risk of infection will be absent. By limiting such prophylaxis to short-course (usually single dose) perioperative use, concerns over adverse reactions, drug resistance and superinfections are greatly reduced.

Antibiotic prophylaxis also has applications in medical practice to prevent infection in at-risk individuals or, in the case of transmissible infections, to reduce spread to close contacts. For example, those with anatomical or functional asplenia are vulnerable to severe sepsis by *Str. pneumoniae* and other pathogens. Long-term penicillin (erythromycin for those hypersensitive to penicillin) is recommended, especially for those under the age of 16 years. Likewise, rifampicin, ceftriaxone or ciprofloxacin as single dose or short-course therapy is given to close contacts of patients with meningococcal meningitis or septicemia to prevent secondary cases.

FAILURE OF ANTIBIOTIC THERAPY

Despite adhering to the above principles of prescribing, some infections fail to respond to treatment. Hence, it is important to monitor progress in an individual patient.

Failure to respond to antibiotic treatment may be the result of a variety of factors. The nature of the original diagnosis may have been incorrect or may have been more complex than originally conceived (e.g. cellulitis complicated by underlying osteomyelitis). The microbiological nature of the infection should also be reassessed – for example, an atypical pneumonia unresponsive to β -lactams, or a mixed aerobic/anaerobic intra-abdominal infection, while drug-resistant pathogens are increasingly recognized.

Other important causes of failure of treatment include infection related to implanted medical devices (e.g. intravascular catheters), prosthetic devices and retained surgical sutures or pus that requires drainage. Micro-organisms adhere to foreign materials, form biofilms and are then relatively protected from conventional antibiotic therapy. Likewise, antibiotics may be either inactivated or fail to penetrate collections of purulent material which require incision and drainage for their resolution.

THE ROLE OF THE LABORATORY IN DIAGNOSIS AND TREATMENT

In clinical practice it is often impossible to determine the identity let alone the drug susceptibility of the causal agent, hence the importance of sound microbiological practice and good communication between the clinician and the laboratory. Nevertheless, even where laboratory services are not available, by employing the principles of antibiotic use it is often possible to make a logical and successful choice of agent. Laboratory investigations range from simple to sophisticated fully automated methods. Much valuable rapid diagnostic information can be gleaned from reliably performed Gram stains and Ziehl–Neelsen stains of cerebrospinal fluid (CSF) or pus, as well as microscopic analysis of urine and CSF.

It is important that all relevant specimens be collected before treatment is started (an occasional exception is the need sometimes to begin treatment in acute meningitis before lumbar puncture is done) and that these be handled properly and expeditiously. The responsibility for this stage in diagnosis, falling as it does between clinician and laboratory, may, if badly executed, result in missed opportunities for diagnosis. The proper collection, handling and examination of specimens in the diagnosis and management of infection are paramount.

Culture-based laboratory methods remain important in the management of bacterial infections. The growth, isolation and subsequent identification of the pathogen(s) from a clinical specimen add precision to the clinical diagnosis and furthermore guide therapeutic management as a result of antibiotic susceptibility testing. This is of increasing importance as drug-resistant pathogens become dominant and is of particular importance in the management of infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA) and other staphylococci, glycopeptide-resistant enterococci and multidrug-resistant Enterobacteriaceae, *Acinetobacter* and *Pseudomonas* spp. Such pathogens are increasingly isolated from hospitalized patients in high dependency and transplant units.

Drug resistance is no longer restricted to bacteria and is increasing among fungi (notably *Candida* spp. to antifungals) and viruses where it has had a major impact on the management of HIV/AIDS with antiretroviral drugs. Laboratory testing for susceptibility to such agents is of increasing importance.

The occasional consequences of antibiotic use also include the selection of fungi and *C. difficile* which in turn may result in secondary infection. Here, laboratory investigations are key to their recognition and management.

ANTIBIOTIC FORMULARIES AND POLICIES (SEE CH. 11)

Antibiotic formularies are in widespread use. In their simplest form they are a listing of the classes and drugs available or licensed. These may be produced locally (to indicate what agents are stocked), nationally (e.g. *British National Formulary*) or internationally as, for example, the World Health Organization's *Model Lists of Essential Medicines*.² Formularies increasingly contain guidance on the indications, dosage regimens, adverse drug reactions and other information linked to usage.

In order to support good prescribing practice, avoid unnecessary use and to counter the threat from antibiotic resistance, prescribing guidance has evolved into policies with increasing levels of prescribing support and audit. Again, these may be developed locally, by institutional Drug and Therapeutics Committees or their equivalent, or be developed nationally. These increasingly provide detailed prescribing recommendations for specific diseases and conditions. Such recommendations are increasingly

based on guidance derived from an evidence-based assessment of published studies for specific target diseases. They may be produced by professional societies, international collaborations of experts and national agencies, such as the National Institute of Health and Clinical Excellence (NICE) in the UK.

Antibiotic prescribing is increasingly subject to monitoring and audit. Antibiotic usage data collection varies in sophistication from a simple quantitative assessment of drug purchased or prescribed, to more detailed monitoring of primary care prescriptions as in the UK; this identifies prescribing patterns by individual practices or practitioners. International comparisons of prescribing rates are published annually by the European Surveillance of Antimicrobial Consumption,³ where the unit of prescribing is based on the defined daily dose (DDD) per 1000 inhabitants. Such surveillance systems are helpful in informing local and, indeed, national strategies to improve or modify prescribing practice. However, they fail

to provide day-to-day support for the prescriber. Here, online IT systems are essential – but not universally available. By linking prescribing to the medical record and patient-specific laboratory information, a much more sophisticated support system can be created. Prescribing guidance by diagnosis can also support good clinical practice and permits audit of a variety of management and clinical outcomes.

Laboratory control of antimicrobial therapy

Gunnar Kahlmeter and Derek Brown

Most antimicrobial therapy is empirical. However, empirical therapy is based on scientific evaluation of the outcome of clinical trials in which the results of drug therapy have been related to laboratory tests of the antimicrobial susceptibility of the causative micro-organisms and on clinical experience built up during the years following registration of a new antibiotic. The scientific proof of the effectiveness of a drug against certain micro-organisms in specific clinical situations is usually based on results with micro-organisms that lack resistance mechanisms because acquired or mutational resistance (i.e. resistance caused by a genetic alteration) is rare when the drug is new or because organisms with resistance to the drug are excluded by the clinical trials protocol. If factors determining therapeutic success (indications for therapy, drug formulation and dosing, target micro-organisms and antimicrobial susceptibility of target micro-organisms) were constant over time, antimicrobial susceptibility testing in the routine microbiological laboratory would be unnecessary. However, due to the worldwide rapid increase in antimicrobial resistance, empirical therapy becomes more and more uncertain and the foundation for empirical therapy needs constant re-evaluation. Due to sometimes major local differences in the occurrence of resistance, this re-evaluation has to be based on local resistance frequencies.

WHY SUSCEPTIBILITY TESTING?

Susceptibility testing is performed:

- to predict the outcome of antimicrobial chemotherapy in individual patients, i.e. as an instrument for directing antimicrobial chemotherapy;
- to predict the outcome of antimicrobial chemotherapy in future patients, i.e. for continuous evaluation of the basis for empirical therapy;
- to permit epidemiological intervention through:
 - the early detection of bacteria with certain resistance mechanisms in the hospital, e.g. methicillin-resistant *Staphylococcus aureus* (MRSA), glycopeptide non-susceptible enterococci or staphylococci, extended spectrum β -lactamase

(ESBL)-producing Gram-negative bacteria, and in the community, e.g. multiresistant *Mycobacterium tuberculosis*, multiresistant *Salmonella enterica* serotype Typhimurium, penicillin and multiresistant *Streptococcus pneumoniae*;

- the early detection of trends in resistance frequencies and the identification of factors affecting the dynamics of such trends, such as consumption of antibiotics, infection control, associated resistance to other antibiotics or other substances, overcrowded conditions in hospitals and in society at large, etc.

Knowledge obtained in this way forms the basis for national and local antibiotic policies and interventions, and affects national and international legislation (e.g. the prohibition of the use of some antimicrobials as growth promoters in animal husbandry).

THE CATEGORIZATION OF ANTIMICROBIAL SUSCEPTIBILITY

The antimicrobial susceptibility of bacteria and fungi is traditionally categorized with the letters S for *Susceptible* or *Sensitive*, I for *Intermediate* or *Indeterminate* and R for *Resistant*. There is some variation in the definitions of the different categories of susceptibility which can lead to confusion, particularly with the intermediate category. The International Organization for Standardization (ISO)¹ has defined susceptibility categories as follows:

- *Susceptible*: A bacterial strain inhibited in vitro by a concentration of an antimicrobial agent that is associated with a high likelihood of therapeutic success.
- *Resistant*: A bacterial strain inhibited in vitro by a concentration of an antimicrobial agent that is associated with a high likelihood of therapeutic failure.
- *Intermediate*: A bacterial strain inhibited in vitro by a concentration of an antimicrobial agent that is associated with uncertain therapeutic effect.

The ‘uncertain effect’ in the intermediate category implies that an infection due to the isolate can be appropriately treated in body sites where the drugs are physiologically concentrated (e.g. lower urinary tract) or when a high dosage of drug can be used. It may be taken as a signal from the microbiologist to the clinician that the bacterium is now compromised (i.e. has acquired some degree of resistance) and that the interpretation is difficult in the individual patient and/or that a higher dosage than that normally used may be required. There is also a long tradition for breakpoint committees to use the I category as a ‘buffer zone’ to prevent small, uncontrolled technical factors from causing major discrepancies in interpretation of in-vitro tests.

Differences in breakpoints recommended by different national or international breakpoint committees can be significant. For example, a comparison of breakpoints from the European Committee on Antimicrobial Susceptibility Testing (EUCAST; <http://www.eucast.org>) and the USA Clinical and Laboratory Standards Institute (CLSI; <http://www.clsi.org>) shows that, of 36 breakpoints for drugs used to treat infections caused by Enterobacteriaceae, not a single set of breakpoints (S/R) is currently the same. The corresponding numbers for staphylococci are 4/31, streptococci 2/25, *Str. pneumoniae* 3/29, enterococci 0/14, *Haemophilus influenzae* 0/27, *Pseudomonas* 1/18 and *Acinetobacter* 1/11. Some of the differences in minimum inhibitory concentration (MIC) breakpoints are quite pronounced and should be resolved.

A useful supplement to the classic clinical definitions of susceptibility categories was the introduction by EUCAST of the ‘epidemiological MIC cut-off values’ (or ‘microbiological breakpoints’) designed to delineate the ‘wild type’ of each species and to provide a means of early detection and sensitive quantitative description of the emergence of resistance. Clinical breakpoints should be based on the correlation between MICs and clinical outcome of therapy, where doses and duration of therapy are selected on the basis of pharmacological and pharmacodynamic data. The epidemiological cut-off values should be based on the correlation between MICs and the presence and absence of resistance mechanisms to the drug, or class of drug, in question. Epidemiological breakpoints can be used for epidemiological surveillance, for determining factors important for resistance development, and for planning and measuring the effects of interventions to counteract resistance development.

DETECTION OF ANTIMICROBIAL RESISTANCE

The detection of resistance can be phenotypic or genotypic. Phenotypic methods include disk diffusion and automated systems, which are in some way related to the MIC of the organism, and methods detecting a resistance mechanism, such as the detection of β-lactamases or of PBP 2a (indicating methicillin resistance in staphylococci). Genotypic methods detect a defined gene(s), such as *mecA* coding for methicillin

resistance in staphylococci or the *van* genes coding for glycopeptide resistance in enterococci. Genotypic tests tend to be ‘either/or’, i.e. if positive, the organism is considered resistant to the drug or class of drug. All susceptibility tests require both methodological standardization to ensure reproducibility and appropriate interpretive criteria to ensure that results are clinically or epidemiologically meaningful.

THE MINIMUM INHIBITORY CONCENTRATION (MIC)

In MIC tests the micro-organisms are subjected to a range of antibiotic concentrations, conventionally two-fold, in solid or liquid medium, in a defined atmosphere, at a defined temperature and for a defined period of time. The macroscopic inhibition of growth is measured as the absence or near absence of growth on a solid medium or as the absence of turbidity in a liquid medium. The MIC is defined as the lowest concentration which clearly inhibits the growth of the micro-organisms. The MIC is traditionally the antimicrobial susceptibility testing standard against which other methods are assessed. Performance of the methods is affected by technical factors including medium, additives, pH, ion content, incubation time, temperature, atmosphere, etc. Hence methods need to be standardized.

BREAKPOINT METHODS

Most models for susceptibility testing use two MIC breakpoints to divide bacteria into the three susceptibility categories S, I and R defined above. In some susceptibility testing techniques only the breakpoint concentrations are incorporated in solid or liquid media, in which case only two plates or two tubes/microdilution plate wells are needed. Growth at neither the low nor the high concentration indicates that the organism is susceptible, growth at the lower but not the higher concentration indicates intermediate susceptibility and growth at both concentrations is interpreted as resistance. Breakpoint methods are more difficult to control than full MIC determinations or agar disk diffusion because MIC values for control strains are often not close to tested concentrations. Hence the controls may fail to detect significant changes in test concentrations.

AUTOMATED SYSTEMS

A number of automated or semi-automated systems on the market utilize the breakpoint principle, some including additional dilutions around the breakpoints. With additional dilutions a restricted range MIC value for the isolate can be given, together with the corresponding interpretation. With the one- or two-concentration breakpoint system only the

interpretation is given. Automated systems are widely used and have some advantages over manual systems in the standardization of methodology, labor saving and data handling.

GRADIENT METHODS

Gradient methods such as the Etest® (BioMérieux) or MICE® (Oxoid) are a variation on MIC determination. A series of two-fold dilutions of an antibiotic are incorporated on a plastic carrier strip from which the antibiotic diffuses freely into the agar, creating a diffusion gradient along the length of the strip. After incubation overnight, the MIC is read as the point where the growth inhibition ellipse intersects the MIC scale on the strip. Recommendations are provided by the manufacturers for standardization of the inoculum, type of medium to be used for different organisms and reading of the tests. Gradient tests have brought MIC determination to those clinical laboratories that did not previously have the facilities or expertise to do the rather elaborate work needed to set up a standard MIC test in solid or liquid medium.

AGAR DISK DIFFUSION

The diameter of the zone of growth inhibition which forms during incubation of the agar plate constitutes a measure of the susceptibility of the bacterium to the antibiotic. Zone diameters are traditionally correlated with MICs through a regression analysis performed on the parallel MIC and disk diffusion test results obtained with collections of isolates with a range of susceptibilities. The MIC breakpoints are then transformed into corresponding zone diameter breakpoints through the regression line. In the classic Kirby–Bauer² and Ericsson and Sherris³ regression analyses, a collection of bacteria was analyzed in a regression analysis involving many different species and all species received common MIC and zone diameter breakpoints. To be able to characterize the slope of the regression line, it is often necessary to include species inherently insensitive to the drug, which may be poorly representative of bacteria with acquired resistance. Thus, multi-species regression lines may not reflect the relationship between MIC and zone diameter for future isolates with acquired resistance and may not be valid for some species. Species-related zone diameter breakpoints are now usually set in line with species-related MIC breakpoints, and zone diameter breakpoints are more commonly set by adjusting breakpoints so that errors in reporting are as low as possible (the ‘error-minimization’ approach).

Disk diffusion methods are versatile, economic and remain the most widely used approach to routine susceptibility testing in many countries. The Kirby–Bauer method² is the basis of the recommendations of the CLSI in the USA, with Mueller–Hinton agar as the only approved medium and an inoculum

of confluent growth. Standardized methods in Europe have been based on the recommendations in the Ericsson and Sherris³ International Collaborative Study (ICS) report, with either Mueller–Hinton agar or other defined media and semi-confluent inoculum, with which it is easier to see when the correct inoculum is not obtained.

Agar disk diffusion as a screening test

In situations where resistance is rare but clinically or epidemiologically important, and provided the zone diameter breakpoints are specific to the species and set very close to the wild-type population, a standard disk diffusion test can be used as a test to screen for suspicious isolates for further testing (e.g. methicillin resistance in *Staph. aureus*, penicillin resistance in *Str. pneumoniae*, fluoroquinolone resistance in Enterobacteriaceae). In some cases the next step is a confirmatory test such as a polymerase chain reaction (PCR) test for the detection of the specific gene responsible for a known resistance mechanism (e.g. *mecA* gene indicating methicillin resistance in staphylococci). In other cases a follow-up MIC test provides a means for laboratories to define more closely the degree of reduced susceptibility (e.g. *Str. pneumoniae* with penicillin).

MIC AND ZONE DIAMETER BREAKPOINTS

To decide on national MIC and zone diameter breakpoints, and in some instances to describe national methods and standards for susceptibility testing, several countries have breakpoint committees or antibiotic reference groups (*see below*) consisting of clinical microbiologists and infectious disease specialists, and sometimes pediatricians, general practitioners, clinical pharmacologists and representatives of the pharmaceutical industries. Several of these groups in Europe have combined and harmonized their breakpoints as part of the European Committee on Antimicrobial Susceptibility Testing (EUCAST).

The MIC and zone diameter breakpoints published during the 1960s and 1970s were, with a few exceptions (*Neisseria gonorrhoeae*, *M. tuberculosis*), common for all bacterial species and for all clinical situations. The Swedish Reference Group for Antibiotics (SRGA) was first systematically to collect large species-defined parallel databases of MIC values and zone diameter distributions for bacteria lacking resistance mechanisms. Their original database of MIC and disk diffusion zone diameter distributions was later enlarged considerably under the auspices of EUCAST and is now in the public domain on the internet: <http://www.eucast.org>. The database now consists of over 20 000 MIC distributions and some distributions include as many as 120 000 MIC values. The collated distributions include contributions from many sources, including individual investigators, resistance surveillance programs and

companies from all over the world. The species-defined database underlined two particular points:

- Unimodal distributions of MICs or zone diameters for any organism with a particular antibiotic were identical irrespective of where in the world and when the isolates were collected, and in non-unimodal distributions only that part of the wild-type distribution consisting of non-wild-type strains was affected (Figure 9.1). Furthermore, it was evident that distributions of MICs or inhibition zone diameter values for a species were identical

irrespective of whether the isolates were from humans or animals. This is illustrated for tigecycline in *Escherichia coli* in Figure 9.2.⁷ Distributions based on isolates from different individuals and on data from repeat testing of the same isolate were very similar (Figure 9.2), indicating limited biological variation among wild-type individuals of a species in their susceptibility to an antimicrobial agent.

- Breakpoints common to all species often failed in one of two principal ways. Either the breakpoints would divide biologically homogenous populations of a species in such

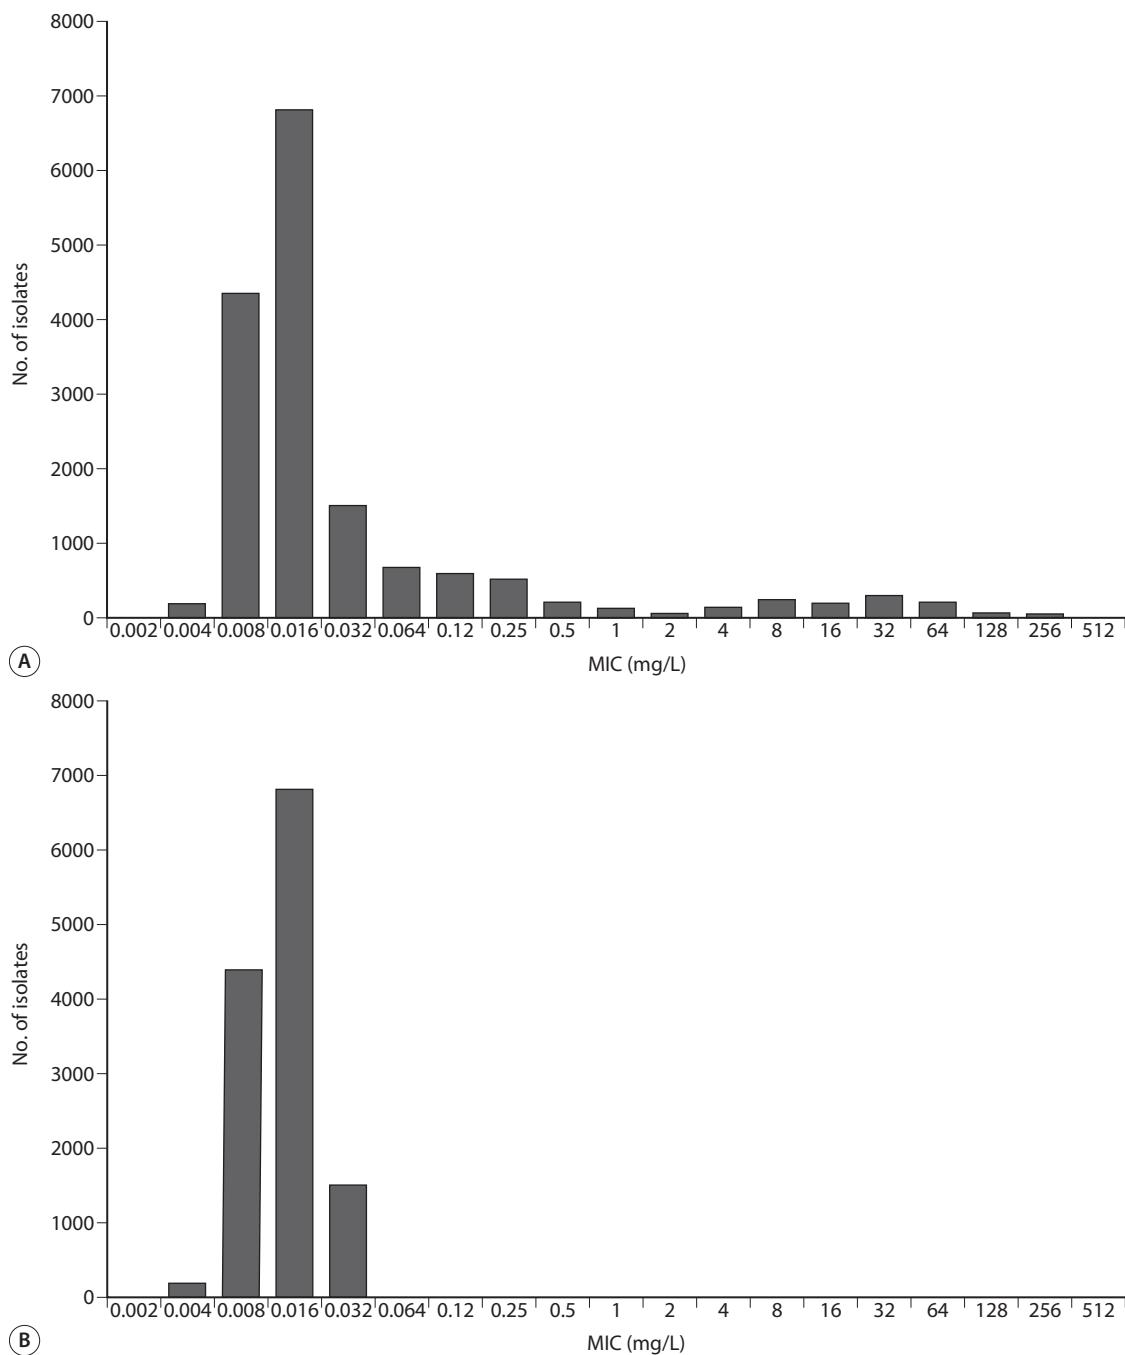

Fig. 9.1 *Escherichia coli* ciprofloxacin MIC (mg/L) distributions from the EUCAST website (<http://www.eucast.org>) where graph A shows all available data on 16 247 isolates from 81 data sources and graph B shows data on the 12 836 isolates (same data sources) considered devoid of fluoroquinolone resistance mechanisms. The highest MIC value for isolates devoid of resistance mechanisms has been designated by EUCAST the 'epidemiological cut-off value' or ECOFF (for *Esch. coli* against ciprofloxacin, the ECOFF is 0.032 mg/L).

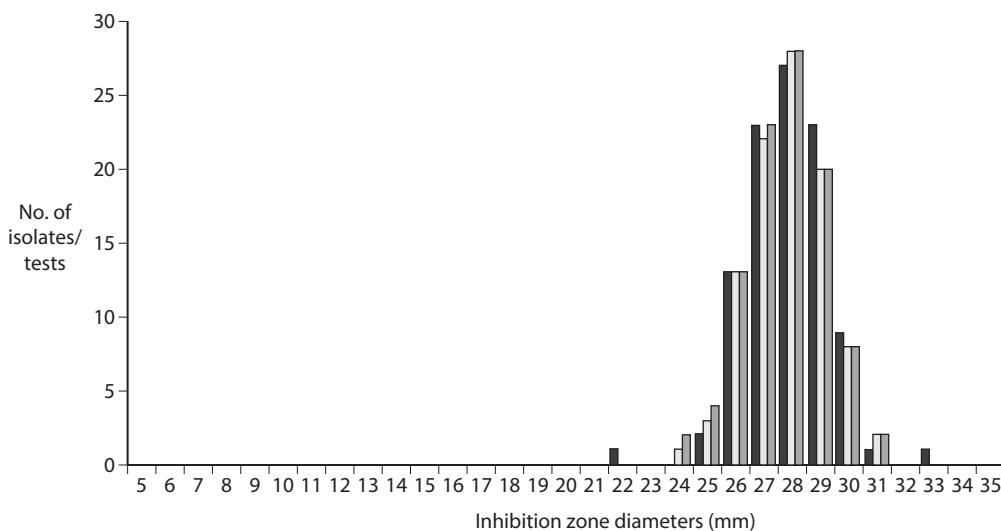

Fig. 9.2 Tigecycline activity (inhibition zone diameters in disk diffusion testing on Mueller–Hinton agar) against *Escherichia coli* from human bloodstream infections (100 consecutive patient isolates, black bars), the gut of 99 arctic non-migrating gulls from three widely separate arctic areas (white bars) and against type strain *Esch. coli* ATCC 25922 (repeat testing of the same strain; gray bars). (Adapted from Sjölund M, Bengtsson S, Bonnedahl J, Hernandez J, Olsen B, Kahlmeter G. *Clin Microbiol Infect.* 2009;15(5):461–465. Epub 2009 Mar 2, with permission from Wiley.⁷)

a way that organisms without biological difference in their relationship to the drug in question would be classified as being different (this is not only unhelpful from a clinical point of view but also detrimental to the reproducibility of susceptibility results) or, because the drug was very active against a certain species (e.g. fluoroquinolones and *Neisseria* or *Haemophilus* spp.), the common breakpoint was so generous that resistance development would go undetected. This is especially true for broad-spectrum antimicrobials considered active against both Gram-positive and Gram-negative bacteria. The solution to this problem is to make species-related adjustments to breakpoints to avoid dividing wild-type populations. This need is now recognized by most breakpoint committees and is one of the guiding principles for setting breakpoints by EUCAST.

ANTIBIOTIC BREAKPOINT COMMITTEES AND/OR REFERENCE GROUPS FOR ANTIBIOTICS

Many countries have their own antibiotic breakpoint committees and/or reference groups for antibiotics, e.g.:

- **BSAC** (British Society for Antimicrobial Chemotherapy, UK; <http://www.bsac.org.uk>)
- **CA-SFM** (Comité de l'antibiogramme de la Société Française de Microbiologie, France; <http://www.sfm.asso.fr>)
- **CLSI** (Clinical and Laboratory Standards Institute, USA; <http://www.clsi.org>)
- **CRG** (Commissie Richtlijnen Gevoeligheids-bepalingen, The Netherlands)

- **DIN** (Deutsches Institut für Normung, Germany; <http://www.din.de>)
- **NWGA** (Norwegian Working Group on Antibiotics, Norway; <http://www.unn.no/category10274.html>)
- **SRGA** and **SRGA-M** (Swedish Reference Group for Antibiotics and its subcommittee on methodology, Sweden; <http://www.srga.org>).

Many of the reference groups are more than just breakpoint committees. Several publish guidelines on methodology, on quality assurance and on the use of reference strains. Some undertake education of laboratory personnel, surveillance of antimicrobial resistance and liaison with regulatory bodies, the medical profession and the pharmaceutical industry.

In 2002, the national reference groups in Europe and the European Society of Clinical Microbiology and Infectious Diseases (ESCMID; <http://www.escmid.org>) co-organized a joint committee, EUCAST, with the principal purpose of achieving harmonized MIC breakpoints and methods in Europe. EUCAST is funded by the European Centre for Disease Prevention and Control (ECDC), ESCMID and the national committees. EUCAST has specialist subcommittees on antifungal susceptibility testing, expert rules and anaerobes. In 2009 the process of harmonization of MIC breakpoints for all commonly used agents was completed. MIC breakpoints for new agents are now set by EUCAST as part of the licensing process for new agents through the European Medicines Agency (EMEA). Reference MIC methods have been described and a disk diffusion method calibrated to EUCAST MIC breakpoints has been developed. Full details of the EUCAST structure and organization are given on the EUCAST website at <http://www.eucast.org>.

TESTS FOR β -LACTAMASE

Various methods are available for detection of β -lactamase activity (http://www.bsac.org.uk/_db/_documents/Chapter_6.pdf). An increasing array of PCR methods for specific detection or typing of β -lactamases is available but these are rarely used for routine purposes. The most commonly used routine test is the nitrocefin test, which is commercially available in various formats. Nitrocefin is a β -lactam molecule that changes color when hydrolyzed by a β -lactamase. The color change is often rapid but can take up to 60 min. The nitrocefin test works well with *H. influenzae*, *Moraxella catarrhalis*, *N. gonorrhoeae*, *N. meningitidis* and *Enterococcus faecalis* (β -lactamase production in the last two is very rare). The method is less reliable with *Staph. aureus*, where induction with penicillin or oxacillin may be required and, because of false-positive reactions, the nitrocefin test should not be used for *Staph. saprophyticus*. Alternative methods are the ‘clover leaf’ test, the acidometric method and the iodometric method.

Enterobacteriaceae exhibit a multitude of β -lactamases, most of which are cell bound and not reliably detected in conventional β -lactamase tests unless induced and extracted. The phenotypic resistance conferred by β -lactamases depends on the level of expression, the substrate profile of the particular enzyme or combination of enzymes, and the presence of other complementary resistance mechanisms, such as permeability/efflux. For this reason the detection of β -lactamase-mediated resistance in the clinical laboratory is based on phenotypic susceptibility testing of penicillins (with and without β -lactamase inhibitors) and cephalosporins.

Detection of resistance mediated by extended-spectrum β -lactamases (ESBLs) is usually based on detection of resistance to specific indicator β -lactams – for example, cefotaxime (or ceftriaxone) plus ceftazidime, or cefpodoxime alone. Provided breakpoints are set close to the wild-type populations (epidemiological cut-off values) of relevant species of Enterobacteriaceae, the susceptibility test will detect most ESBL-mediated resistance. Confirmation of ESBL production is usually based on detection of β -lactamase inhibition by clavulanate.

AmpC enzymes are mostly chromosomal and are inducible in most *Enterobacter* spp., *Citrobacter freundii*, *Serratia* spp., *Morganella morganii*, *Providencia* spp. and *P. aeruginosa*. With *Enterobacter* spp. and *C. freundii*, induction by cefoxitin antagonizes the activity of third-generation cephalosporins, which do not induce enzyme production. Resistance is usually obvious in strains with mutation to derepressed production of AmpC enzymes. The presence of AmpC enzymes may be indicated in tests with boronic acid, which inhibits AmpC activity.

Detection of resistance mediated by carbapenemases can be challenging as carbapenem MICs may be low. As with ESBLs, if breakpoints are set close to the wild-type populations (epidemiological cut-off values) of relevant species, the susceptibility test will detect most carbapenemase-mediated resistance, particularly with ertapenem. The clover leaf test

is a particularly sensitive method for detection of carbapenemases and the presence of metallo-enzymes can be indicated in tests based on detection of β -lactamase inhibition by EDTA, although false positives have been reported for both these methods.

DETECTION OF RESISTANCE GENES WITH MOLECULAR TECHNIQUES

Many different genotypic tests have been described for the detection of resistance genes or organisms carrying resistance genes.⁴ PCR methods can be used for the detection of most resistance mechanisms – for example, methicillin resistance in staphylococci (MRSA, MRSE) where detection of the *mecA* gene coding for PBP 2a classifies the organism as resistant to all currently marketed β -lactam antibiotics except ceftobiprole; and glycopeptide resistance mediated by the *van* genes in enterococci. PCR techniques for the detection of genes coding for β -lactamases, aminoglycoside-inactivating enzymes, macrolide resistance and others have also been described. Molecular methods might be used to detect resistant organisms directly in clinical specimens, although mixtures with normal flora that may contain resistance genes are a problem. This problem has been largely overcome in one method for direct detection of MRSA where the PCR target identifies both *Staph. aureus* and the SCC mec elements that include the *mecA* gene. Where resistance is sometimes equivocal in phenotypic tests, such as with MRSA or glycopeptide-resistant enterococci, PCR is a very useful confirmatory tool, especially in low-prevalence areas where epidemiological intervention in the form of sometimes cumbersome activities may be undertaken to prevent dissemination of resistance. Molecular tests are also valuable in epidemiological studies of the spread of particular resistance genes and may be used as the reference method in evaluation of susceptibility tests for some resistances. However, it is not yet practical routinely to detect the very wide range of genes that might confer resistance. Furthermore, molecular techniques will detect only the genes included in the particular tests, so new resistance genes or mutations in existing genes may be missed, and they give no indication of the level of expression or the effects of combinations of genes, which may significantly affect phenotypic susceptibility. Therefore, phenotypic susceptibility tests are most commonly used to discriminate between resistant and susceptible isolates.

QUALITY ASSURANCE

All susceptibility testing needs effective control to ensure the quality of results. The manufacturers of media, antibiotic disks, gradient strips, microdilution plates with ready-made antibiotic concentrations, etc., and the producers of automated or semi-automated systems, have a responsibility to ensure that their products are of adequate quality. The laboratory has a

responsibility to ensure that the reagents and systems are used correctly and to include control tests to detect problems in performance of the tests.

INTERNAL QUALITY CONTROL

Quality control must be part of the daily routine in the laboratory. Well-defined strains representing non-fastidious and fastidious Gram-negative and Gram-positive bacteria can be obtained from type culture collections (e.g. ATCC, NCTC, CCUG) and from some national antibiotic reference groups. Most standardized methods recommend type strains of *Esch. coli*, *Ps. aeruginosa*, *Staph. aureus*, *E. faecalis*, *Str. pneumoniae*, *H. influenzae* and *N. gonorrhoeae* and that they should be tested daily (some methods permit less frequent testing when daily testing has shown the method to be in control) against the panels of antibiotics used in the daily routine. Control strains should be handled exactly as patient isolates. The MICs or the zone diameters should be recorded and may be plotted in a Shewhart diagram to facilitate visual inspection. Target values and/or control limits for control strains are published for all national guidelines and defined action should be taken if results fall outside these limits.

EXTERNAL QUALITY ASSESSMENT

In external quality assessment (EQA), organisms of known but undisclosed susceptibility are distributed by a central laboratory; participants test the organisms by their routine procedures and send the results back to the central laboratory. The expected results based on reference methods and a summary of the results of all participants are sent to participants so they can evaluate their performance in relation to the expected result and other participants' results. Most EQA programs distribute micro-organisms with defined resistance mechanisms as well as fully susceptible isolates. The international external quality assessment scheme for clinical microbiology organized from the UK (UK NEQAS; <http://www.ukneqas.org.uk>) has a wide coverage, with laboratories from all over Europe and many other parts of the world as subscribers. As well as detecting poor-performing laboratories, which are offered guidance where appropriate, the UK NEQAS scheme has highlighted inadequate performance in some areas of susceptibility testing, such as penicillin resistance in *Str. pneumoniae*, low-level glycopeptide resistance in enterococci and β-lactamase-negative ampicillin resistance in *H. influenzae*. Associations have also been demonstrated between laboratory performance and methods used.⁵

External quality assessment programs have been criticized for distributing strains that are not challenging as susceptibility is too obvious, but strains with borderline susceptibility or difficult resistances are now commonly distributed, and a small proportion of laboratories fail even when strains are obviously resistant or susceptible. In some countries

participation in EQA is not mandatory and it may be that laboratories subscribing to EQA programs are more proficient than those that do not. National efforts, including accreditation requirements, to encourage laboratories to take part in EQA programs, are needed.

ANTIBIOTIC ASSAY

Assays of antibiotic concentrations in serum and other body fluids were developed with the introduction of the modern aminoglycosides during the 1960s and 1970s. A vast number of articles described various assay methods and nomograms for ensuring therapeutic and non-toxic concentrations of gentamicin, tobramycin, amikacin and netilmicin. At the same time the first serious attempts were made to measure and describe antimicrobial tissue concentrations and their relation to therapeutic effect. Pharmacokinetic and eventually pharmacodynamic modeling also depended on the development of assays for measuring the concentration of antimicrobial drugs.

The monitoring of antimicrobial drug therapy is undertaken for four main reasons:

- To ensure therapeutic concentrations – especially where the therapeutic margin is narrow (aminoglycosides, vancomycin) or where there are wide individual variations in the pharmacokinetics of the drug (e.g. rifampicin [rifampin], isoniazid).
- To avoid potentially toxic concentrations (e.g. aminoglycosides, vancomycin).
- To prevent accumulation of drug (aminoglycosides, fluoroquinolones in the elderly) – most often caused by deteriorating renal function.
- To ensure compliance and bioavailability in long-term oral therapy.

Apart from the listed reasons, it is preferable to optimize drug therapy in very sick patients on multidrug therapy in whom drug interactions, failing renal function, dialysis and other factors affecting pharmacokinetics may make dosing difficult even at the best of times.

Clinical laboratories that take on drug monitoring should be prepared to measure and advise on the serum concentrations of at least one aminoglycoside and vancomycin. For both these classes of drugs clinicians trying to avoid potentially toxic serum levels run the risk of underdosing the patient. On the other hand, aminoglycoside therapy administered as part of intensive care or over longer periods is always accompanied by some degree of renal function deterioration (i.e. the drug negatively affects its own major pathway of elimination). Toxic effects such as further damage to the proximal tubular cells and ototoxicity due to accumulation of drug, common when therapy goes beyond 3–5 days, can be counteracted by monitoring pre-dose levels. Vancomycin serum levels are measured mainly to ensure that therapeutic levels are attained but high levels of vancomycin should be avoided. The reader is referred to the excellent publication *Clinical Antimicrobial Assays*⁶ for more detailed information on assay of antimicrobial drugs.

CHAPTER

10

Principles of chemoprophylaxis

S. Ragnar Norrby

Chemoprophylaxis aims at preventing clinical infections and should be separated from early treatment. Prophylactic use of antimicrobial drugs has been established in several types of surgery to prevent post-operative infections. In patients with certain heart disorders antibiotic treatment is recommended to prevent endocarditis following invasive procedures that may lead to bacteremia (e.g. dental treatment and urogenital surgery). Patients who are neutropenic or otherwise immunocompromised often receive prophylactic antibiotics and/or antifungal or antiviral agents to prevent infections.

These are all examples of primary prophylaxis; the aim is to prevent infections occurring. Other examples include prophylactic use of anti-malarial drugs in travelers (see Ch. 62) and prophylaxis against *Pneumocystis jirovecii* pneumonia in HIV-infected patients with low CD4 lymphocyte counts. Following certain infections in immunocompromised patients (e.g. those with AIDS who have had *P. jirovecii* pneumonia or *Cryptococcus neoformans* meningitis) secondary chemoprophylaxis is used to prevent recurrences of the infections for as long as the patient remains immunodeficient.

SURGICAL PROPHYLAXIS

Several surgical procedures (such as abdominal surgery with enterotomies, transvaginal surgery and lung surgery) will result in spillage of material that contains the normal bacterial flora. In other types of surgery the risk of postoperative infection is increased by the use of foreign material, such as hip and knee prostheses. Prophylactic use of antibiotics has been found to reduce the incidence of postoperative bacterial infections in these procedures. In other types of surgery in which spillage is not a major problem and where foreign bodies are not implanted, advantages of prophylaxis cannot be proven and its use is often doubtful. Table 10.1 gives examples of types of surgery where antibiotic prophylaxis has been proven to be beneficial, where it is routinely used but with no solid documentation of efficacy and where it has been proven not to reduce the incidence of postoperative infections.¹

Correct timing of antibiotic prophylaxis in surgery is essential. Treatment should aim at obtaining high antibiotic concentration in tissue and tissue fluids during the surgical procedure, and in particular when there is a high risk of contamination (e.g. when an enterotomy is performed). One study demonstrated that if antibiotics with short plasma half-lives were used, administration more than 2 h before or 3 h after surgery resulted in poor prophylactic effect.² Today it is agreed that surgical prophylaxis should be perioperative, i.e. it should be administered during surgery and terminated when the wound is closed.³⁻⁷ Prolonged antibiotic prophylaxis is costly, gives no further benefits and increases the risk of selection of antibiotic-resistant bacteria.

An alternative to systemic antibiotic prophylaxis might be topical application of antibiotics, which has been proven to be effective when chloramphenicol was compared to placebo in 'high risk' wounds.⁸

ENDOCARDITIS PROPHYLAXIS

It is generally recommended that patients who have had endocarditis or known cardiac valvular defects and/or prostheses should be considered for antibiotic prophylaxis when subjected to certain procedures, including extensive dental surgery and treatment, and genitourinary, gastrointestinal and respiratory tract surgery (i.e. medical interventions which increase the risk of bacteremia and the number of bacteria in bacteremia).⁹ However, the scientific background for using antibiotic prophylaxis has recently been questioned.¹⁰

The choice of antibiotics in endocarditis prophylaxis has been modified in the latest recommendations from the American Heart Association.⁹ For example, the standard regimen before dental and respiratory procedures is today 2 g amoxicillin 1 h before dental treatment or surgery; in patients hypersensitive to penicillin, erythromycin has been replaced by clindamycin or azithromycin. The use of amoxicillin is further supported by a study in which placebo, amoxicillin,

Table 10.1 Need for antibiotic prophylaxis in various surgical procedures

Procedures for which antibiotic prophylaxis is documented and indicated

- Esophageal, gastric and duodenal surgery
- Intestinal surgery (including appendectomy)
- Acute laparotomy
- Inguinal hernia repair
- Transurethral or transvesical prostatectomy
- Total hysterectomy
- Cesarean section
- Surgical legal abortion
- Amputations
- Reconstructive vascular surgery (not surgery on the carotid arteries) with or without the use of grafts
- Cardiac surgery
- Pulmonary surgery

Procedures for which antibiotic prophylaxis is often used but with incompletely documented efficacy

- Pancreatic surgery
- Liver surgery (resection)
- Urological surgery with enteric substitutes
- Implanted urological prostheses
- Transrectal prostate biopsy
- Hemiplastic surgery in patients with cervical hip fractures
- Back surgery with metal implantation
- Aortic graft-stents
- Neck surgery

Procedures for which antibiotic prophylaxis is not documented or indicated

- Biliary tract surgery in patients with normal bile ducts and no stents
- Endoscopic examination of the urinary tract
- Reconstructive urethral surgery
- Arthroscopic procedures

From the Swedish-Norwegian Consensus Group. Antibiotic prophylaxis in surgery: summary of a Swedish-Norwegian consensus conference. *Scand J Infect Dis.* 1998;30:547–557.¹

clindamycin or moxifloxacin was given to patients undergoing dental extractions.¹¹ The frequencies of bacteremia were 96%, 46%, 85% and 57%, respectively.

PREVENTION OF TRAVELERS' DIARRHEA

Up to 50% of travelers to tropical and subtropical countries will develop travelers' diarrhea. The most common pathogens causing this condition are strains of *Escherichia coli* producing enterotoxin (ETEC), *Campylobacter* spp., *Vibrio parahaemolyticus*,

Vibrio cholerae, *Salmonella enterica* serotypes and *Shigella* spp. In addition, diarrhea may be the result of food poisoning with bacterial toxins produced by *Staphylococcus aureus*, *Bacillus cereus* or *Clostridium perfringens*. Vaccines are available only against *V cholerae* (one of the cholera vaccines may also give short-term protection against ETEC) and *Salmonella Typhi*.

Chemoprophylaxis using trimethoprim-sulfamethoxazole, doxycycline, fluoroquinolones or other antibiotics effectively decreases the incidence of travelers' diarrhea. Arguments against such use of antibiotics are the risks of adverse effects and of emergence of resistance. However, prophylaxis should be considered in individuals with underlying diseases that may be complicated by acute diarrhea (e.g. people with diabetes mellitus, reactive arthritis or inflammatory bowel disease). Patients treated with drugs that reduce the gastric acidity should also be considered for prophylaxis because they are at increased risk of developing diarrhea due to a defective acidic barrier.

PROPHYLAXIS AGAINST MENINGOCOCCAL DISEASE

It is well known that individuals who have had close contact with a patient with meningococcal disease are at increased risk of developing the disease. Two types of prophylaxis have been used. The most common one is to use ciprofloxacin or rifampicin (rifampin) in order to eradicate carriage of *Neisseria meningitidis*. Another approach, commonly used in Norway, is to treat contacts of a patient with meningococcal disease with penicillin V for 7 days. Such a regimen will prevent disease but will not eradicate carriage. For further details, see Chapter 50.

CHEMOPROPHYLAXIS IN PATIENTS WITH IMMUNE DEFICIENCIES

Prophylactic antibiotics and antiviral drugs are commonly used in patients with various types of immune deficiency and are summarized in Table 10.2. The use of primary and secondary prophylaxis against *P. jirovecii* pneumonia with trimethoprim-sulfamethoxazole (which also seems to prevent *Toxoplasma*

Table 10.2 Primary chemoprophylaxis in immunodeficient patients

Type of immune deficiency	Prophylaxis against	Drugs used
Organ transplantation (Chapter 40)	<i>Pneumocystis jirovecii</i> Herpes simplex Cytomegalovirus <i>Candida</i> infections	Trimethoprim-sulfamethoxazole Aciclovir Ganciclovir, aciclovir Azole antifungals
Neutropenia (Chapter 40)	Bacterial infections <i>Candida</i> infections	Various Azole antifungals
Asplenia	Pneumococcal infections	Penicillin V
HIV infection (Chapter 43)	<i>P. jirovecii</i> <i>Toxoplasma gondii</i> Atypical mycobacteria Neonatal transmission	Trimethoprim-sulfamethoxazole Trimethoprim-sulfamethoxazole Various Antiretroviral drugs

gondii encephalitis) and secondary prophylaxis against *C. neoformans* meningitis have been proven to be effective. Primary prophylaxis against fungal infections, especially those caused by *Candida* spp. in HIV-positive patients, seems more doubtful since the time during which prophylaxis is used by necessity must be long and might result in selection of resistant strains, especially when oral treatment with an azole antifungal agent such as fluconazole or itraconazole is used. Importantly, it has been demonstrated that during effective, so-called 'highly active' antiretroviral treatment (HAART), pneumocystis prophylaxis can be discontinued without negative effects.¹²

Another type of prophylaxis in HIV-infected patients that has been proven to be effective is the administration of anti-retroviral drugs to pregnant women and to their newborn children in order to prevent intrauterine and neonatal transmission of HIV.

11 Antibiotic policies

Peter G. Davey, Dilip Nathwani and Ethan Rubinstein

Antibiotic resistance is a global public health problem.^{1,2} In Europe in 2008 16 countries had developed a national strategy to contain antimicrobial resistance and nine countries had an action plan.³ A core component of most of these strategies is antimicrobial stewardship, which has been defined as a set of measures delivered by a multidisciplinary team working in healthcare institutions to optimize antimicrobial use amongst patients in order to improve patient outcomes, ensure cost-effective therapy and reduce adverse sequelae of antimicrobial use, including ecological effects such as resistance and *Clostridium difficile* infections.^{4,5} Targets for antimicrobial stewardship include appropriate antibiotic selection, dosing, route, and duration of therapy. Antimicrobial stewardship combined with infection prevention measures will limit the emergence and transmission of antimicrobial resistance.⁶

Antibiotic policies are an integral component of antimicrobial stewardship programs. The terms 'guidelines', 'formularies' and 'policies' are often used interchangeably but they are separate, complementary components of a strategy for prudent antimicrobial use.

- *Guidelines* provide advice about what drug should be prescribed for a specific clinical condition. They may take the form of a care pathway or flow chart outlining processes of care, including investigations and therapies other than just antimicrobial compounds (e.g. oxygenation in a pneumonia guideline). National guidelines have been published as templates for local consultation and adaptation.^{7,8}
- A *formulary* is a limited list of drugs available for prescription. It may include information about available dosing instructions and advice about safety or interactions but it does not include detailed guidance for use.
- An *antimicrobial policy* contains guidelines about treatment of specific conditions. This can also include a limited list of antimicrobial agents that are generally available to all prescribers – in other words an antimicrobial formulary. In addition to guidance, antimicrobial policies may include enforcement strategies such as compulsory order forms for restricted drugs.
- An *antimicrobial management team* is a multidisciplinary team in which each member is given specific roles and which collectively takes responsibility for implementation of local policies (see Figure 11.1). To be effective the team must have

full support from hospital leadership, work closely with infection control teams and provide regular feedback to individual clinicians and clinical teams about their compliance with policies.

There is considerable variation in the use of antibiotic policies and control measures in European hospitals.⁹ Consequently, efforts to coordinate and standardize antimicrobial stewardship programs across multiple hospitals and primary care organizations have been initiated by countries (e.g. Scotland,¹⁰ Sweden¹¹) or networks such as the European Union antibiotic stewardship program (ABS International¹²).

Antibiotic policies have been used since the 1950s and have evolved in complexity over time.¹³ In 1990 the *Drug and Therapeutics Bulletin* concluded that local prescribing policies are worth the time and money they take to produce, improve the quality of prescribing and reduce overall costs in hospitals and in general practice.¹⁴ Nonetheless, in 1994 only 62% of 427 UK hospitals had a policy for antibiotic therapy and 75% had an antibiotic formulary.¹⁵ In 2001 the House of Lords Select Committee on Science and Technology again had to urge the Department of Health to pursue any hospitals that did not have a formal prescribing policy.¹ A further survey of acute healthcare trusts in England in 2004/5 revealed that an antimicrobial policy was in place in 89% of responding trusts (109/123).¹⁶ This is clearly an improvement on the previous survey result but it is disappointing that 11% of responding hospitals had not taken the essential first step of writing an antibiotic policy. In the USA 100% of 47 hospitals surveyed in 2000 had an antibiotic formulary.¹⁷ However, only 47% had written policies for surgical prophylaxis, a key area of antibiotic misuse.¹⁸

The problems of antibiotic resistance linked to widespread prescribing of antibiotics are even more pressing in developing countries. In India and Sri Lanka 66% of community prescriptions include an antimicrobial; in Bangladesh and Egypt antibiotic use accounts for 54% and 61%, respectively, of all hospital prescribing.¹⁹ The potential value of antibiotic policies in such countries and their current role have recently been reviewed.²⁰

In this chapter we review the aims of antibiotic policies, the methods for policy implementation and the evidence that policies achieve their aims.

STIMULI FOR THE INTRODUCTION OF ANTIBIOTIC POLICIES

Many of the stimuli for antibiotic policies are common to policies for other drug groups, but some are unique to antibiotics (Table 11.1). The general advantages of defining a core list of drugs that are used regularly have been recognized for many years by the World Health Organization.²¹ The aim is to encourage rational prescribing, which is based on knowledge of pharmacology, efficacy, safety and cost. Drug resistance amongst microbes is a unique stimulus to control of antibiotic prescribing.

Table 11.1 General and specific advantages of an antibiotic policy

Category	Benefits
Knowledge	<p><i>General</i> Promotes awareness of benefits, risks and cost of prescribing Facilitates educational and training programs within the healthcare setting Reduces the impact of aggressive marketing by the pharmaceutical industry Encourages rational choice between drugs based on analysis of pharmacology, clinical effectiveness, safety and cost</p> <p><i>Specific to antimicrobials</i> Provides education about local epidemiology of pathogens and their susceptibility to antimicrobials Promotes awareness of the importance of infection control</p>
Attitudes	<p><i>General</i> Acceptance by clinicians of the importance of setting standards of care and prescribing Acceptance of peer review and audit of prescribing</p> <p><i>Specific to antimicrobials</i> Recognition of the complex issues underlying antimicrobial chemotherapy Recognition of the importance of the special expertise required for full evaluation of antimicrobial chemotherapy: Diagnostic microbiology Epidemiology and infection control Clinical diagnosis and recognition of other diseases mimicking infection Pharmacokinetics and pharmacodynamics</p>
Behavior	<p><i>General</i> Increased compliance with guidelines and treatment policies Reduction of medical practice variation</p> <p><i>Specific to antimicrobials</i> Improved liaison between clinicians, pharmacists, microbiologists and the infection control team</p>
Outcome	<p><i>General</i> Standardization and reduction in practice variation are key strategies for improving the quality of healthcare Improved efficiency of prescribing by increasing sensitivity (patients who can benefit receive treatment) and specificity (treatment is not prescribed to patients who will not benefit) Improved clinical outcome Reduces medicolegal liability</p> <p><i>Specific to antimicrobials</i> Limit collateral damage (emergence and spread of drug-resistant strains or superinfection by <i>Clostridium difficile</i>, other bacteria or fungi)</p>

PRACTICAL ADVANTAGES OF LIMITING THE RANGE OF ANTIMICROBIALS PRESCRIBED

In the hospital, the prescription of an antimicrobial by a clinician has implications for nurses, pharmacists and microbiologists who will all be involved in preparation, administration and monitoring of the prescribed drug. Limiting the range of drugs used allows the team to become familiar with the necessary processes.²² Many of the staff who take responsibility for these processes will rotate through several departments in the hospital or will provide cross cover outside working hours. Having common policies within and between clinical directorates reduces the need for time-consuming retraining of staff as they move between clinical units. The need for national guidance about antibiotic prescribing in primary care has also been recognized⁷ in response to earlier evidence of considerable variation in content and quality across policies in primary care.²³

Providers of healthcare are increasingly being asked for evidence about quality assurance. Auditing practice is only possible if standards of care have been defined. The narrower the range of drugs, the easier it is to write and audit detailed standards of care. It is also likely that staff will find it easier to comply with policies that cover a limited range of drugs.

COST

Antibiotics account for 3–25% of all prescriptions and up to 30% of the drug budget in a hospital.²⁴ New drugs are inevitably more expensive than old drugs and new drugs will be heavily promoted by pharmaceutical companies. One of the aims of antibiotic policies is to encourage prescribers to continue to use older, more familiar drugs unless there are good reasons not to. Intravenous antibiotics are usually about 10-fold more expensive than equivalent oral formulations and intravenous administration requires additional consumables and staff time.²⁵ Policies that include specific recommendations about route of administration may reduce costs considerably.⁴ Limiting the range of drugs also reduces the range of stock that is sitting on the pharmacy shelves.

QUALITY AND SAFETY OF PRESCRIBING

Prescribing drugs that do not benefit the patient exposes them to unnecessary risk and one study found that 26% of all adverse drug reactions in a hospital were caused by drugs that were prescribed unnecessarily.²⁶ Unnecessary prescribing of antimicrobials carries additional risks for the patient (increased risk of cross infection by resistant organisms or *C. difficile*) and the environment (selection of drug-resistant bacteria, e.g. *Enterococcus faecalis*). Therefore, assessment of the quality of prescribing must consider several elements, including the risks and benefits of introducing another drug and of intravenous versus oral administration. In practice it is very difficult to assess the appropriateness of an entire course

of treatment, particularly in hospital. What is appropriate on one day may be inappropriate the next. This problem has been recognized in a practical system for reviewing each day of an antibiotic prescription and then computing the proportion of inappropriate days.²⁷ The term ‘inappropriate’ covers a multitude of sins and encompasses both undertreatment and unnecessary overtreatment. Judgment of appropriateness is therefore complex and it is worrying that the few studies of interrater reliability show very poor agreement.²⁸ Use of computerized case vignettes may provide a more reliable system of assessing inpatient antimicrobial appropriateness.²⁹

Monitoring of community prescribing is challenging, especially where drugs are freely available over the counter. Self-medication rates reported include 51% in Ecuador, 70% in Thailand, 75% in Brazil, 82% in Ethiopia and 92% in the Philippines.¹⁹ There are undoubtedly some potential advantages to increasing the availability of antibacterials without prescription, such as convenience for the patient, faster initiation of treatment and reduction in primary care workload.³⁰ However, in the European Union² and in North America,³¹ the risks of increasing access to antibacterials are thought to outweigh these benefits.

In the second half of the 20th century there was an inexorable increase in the number of prescriptions for antibiotics in the community in developed countries.³² More recently this trend has reversed and several countries have reported a significant reduction in antibiotic prescribing in primary care.^{11,33–35} Nonetheless, there is still plenty of room for improvement. For example, although the Netherlands has the lowest overall use of antibiotics in Europe,³⁶ a detailed investigation suggested that 75% of prescriptions for otitis media in primary care might be unnecessary.³⁷ Longitudinal analysis that combines quantitative and qualitative methods is required to understand how socioeconomic factors and changes in the delivery of care might influence antibiotic use.^{38,39}

Educational training and support is an important component of improving the quality and safety of prescribing. The skills and competencies required are both technical and non-technical.⁴⁰ These skills are applicable to all professional prescribers.⁴¹ Some of this knowledge can be acquired through the use of a range of high-quality educational web-based resources.⁴² The British Society for Antimicrobial Chemotherapy (BSAC) and the European Society for Clinical Microbiology and Infectious Diseases (ESCMID) are collaborating on a teaching resource that uses common clinical infection vignettes as a means of learning about infection management and use of local policies.⁴³

COLLATERAL DAMAGE FROM ANTIBIOTIC USE: RESISTANCE AND CROSS-INFECTION

The mechanisms and epidemiology of drug resistance are described in Chapter 3. Control of antibiotic resistance has always been a strong stimulus to the development of antibiotic

policies.¹³ Antibiotic use stimulates the emergence of resistance but the spread of resistance mainly occurs through cross-infection of resistant strains from one patient to another. The epidemiology of resistance shows that the probability of infection with resistant bacteria is related to both the previous intensity of antibiotic use in the environment or population and the exposure of individual patients who enter the environment or population. Previous use facilitates the emergence of resistance in the environment or population, while exposure of individual patients facilitates persistence of resistant strains.⁴⁴ Because acquisition of resistant strains is almost always determined by cross-infection, infection control must be integrated with antimicrobial stewardship (Figure 11.1).

In addition to antimicrobial resistance, collateral damage from antibiotic use includes infection by *Clostridium difficile* and by fungi. The same principles apply to these infections; antimicrobial stewardship will only work if it is combined with infection control (Figure 11.1).

WHAT INTERVENTIONS CHANGE ANTIBIOTIC PRESCRIBING?

The evidence base for antibiotic policies is the subject of two Cochrane Systematic Reviews, one of interventions for patients in ambulatory care⁴⁵ and one of interventions for hospital inpatients.⁴⁶ A variety of resources linked to the hospital inpatients review can be accessed from the BSAC website (<http://www.bsac.org.uk>), including all publications, additional details of included studies with microbial outcomes and slide sets with explanatory notes.⁴⁷

The majority of interventions in both reviews were successful: 81 (76%) of 106 interventions on prescribing to hospital inpatients⁴⁶ and 30 (75%) of 40 interventions on prescribing in ambulatory care⁴⁵ were associated with statistically significant improvements in the primary outcome. However, these two reviews reveal important differences between ambulatory and hospital care in the targets for intervention, the types of intervention and the outcomes that have been measured (Table 11.2).

TARGET FOR THE INTERVENTION

In hospitals, 19 (18%) of the interventions aimed to increase the intensity of antibiotic treatment (Table 11.2). Examples include ensuring that antibiotics were received by patients who would benefit from them⁴⁸ or reducing time from admission to start of antibiotic treatment for patients with pneumonia.⁴⁹ In contrast, none of the interventions in ambulatory care aimed to increase the intensity of antibiotic treatment (Table 11.2). In hospitals, the commonest target for intervention was the choice of drug (80%), whereas in ambulatory care only 45% of the interventions targeted the choice of drug (Table 11.2). In ambulatory care the commonest target for interventions was the decision to

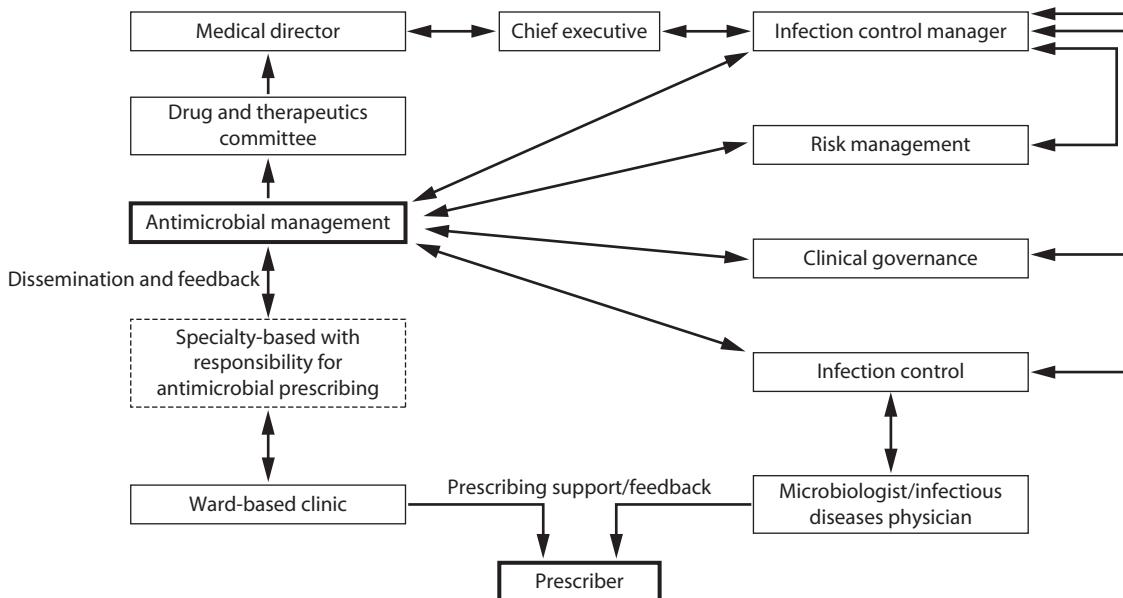

Fig. 11.1 Model pathway for implementing improvements in antimicrobial prescribing practice in hospitals. The antimicrobial management team has a central coordinating role in feedback of information to individual prescribers, clinical teams and senior management. (From Nathwani D. Antimicrobial prescribing policy and practice in Scotland: recommendations for good antimicrobial practice in acute hospitals. *J Antimicrob Chemother.* 2006;57:1189–1196, by permission of Oxford University Press.¹⁰)

prescribe an antibiotic, with 26 (65%) of the studies aiming to reduce the proportion of patients who received an antibiotic (Table 11.2). In contrast, in secondary care, only 8 (8%) of the studies targeted the decision to prescribe and in three of these the aim was to increase the proportion of patients who received effective antibiotic therapy so that only 5 (5%) of the studies on hospital inpatients aimed to reduce the proportion of patients who received an antibiotic. Computerized decision support is a promising method for reducing the number of patients who receive unnecessary antibiotics⁵⁰ and one study has clearly shown the potential for this approach in hospital care.⁵¹

TYPE OF INTERVENTION

In hospital, 47 (44%) of the interventions included a restrictive component, which limited the choice of professionals (Table 11.3). In contrast, in ambulatory care all but two of the interventions were persuasive, the two exceptions being a restrictive primary care formulary that limited the use of fluoroquinolones and an intervention to change the reimbursement and organization of services in primary care.⁴⁵ The two commonest persuasive interventions used in hospitals were distribution of educational materials and reminders, whereas in ambulatory care they were educational meetings and educational outreach visits (Table 11.3). Only 10% of interventions in either setting used audit and feedback (Table 11.3). Patient-based interventions were only used in ambulatory care (Table 11.3). These were either patient information sheets or delayed prescriptions, which allowed patients

to obtain an antibiotic without reconsulting the doctor if they had persistent symptoms (Table 11.3).

DESIGN OF EVALUATION OF INTERVENTIONS

The commonest method for evaluation of interventions was an interrupted time series (ITS) in hospitals (55% of studies) whereas in primary care it was a randomized controlled trial (RCT, 63% of studies, see Table 11.2). The Cochrane Effective Practice and Organisation of Care Group have recently updated their criteria for assessing risk of bias in studies.⁵² These criteria have been applied to the 106 studies in the review of interventions to improve antibiotic use for hospital inpatients (Table 11.4). ITS was the evaluation design that had the lowest risk of bias and was the only design with <50% of studies at high risk of bias (Table 11.4). In contrast, 67% of RCTs were at high risk of bias and only one RCT had a low risk of bias (Table 11.4). The reason is that it is virtually impossible to conceal allocation and avoid contamination in a trial in which professionals are randomly assigned to receive an intervention in a hospital. This can only realistically be achieved in a large RCT that involves multiple hospitals.⁵³ In contrast, in an ITS study, the control and intervention periods are separated and studies will have a low risk of bias provided that they have reliable primary outcome measures and enough data to show that the intervention effect is likely to be independent of seasonal variation. Consequently, ITS is usually the best design for evaluation of the impact of an antibiotic policy in a single hospital. For research, the strengths of ITS and RCT can be combined in a design called a stepped wedge.⁵⁴

Table 11.2 Comparison of evaluations of interventions to improve antimicrobial prescribing for hospital inpatients and in ambulatory care

Comparison	Hospital inpatients		Ambulatory care	
	Number	% ¹	Number	% ¹
Design

SUMMARY: WHAT INTERVENTIONS CHANGE ANTIBIOTIC PRESCRIBING?

These two reviews of interventions in hospital and ambulatory care reinforce the message that there are ‘No magic bullets’, meaning that it is not possible to provide general guidance about the most appropriate method for improving professional practice in any context.⁵⁵ Both reviews provide further evidence that the most successful interventions are those which involve the professionals who are the targets for change in both the development and dissemination phases, and provide concurrent feedback of information about implementation.^{55–57}

However, this approach requires considerable investment of time by professionals, plus information systems that are capable of providing concurrent feedback. Simply providing prescribers with educational information may be relatively unsuccessful; however, as it requires much less in the way of resources, it could be a more cost-effective method for achieving change. As in most areas of medicine, the most complex and effective intervention available is not necessarily the most appropriate and it makes sense to test interventions in order of complexity, starting with the simplest.⁵⁶

In hospitals restrictive interventions were associated with a greater immediate impact than persuasive interventions.⁴⁶ However, the impact of persuasive and restrictive

Table 11.3 Types of intervention used to influence antibiotic prescribing

Intervention	Description	Hospital inpatients		Ambulatory care	
		Number	%	Number	%
Persuasive professional interventions					
Distribution of educational materials	Distribution of published or printed recommendations for clinical care, including clinical practice guidelines, audiovisual materials and electronic publications. The materials may have been delivered personally or through mass mailings	56	53	4	10
Educational meetings	Healthcare providers participating in conferences, lectures, workshops or traineeships	14	13	10	25
Educational outreach visits	Use of a trained person who meets with providers in their practice settings to give information with the intent of changing the providers' practices. The information given may have included feedback on the performance of the provider(s)	4	4	8	20
Local opinion leaders	Use of providers nominated by their colleagues as 'educationally influential'. The investigators must have explicitly stated that their colleagues identified the opinion leaders	2	2	0	0
Patient-mediated interventions	New clinical information (not previously available) collected directly from patients and given to the provider	0	0	5	13
Audit and feedback	Any summary of clinical performance of healthcare over a specified period of time. The summary may also have included recommendations for clinical action. The information may have been obtained from medical records, computerized databases or observations from patients	11	10	4	10
Reminders	Patient or encounter-specific information provided verbally, on paper or on a computer screen, which is designed or intended to prompt a health professional to recall information. This would usually be encountered through their general education, in the medical records or through interactions with peers, and so remind them to perform or avoid some action to aid individual patient care. Computer-aided decision support and drug dosage are included	44	42	3	8
Other types of intervention					
Healthcare system	Restriction of professional choice through removal of drugs from stock, compulsory order forms that limit drugs to specific conditions, requiring signed approval by another professional, therapeutic substitution of the physician's original choice of antibiotic by another professional, automatic stop order after a fixed duration of treatment or prophylaxis Changes in methods of physician remuneration	47	44	2	5
Structural	Inclusion of equipment where technology in question is used in a wide range of problems and is not disease specific (e.g. rapid laboratory testing or therapeutic drug monitoring)	8	8	0	0

interventions was similar after 6 months and after 12 months there was a suggestion that persuasive interventions had greater impact.

In ambulatory care all five studies that included patient-based interventions (information sheets or delayed antibiotic prescriptions) resulted in a statistically significant reduction in antibiotic use. The review authors concluded that in ambulatory care multifaceted interventions combining physician, patient and public education in a variety of venues and formats were the most successful in reducing antibiotic prescribing for inappropriate indications.⁴⁵ However, in hospitals multifaceted interventions were not associated with greater impact than single component interventions.⁴⁶

TO WHAT EXTENT DO ANTIBIOTIC POLICIES ACHIEVE THEIR SECONDARY AIMS?

CAN ANTIBIOTIC POLICIES REDUCE HEALTHCARE COSTS?

The literature is full of claims that implementation of antibiotic policies reduces healthcare costs, in hospital or in the community. However, the Cochrane Systematic Reviews revealed significant gaps in the evidence base. In hospital care 31% of studies estimated the financial savings from reduction in use of the target drugs but only 12% of studies included

Table 11.4 Rigorous designs for evaluation of interventions to change practice and organization of care*

Design	Criteria for assessment of quality	Description	Total	Risk of bias					
				Low		Medium		High	
				N	%	N	%	N	%
Studies with a separate control group	Was the allocation sequence adequately generated? Was the allocation adequately concealed? Were baseline outcome measurements similar? Were baseline characteristics similar? Were incomplete outcome data adequately addressed? Was knowledge of the allocated interventions adequately prevented during the study? Was the study adequately protected against contamination? Was the study free from selective outcome reporting? Was the study free from other risks of bias?	<i>Randomized controlled trial</i> Participants (patients, doctors, healthcare teams, etc.) were assigned by random allocation (e.g. random number generation, coin flips)	30	1	3	9	30	20	67
				3	0	0		3	100
		<i>Controlled before and after study</i> Involvement of intervention and control groups other than by random process, and inclusion of baseline period of assessment of main outcomes	15	0		1	7	14	93
Interrupted time series	Was the intervention independent of other changes? Was the shape of the intervention effect pre-specified? Was the intervention unlikely to affect data collection? Was knowledge of the allocated interventions adequately prevented during the study? Were incomplete outcome data adequately addressed? Was the study free from selective outcome reporting? Was the study free from other risks of bias?	A change in trend attributable to the intervention, with repeated measures of the main outcomes before and after the intervention.	58	25	24	31	29	50	47

*Includes criteria for assessment of quality and the risk of bias in 106 studies of interventions to improve antibiotic prescribing in hospitals. The minimum criteria for any design are objective measurement of performance, behavior or health outcomes in a clinical, not test, situation and relevant and interpretable data presented or obtainable.

information about the cost of design and implementation of the intervention, which is essential to the overall assessment of cost-effectiveness.⁴⁶

In ambulatory care only three (7.5%) of the studies reported the impact of the intervention on total antibiotic costs and none reported the impact on other costs (e.g. number of practice visits). None of the ambulatory care studies reported the cost of designing, disseminating or implementing the intervention.

CAN ANTIBIOTIC POLICIES CONTROL COLLATERAL DAMAGE?

In hospitals 31 (29%) of the studies provided reliable data about microbial outcomes and 24 interventions were associated with significant improvement. Studies with microbial outcomes are subject to additional risks of bias.⁵⁸ Nonetheless, there are examples of studies with medium or low risk of bias that demonstrate sustained reduction in the prevalence

of antimicrobial-resistant bacteria and *C. difficile* infections associated with change in antibiotic policy (Figure 11.2). Unfortunately, some published studies use inappropriate statistical methods and report unreliable conclusions about the impact of antibiotic policies^{58,60} – for example, changes in a hospital formulary were made to limit an outbreak of vancomycin-resistant enterococci.⁶¹ In the published report, the effect of this formulary change on other resistant pathogens was analyzed with parametric statistics, which are not appropriate for microbial outcomes.⁶⁰ Segmented regression analysis shows that the change in antibiotic policy was associated with a small but not statistically significant decrease in ceftazidime-resistant *Klebsiella pneumoniae* and methicillin-resistant *Staphylococcus aureus* (MRSA), whereas there was a statistically significant increase in cefotaxime-resistant *Acinetobacter* spp. (Figure 11.3).

In ambulatory care four studies in the systematic review included microbial outcomes (one macrolide-resistant streptococci and three penicillin-resistant pneumococci).⁴⁵ Only one of these studies showed that reduction in antibiotic use

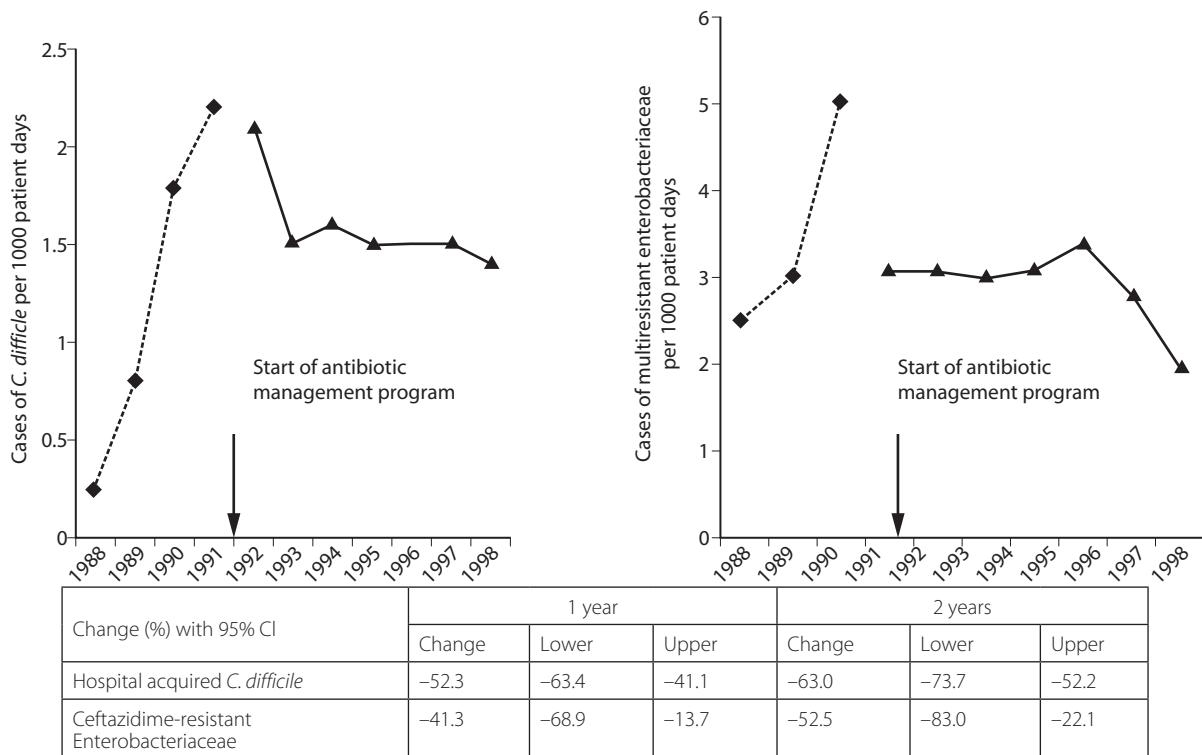

Fig. 11.2 Examples of interrupted time series analysis of the impact of antibiotic policy change on the prevalence of *Clostridium difficile* infection and infections with ceftazidime-resistant Enterobacteriaceae per 1000 patient days.⁵⁹ The segmented regressions analysis of the effect size was performed for a systematic review of interventions to change antibiotic prescribing in hospitals.⁴⁶ (Redrawn from data from Carling P, Fung T, Killion A et al. Favorable impact of a multidisciplinary antibiotic management program conducted during 7 years. **Infection Control and Hospital Epidemiology**. 2003;24:699–706.⁵⁹)

was associated with a significant reduction in resistance.⁶² There are two possible explanations:

1. Duration of follow-up: the successful study had 4 years of post-intervention data whereas the other three studies all had no more than 1 year.
2. Antibiotic resistance in Gram-positive bacteria is not associated with much fitness cost, meaning that there is little survival advantage for sensitive bacteria even in the absence of antibiotic pressure.^{63,64}

In support of this second explanation, a recent study from Israel showed that a national restriction of ciprofloxacin use was associated with an immediate marked reduction in ciprofloxacin resistance in Gram-negative bacteria isolated from urine.⁶⁵ In contrast with Gram-positive bacteria, resistance to quinolones in Gram-negative bacteria is associated with considerable fitness cost.⁶⁶

WHAT IMPACT DO ANTIBIOTIC POLICIES HAVE ON CLINICAL OUTCOME?

In hospitals, 32 (30%) of the studies included reliable data about clinical outcomes. However, in 12 of these studies the intervention was either wholly ($n = 8$) or partially ($n = 4$) designed to increase the intensity of antibiotic treatment. Clinical outcomes were measured in only 20 (23%) of 87

studies that aimed solely to reduce the intensity of antibiotic treatment. These studies do provide some reassurance that there were no unintended adverse clinical consequences.

In ambulatory care only two (5%) of 40 studies included reliable data about clinical outcome: one showed that delayed antibiotic prescription for otitis media was associated with a 1.1-day increase in the duration of symptoms (95% CI; from 0.5 to 1.5-day increase);⁶⁷ the other showed that reduction in antibiotic prescribing for the common cold had no significant impact on symptom score.⁶⁸ Additional reassurance was provided by a third study, which showed that a reduction in the use of antibiotics for acute bronchitis was not associated with any significant increase in repeat office visits or in hospitalizations for respiratory tract infection.⁶⁹

DEVELOPMENT, DISSEMINATION AND IMPLEMENTATION OF ANTIBIOTIC POLICIES

Development of policies should be informed by the wide variety of resources and information available on the world wide web.⁴² A great deal of information can be captured within a simple flow chart, providing an easily accessible reminder to prescribers on the walls of a treatment room, in a pocket-sized antibiotic policy or available on the hospital intranet and world wide web.⁷⁰

A simple but effective model for improvement⁷¹ is based on three questions:

1. What are we trying to accomplish?
2. How will we know that change is an improvement?
3. What changes can we make that will result in improvement?

In order to answer the first question the team must define a consensus goal for improvement. The second question requires measurement of process or outcome. The third question requires tests of change. These should be small, rapid and repeated.⁴⁸

It is clear that measurement and improvement are intertwined; it is impossible to make improvements without measurement.⁵⁶ There are eight key principles to the use of data to improve daily clinical practice:⁵⁶

1. Seek usefulness, not perfection in the measurement.
2. Use a balanced set of process, outcome and cost measures.
3. Keep measurement simple (think big, start small).
4. Use qualitative and quantitative data.

5. Write down the operational definition of measures.
6. Measure small, representative samples.
7. Build measurement into daily work.
8. Develop a measurement team.

Inclusion of targets for audit of implementation (Box 11.1) is a key component of the assessment of evidence-based guidelines.⁷²

HOW SHOULD COMPLIANCE WITH ANTIBIOTIC POLICIES BE MONITORED?

Hospitals fortunate enough to have sophisticated information systems may be able to use these to monitor compliance with policies.⁷³ However, this remains the exception rather than the rule. Less sophisticated information systems can still provide valuable information but there is often no substitute for collection of data by hand.⁷⁴ This is not necessarily

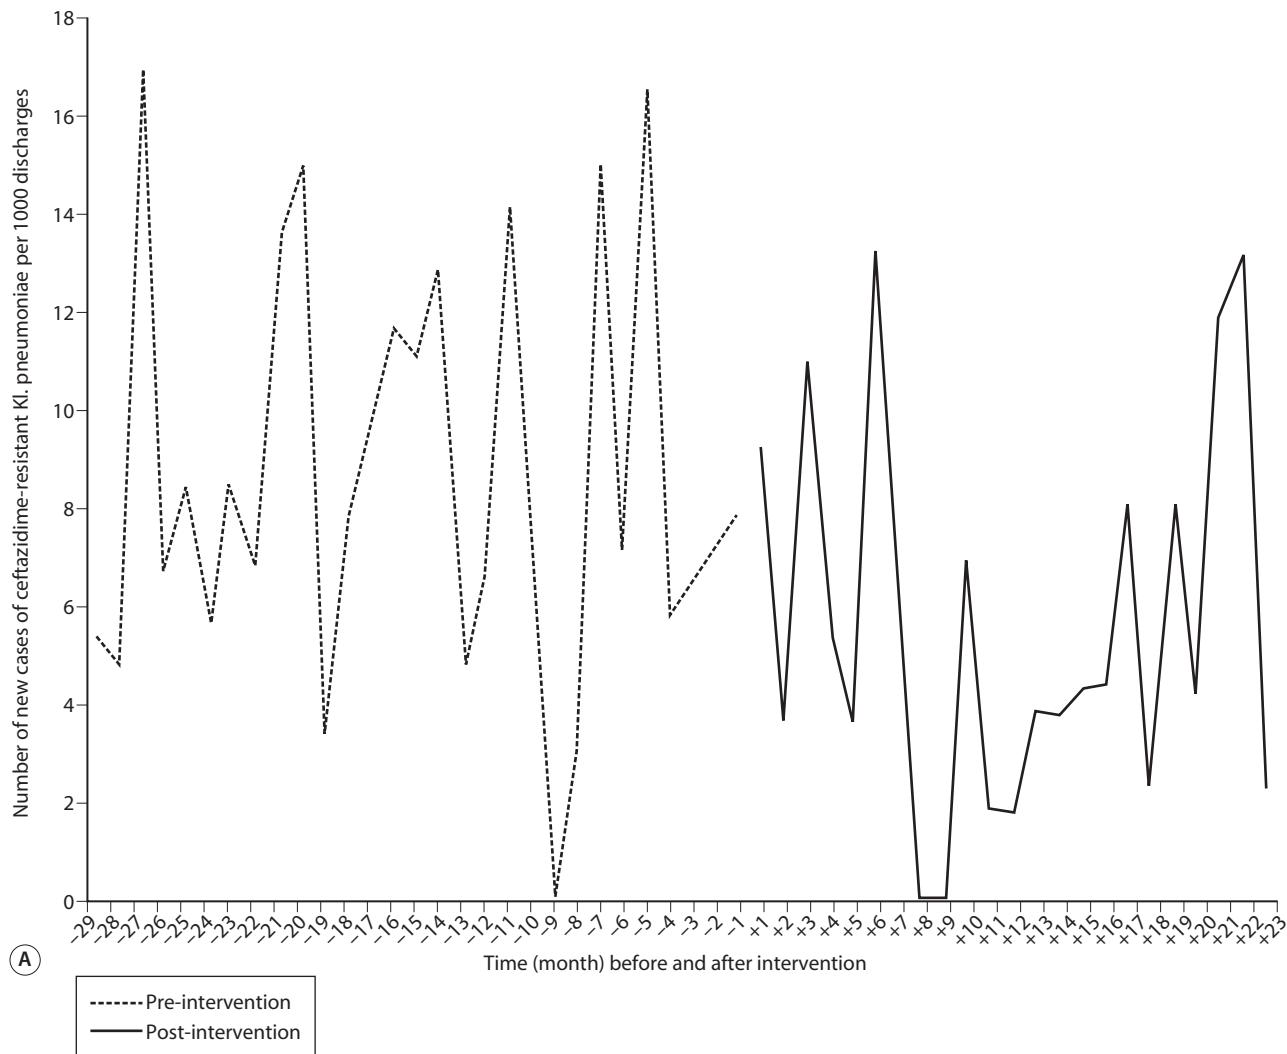

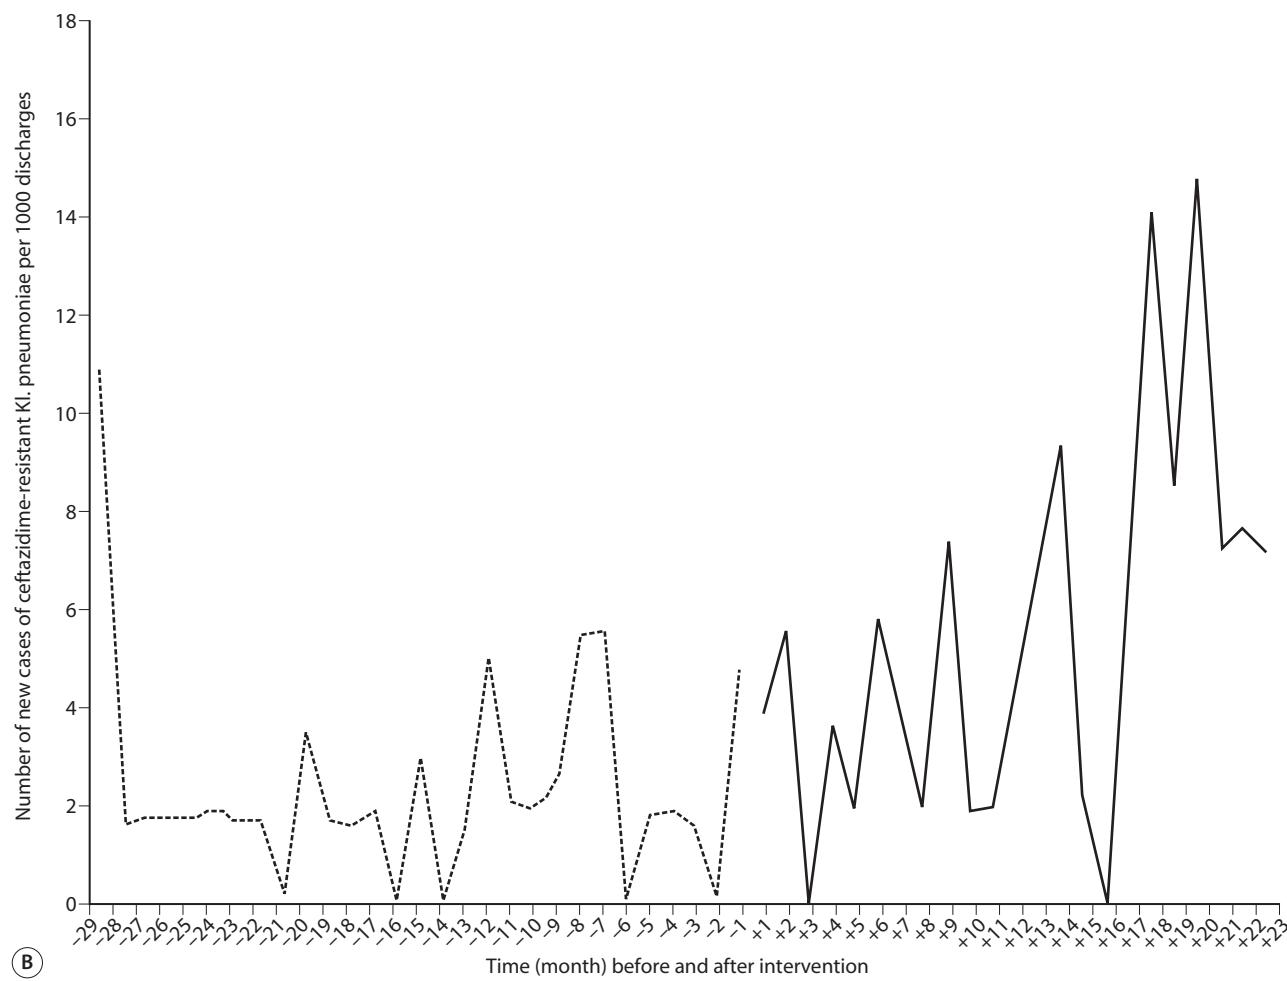

Fig. 11.3 Examples of interrupted time series analysis of the impact of antibiotic policy change on the prevalence of resistant bacteria.⁶¹ The segmented regression analysis of the effect size was performed for a systematic review of interventions to change antibiotic prescribing in hospitals.⁴⁶ (A) New cases of ceftazidime-resistant *Klebsiella pneumoniae* per 1000 discharges.

as daunting as it may seem; a 1-day prevalence survey of an entire hospital can be achieved in a few hours and may be a useful tool to detect deviations from guidelines and provide physicians with educational feedback. The European Surveillance of Antimicrobial Consumption (ESAC) project has adapted a web-based tool for antibiotic surveillance developed in Sweden⁷⁵ and successfully used this for comparative surveillance of hospitals in 20 European countries.⁷⁶ A variety of staff can be involved in auditing policies, including trainee nurses, pharmacists, doctors and medical students.⁷⁷ Participation in data collection is an educational

experience and the information can be used to agree care bundles of three or four essential processes of care that must be completed and documented for every patient to monitor antibiotic compliance and review infection management.⁷⁸ In hospitals bacteremia provides a manageable focus for attention. Review of patients with bacteremia identifies patients who are being overtreated, including those with contaminated blood cultures. However, about one-third of patients reviewed will have inadequate treatment because of delay in starting and selection of the wrong drug, dose or route of administration.^{79–81}

Box 11.1 Core indicators for audit from a national guideline on surgical prophylaxis¹⁸ From Scottish Intercollegiate Guidelines Network (SIGN). Antibiotic Prophylaxis in Surgery. Edinburgh Royal College of Physicians of Edinburgh 2008 <http://www.sign.ac.uk/pdf/sign104.pdf> (15th August 2009, date last accessed).

Process measures

- Was prophylaxis given for an operation included in local guidelines?
- If prophylaxis was given for an operation not included in local guidelines, was a clinical justification for prophylaxis recorded in the case notes?
- Was the first dose of prophylaxis given within 30 min of the start of surgery?
- Was the prescription written in the 'once-only' section of the drug prescription chart?
- Was the duration of prophylaxis greater than 24 h?

Outcome measures

- Surgical site infection (SSI) rate = number of SSIs occurring postoperatively/total number of operative procedures.
- Rate of SSIs occurring postoperatively in patients who receive inappropriate prophylaxis (as defined in guideline) compared with rate of this infection in patients who receive appropriate prophylaxis, expressed as a ratio.
- Rate of *Clostridium difficile* infections occurring postoperatively in patients who receive inappropriate prophylaxis (as defined in guideline) compared with rate of this infection in patients who receive appropriate prophylaxis, expressed as a ratio.

Minimum data set for surgical antibiotic prophylaxis

- Date
- Operation performed
- Classification of operation (clean/clean-contaminated/contaminated)
- Elective or emergency
- Patient weight (especially children)
- Any previous adverse reactions/allergies to antibiotics
- Justification for prophylaxis (e.g. evidence of high risk of SSI) if prophylaxis is given for an operation that is not one of the indications for routine prophylaxis
- Time of antibiotic administration
- Name of antibiotic
- Dosage of antibiotic
- Route of administration
- Time of surgical incision
- Duration of operation
- Second dosage indicated?
- Second dosage given?
- Postoperative antibiotic prophylaxis indicated?
- Postoperative antibiotic prophylaxis given?
- Antibiotic prophylaxis continued for >24 h
- Documentation recorded appropriately (in correct place, clarity)
- Name of anaesthetist
- Name of surgeon
- Designation of surgeon

In primary care routine data about antibiotic prescribing are more generally available and can be used to measure the impact of prescribing interventions.⁸² More sophisticated data systems that include diagnosis may be required to monitor the impact of targeted interventions – for example, to reduce prescribing for bronchitis.⁶⁹ However, as in hospitals, hand collection of data may be the only practical method available.

Community pharmacists have an important potential role in the audit of antibiotic prescribing in primary care.⁸³

Data about measures of professional practice or clinical outcomes are best displayed as run charts or statistical process control charts (Figure 11.4) as these clearly demonstrate progress over time. Small amounts of data collected regularly can be very informative. The statistical process control charts in Figure 11.4 only have one patient observation for every data point so each chart only includes data from 17 patients, yet the charts clearly show the impact of the intervention. Resources for testing change (such as Plan Do Study Act cycles), designing and using measures for improvement are publicly available on clinical effectiveness websites.⁸⁴ For infrequent events (e.g. number of new MRSA or *C. difficile* infections) the time since the last new infection is a powerful method for displaying information.⁸⁵ Posting of 'days since last infection' data allows staff to see at a glance the importance and status of critical infections. In this way, positive feedback is provided as infection-free days accrue, and analysis of cause occurs when the days go back to zero.⁸⁵

LEGAL IMPLICATIONS OF ANTIBIOTIC POLICIES

Having considered the advantages of antibiotic policies, it is important to be aware of their legal implications. It is not unusual for audits to show that only a minority of professionals' practice is fully consistent with antibiotic policies. In that case, are the majority of professionals guilty of negligence? Moreover, is the organization in which the professionals practice also guilty of negligence unless it takes action and achieves 100% adherence to policies? Although interventions can improve adherence to policies, the changes are often small.^{45,46} Even when the best methods for development, dissemination and implementation are used, a majority of professionals may still not adhere to the policy.⁸⁶ The reasons include lack of knowledge, awareness, familiarity, agreement, outcome expectancy and ability to overcome the inertia of previous practice.⁸⁷ Guidelines by their very nature consider common problems in typical patients and may fail to adequately address the needs of individual patients, particularly the elderly and the patient with a complicated course.⁸⁶ Guidelines frequently lack objective parameters, lack graded recommendations and do not favor a multidisciplinary approach.⁸⁸ As has already been noted, a major flaw of much of the literature on the implementation of antibiotic policies is the failure to include measures of clinical outcome (see Table 11.2). For all of these reasons 100% concordance between clinical practice and guidelines is neither desirable nor achievable.

Written policies and practice guidelines have a major impact on courts of law, particularly if they are endorsed by national societies or other professional bodies. As a legal standard, their testimonial relevance, or 'weight' in that respect, is just below regulations issued by the primary or secondary lawmaker. The legal implication of this position is that presentation of a policy or guideline in court may overcome expert opinion, results

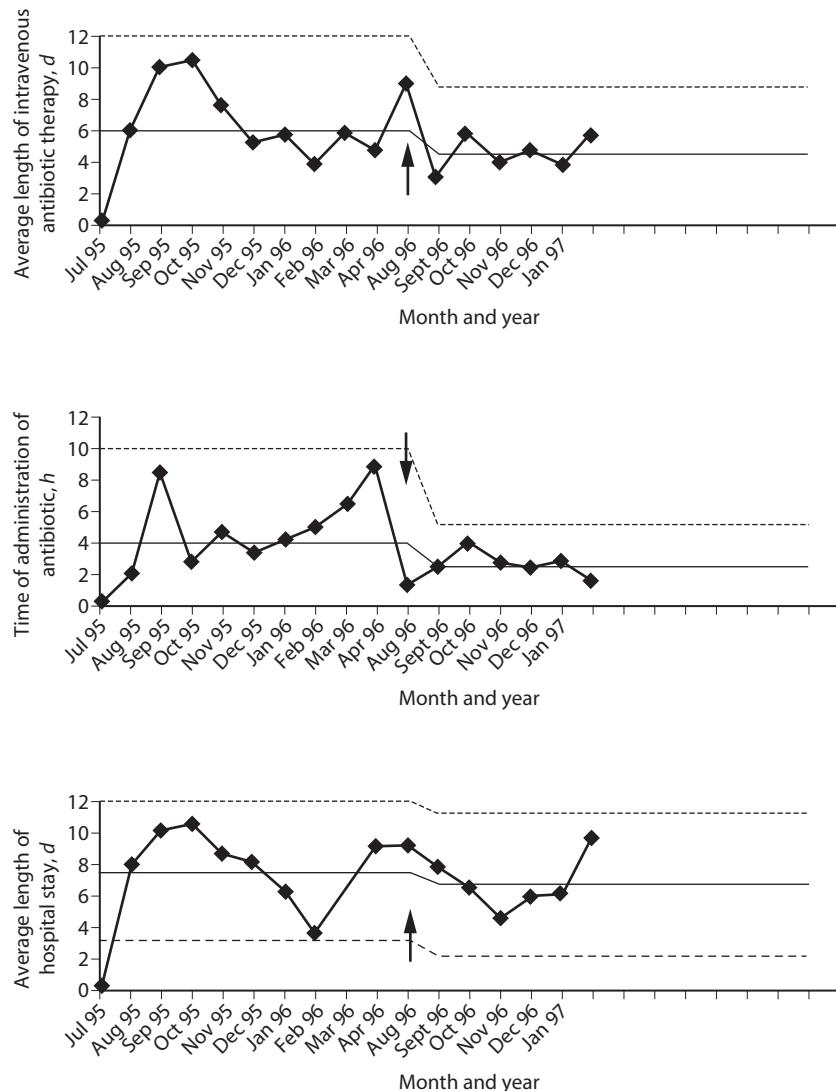

Fig. 11.4 Instrument panel of three statistical process control charts for hospitalized patients with community-acquired pneumonia. Duration of intravenous antibiotic therapy, time to administration of antibiotic therapy and average length of hospital stay were thought to be key measures that the pneumonia care team wanted to follow over time. The solid lines represent the mean values plotted over time. The dotted lines represent the upper and lower control limits or natural process limits for the measured variables (lower limits in the top and middle panels were less than zero and are not shown). The arrows indicate the points at which changes were implemented. The upper and lower natural process limits were computed by using the following formula: mean \pm 2.66 (average point-to-point variation, also called the moving range). This formula is recommended for calculation of process limits when the size of the subgroup is 1; it was chosen because each data point is a measurement from a single patient. From Nelson EC, Splaine ME, Batalden PB et al. Building measurement and data collection into medical practice. Annals of internal medicine 1998;128:460–466, by permission of the American college of Physicians.⁵⁶

of well-conducted studies and even meta-analysis (particularly if published after the guideline was written). Most courts will assign a written policy/guideline a burden of evidence far beyond the importance assigned to the policy/guideline by those who wrote it or use it. Writers of guidelines, such as the Scottish Intercollegiate Guidelines Network, often clearly state that the intention is to provide guidance rather than to impose stiff regulations. Nonetheless, courts of law may still interpret guidelines as minimum standards of care.

Conversely, a court can even declare a policy or guideline as insufficient or unacceptable; the court is sovereign to decide upon the standard according to its own legal policies – which are usually aimed at improving the health of the public.

Thus, if the court finds a certain policy, even if approved by official bodies, to be insufficient, it can declare it as a non-standard and set its own standard. The following quote is from the book *International Medical Malpractice Law*: ‘A common practice (regardless if founded on guidelines) simply may not be good enough to fulfill the standard required by the law.’⁸⁹ In 1993 the supreme court of Canada expressed the view that ‘conformity with standard practice (based on policy or guidelines) in a profession does not necessarily insulate a doctor from negligence where the standard of practice itself is negligent’.⁹⁰ In the UK, the House of Lords has stated the view that the court can, in rare cases, reach a conclusion that a professional standard is not based on a rational analysis,

and that the experts express views that are not logical or responsible.⁹¹ These judgments have important implications for antibiotic policy makers. Concerns about antibiotic resistance may be used to justify restriction of antibiotics even when there is compelling evidence to suggest that this is not in the interests of the individual patient.⁹² However, a court may not agree with this decision; indeed the court is likely to decide that a doctor's primary duty is care of the individual patient. The problem of antibiotic resistance confronts prescribers and the healthcare organizations in which they work with two conflicting ethical duties: one is their duty of fidelity to the individual patient; the other is their duty of stewardship for the resources that have been entrusted to them.⁹³ Rigid enforcement of the duty of fidelity would result in prescription of antibiotics to any patient who might conceivably have infection and selection of an empirical regimen that covers all possible pathogens. Such a policy is clearly not in the long-term interests of the public. However, would a court of law support a healthcare organization that put the long-term interests of the public before the interests of the individual patient?⁹⁴

Antibiotic restriction policy has been implied in farm husbandry in view of human infections with resistant mutants (e.g. fluoroquinolone-resistant *C. jejuni* originating in fluoroquinolone-fed chickens). A quantitative risk assessment model of microbiological risks suggests that these outcomes may be more than coincidental: prudent use of animal antibiotics may actually improve human health, while total bans on animal antibiotics, intended to be precautionary, inadvertently may harm human health. Moreover, the ban of fluoroquinolones as food additives to chicken in the USA and some other jurisdictions was not associated with a decrease in fluoroquinolone resistance among other human pathogens, lessening the impact of antibiotic restrictive policies in agriculture on human disease. A court, when coming to decide on a case in which non-human use of antibiotics was associated with human harm (except for the case of *C. jejuni*), will confront great difficulties in obtaining direct evidence for this association and may thus have uncertainty in its final decision.

Legislation should also be considered as an instrument for helping to achieve the aims of antibiotic policies. Once antimicrobial drug resistance has been recognized as a concern by public health authorities they will ask for legal as well as scientific analysis of the problem, and international organizations such as the European Union and the World Health Organization will also seek legal solutions.⁹⁵ However, cooperative initiatives may be more practical and speedy than legislation, at least in the first instance.⁹⁵ Similarly, at the national level, it has been recognized that development of local solutions may be more productive than imposing national legislation.⁹⁵ Nonetheless, Fidler provides several practical proposals for introducing legislation to help to control antimicrobial prescribing:⁹⁵

1. International legal harmonization of principles for prudent antimicrobial drug use will have to include monitoring and enforcement, as well as financial,

technical and legal assistance by industrialized countries to developing countries.

2. In the USA, Congress could regulate use of antimicrobial drugs by monitoring interstate commerce in these products. Congress probably does not have the authority to regulate antimicrobial prescription practices directly; such authority rests with the states.
3. Perhaps the most powerful US federal strategy would be to make implementation of state policies to curb the misuse of antimicrobial drugs mandatory before states receive federal funds earmarked for public health. In countries where governments subsidize the purchase of antimicrobial drugs, legislative or regulatory changes in these subsidies could lead to a decline in the use of the drugs.
4. Fulfillment of legal duties often hinges on sufficient resources. In many developing countries public health systems may be inadequate. Thus, financial and technical leadership is needed from national governments towards local authorities and from international organizations towards developing countries. A precedent can be found in the proposed Convention on the Provision of Telecommunication Resources for Disaster Mitigation and Relief Operations, which obligates the parties, where possible, to lower or remove regulatory barriers for using telecommunication resources during disasters.
5. Lessons from international environmental efforts suggest that international law must play a major role in setting international standards for implementation domestically and creating the political, technical and financial conditions necessary to integrate international and national law.

KEY QUESTIONS ABOUT ANTIBIOTIC POLICIES AND ANTIMICROBIAL STEWARDSHIP

WHAT IS THE MOST COST-EFFECTIVE METHOD FOR IMPLEMENTING POLICIES?

It is probably unrealistic to expect a definitive answer to this question because of the influence of context as well as the knowledge, attitudes and beliefs of both the professionals who are the targets for change and the patients that they serve.⁹⁶ However, even a partial answer to the question requires more basic information about the cost of development, testing and implementation of antibiotic policies and other interventions (see Table 11.2). In particular, it would be very helpful to have more information about the added value of audit and feedback for implementation of antibiotic policies (see Table 11.3). Only 10% of studies in ambulatory or hospital care used this, yet the quality improvement literature suggests that measurement and feedback are integral to the implementation of change.⁵⁶

WHEN SHOULD RESTRICTIVE STRATEGIES BE USED TO IMPLEMENT ANTIBIOTIC POLICIES?

Restrictive strategies are perceived as dictatorial or punitive and are likely to be less appealing to clinicians.⁹⁷ It is generally acknowledged that practice guidelines achieve their greatest good by expanding medical knowledge, which may not be achieved by punitive measures.⁹⁸ In hospitals the evidence suggests that restrictive interventions have greater short-term effects but that persuasive interventions may have greater long-term effects. More data would be helpful but we believe that the available evidence already suggests that a case should be made for urgency in order to justify restrictive antibiotic policies.

WHAT BALANCING MEASURES SHOULD BE USED TO EVALUATE ANTIBIOTIC POLICIES?

Now that the evidence base on beneficial effects of antibiotic policies is growing, the research and policy agenda needs to pay more attention to reassuring the public and professionals about unintended consequences of antibiotic policies. The few studies that include balancing measures clearly show that unintended consequences can happen (see Figure 11.3B).

Introduction to Section 2

The number and variety of antimicrobial agents has expanded inexorably since the appearance of the first edition of this book nearly 50 years ago and organization of the information on individual agents in a way that helps the reader to make sense of the profusion is a continuing challenge. Once again we have tried to present the information in a uniform, accessible and succinct manner. The authorship reflects the most recent revision based, in most cases, on pre-existing text written by different hands for the various editions of the book that have appeared over the years.

As always, the aim has been to be as inclusive and up to date as possible and we have sought to include all but the most obscure compounds that are available worldwide. Compounds used exclusively in veterinary medicine are mentioned by name if appropriate, but are not otherwise dealt with.

The amount of detail provided for older or less important drugs has been reduced to a short summary of their most important properties. For the rest we have tried to present the most important information in a standard and logical manner, tabulating such information as could be easily accommodated in this form. For large groups of agents, such as the penicillins, cephalosporins, macrolides, aminoglycosides and quinolones, the individual drug monographs are preceded by a general account of the group and its classification.

For the individual monographs, the following conventions have been adopted:

Drug names: The recommended International Non-proprietary Name (rINN) is used throughout, with the United States Adopted Name (USAN) and any other commonly used alternative name given at the beginning of each monograph. An exception has been made for methicillin (rINN: meticillin), since this antibiotic is no longer generally available and the original spelling is commonly used in the context of 'methicillin-resistant *Staphylococcus aureus*'.

Structures: Simple two-dimensional structures of the most important compounds are given, together with the molecular weights and those of appropriate salts.

Antimicrobial activity: For antibacterial agents, minimum inhibitory concentration (MIC) values for the most common Gram-positive and Gram-negative pathogens are tabulated with members of the same drug group appearing in the same Table. Since published MIC

values differ, sometimes quite widely, depending on the methodology used and the source of the micro-organisms tested, those given are representative ones, usually based on fully susceptible strains. Activity against other relevant pathogens is described in the text. Nomenclature of micro-organisms follows current recommendations (e.g. all clinically important salmonellae are described as *Salmonella enterica* serotypes rather than individual species).

Acquired resistance: Common mechanisms of acquired resistance and its general prevalence are described.

Pharmacokinetics: Basic pharmacokinetic parameters are tabulated: oral absorption (if relevant); maximum plasma concentration (C_{max}) for common dosage forms; plasma half-life; volume of distribution (usually in liters or, preferably, L/kg); and plasma protein binding. Values given normally refer to data from healthy adult volunteers and may be altered in disease or at the extremes of age. Unless otherwise stated, the plasma half-life is the β -phase value; when the terminal half-life differs substantially, this is described in the accompanying text. A more extensive account of absorption, distribution, metabolism and excretion characteristics is added for the more important compounds.

Interactions: Some important interactions are described, but a more extensive account is provided in Section 1 (Ch. 6).

Toxicity and side effects: The most important adverse reactions are given. For compounds for which class effects are prominent, this information is to be found in the section on general properties of the class earlier in the chapter.

Clinical use: The most common uses are listed. Information on the mode of use in different clinical settings is dealt with in appropriate chapters of Section 3.

Preparations and dosage: Common proprietary names are given, but others may be used in individual markets, especially for older compounds with many generic forms. Dosages are commonly accepted regimens for adults and children. Since recommended dosage regimens sometimes vary in different countries, the information may differ from that found in local formularies.

Further information: No in-text references are provided, but appropriate up-to-date sources of information are listed. Extensive monographs on many anti-infective drugs can be found in *Therapeutic Drugs*, 2nd edn (Dollery, C. ed.), Churchill Livingstone, Edinburgh, 1999.

CHAPTER

12 Aminoglycosides and aminocyclitols

Andrew M. Lovering and David S. Reeves

The aminoglycoside antibiotics comprise a large group of naturally occurring or semisynthetic polycationic compounds. The therapeutically important members of the group have amino sugars glycosidically linked to aminocyclitols – cyclic alcohols that are also substituted with amino functions. Most are bactericidal agents and share the same general range of antibacterial activity, pharmacokinetic behavior, a tendency to damage one or both branches of the eighth nerve, and a propensity to cause renal damage. The degree and nature of toxicity varies among compounds, and for some it is so great as to preclude systemic use.

Streptomycin was the first aminoglycoside, identified in 1944 by Waksman's group as a natural product of a soil bacterium, *Streptomyces griseus*. This was followed by the discovery of neomycin by the same group in 1949 and of kanamycin by Umezawa and his colleagues in 1957. Gentamicin, the most important aminoglycoside in use today, was first reported in 1963. Thereafter there followed an era in which research on new aminoglycosides concentrated on the chemical modification of known compounds, largely in response to developing resistance.

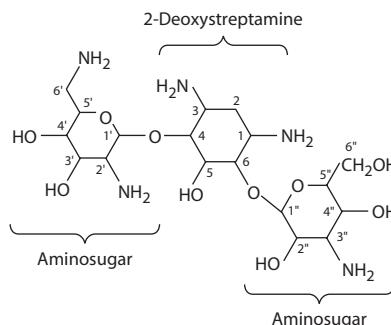

CLASSIFICATION

In most aminoglycosides in regular clinical use, the aminocyclitol moiety is 2-deoxystreptamine; these compounds can be subdivided into the neomycin group, in which there are carbohydrate substitutions at positions 4 and 5 of 2-deoxystreptamine, and the kanamycin and gentamicin groups, in which the aminocyclitol is 4,6-disubstituted. In streptomycin the aminocyclitol ring is another derivative of streptamine, streptidine. Several less important compounds exhibit other structural variations on the aminoglycoside–aminocyclitol theme.

2-Deoxystreptamine-containing aminoglycosides

Gentamicin group	Kanamycin group	Neomycin group	Other aminoglycosides/ aminocyclitols
Gentamicin	Amikacin	Neomycin	Astromicin
Isepamicin	Arbekacin	Paromomycin	Spectinomycin
Micromomicin	Dibekacin		Streptomycin
Netilmicin	Kanamycin		
Sisomicin	Tobramycin		

The nomenclature of the aminoglycoside structure is illustrated by that of kanamycin B:

The carbon atoms in the 2-deoxystreptamine ring are labeled 1 to 6; those in the amino sugar substituted at position 4 are labeled 1' to 6' and those in the 6-position amino sugar 1" to 6".

Some natural aminoglycosides consist of mixtures of closely related compounds. For example, there are four principal gentamicins, three kanamycins and two neomycins, often with interbatch variability in the ratio of these within pharmaceutical preparations. Moreover, there are close relationships between some of the differently named compounds.

For example, tobramycin is 3'-deoxykanamycin B and the substitution of an amino for a hydroxyl group in paromomycin I gives neomycin B. The chemical differences are particularly important in determining sensitivity of the compounds to inactivation by bacterial aminoglycoside-modifying enzymes.

ANTIMICROBIAL ACTIVITY

The activity of the more important aminoglycosides against common pathogens is summarized in Table 12.1. They are active to different degrees against *Staphylococcus aureus*, coagulase-negative staphylococci and *Corynebacterium* spp., but the activity against many other Gram-positive bacteria, including streptococci, is generally limited. However, they interact synergistically with antibiotics such as penicillin against streptococci, enterococci and some other organisms, and this combination is used as first-line therapy in enterococcal endocarditis (p. 591).

As a group, they are widely active against the Enterobacteriaceae and other aerobic Gram-negative bacilli including, for some compounds, *Pseudomonas aeruginosa*. Several, including streptomycin, are active against *Mycobacterium tuberculosis* and some other mycobacteria. Aminoglycosides require a threshold membrane potential to cross the bacterial cell membrane and, as this is diminished under anaerobic conditions, aminoglycosides are not active against anaerobic bacteria.

They are generally bactericidal in concentrations close to the minimum inhibitory concentration (MIC) and the rate of killing increases directly with the concentration, up to about

10 times the MIC value. Activity is increased by low Mg²⁺ and Ca²⁺ concentrations and diminished under anaerobic or hypercapnic conditions.

AMINOGLYCOSIDE TRANSPORT

Diffusion of such highly polar cationic compounds across the bacterial cell membrane is very limited and intracellular accumulation of the drugs is brought about by active transport, which occurs in three phases:

- Initial energy-independent binding of the compounds to the exterior of the cell, which is inhibited by Ca²⁺ and Mg²⁺ ions.
- Energy-dependent phase I (so called because it is abolished by molecules that inhibit energy metabolism), in which the aminoglycosides are driven across the cytoplasmic membrane by the negative electrical potential difference across the membrane.
- A faster, energy-dependent phase II, which starts after aminoglycosides have bound to ribosomes and seems to be an effect, rather than a cause, of their action on the cell.

Uptake is adversely affected by low pH and reduced oxygen tension as they affect the membrane potential. Consequently, activity of the drugs *in vitro* is reduced in acid media or anaerobic conditions and by the presence of divalent cations; the susceptibility of *Ps. aeruginosa* is particularly sensitive to the cation concentration. Because of the effects of pH on activity, it is hard to be sure that the relatively high MICs seen for organisms that require carbon dioxide truly reflect their degree of resistance.

Table 12.1 Median MICs (mg/L) of aminoglycosides for common pathogenic bacteria

Bacterium	Gentamicin	Netilmicin	Tobramycin	Amikacin	Kanamycin	Neomycin	Streptomycin	Spectinomycin
<i>Staphylococcus aureus</i>	0.25	0.25	0.25	1	1	0.5	4	64
Coagulase-negative staphylococci	0.03	0.03	0.03	0.25	0.5	0.06	2	32
<i>Streptococcus pyogenes</i>	4	4	16	32	32	16	8	32
<i>Str. pneumoniae</i>	4	8	16	64	64	128	32	8
<i>Enterococcus faecalis</i>	16	8	16	128	64	32	128	64
<i>Neisseria meningitidis</i>	16	16	16	32	32	4		8
<i>N. gonorrhoeae</i>	4	4	4	16	16	16	8	16
<i>Haemophilus influenzae</i>	0.5	0.5	1	1	1	2	2	4
<i>Escherichia coli</i>	0.5	0.5	1	2	4	1	8	8
<i>Klebsiella pneumoniae</i>	0.5	0.5	0.5	2	2	1	4	16
<i>Bacteroides fragilis</i>	R	R	R	R	R	R	R	R
<i>Mycobacterium tuberculosis</i>	R		R	1	8	0.5	0.5	
<i>M. avium</i>	4			8	4		2	

R, resistant; no useful activity at clinically achievable concentrations.

ACQUIRED RESISTANCE

Resistance in many organisms originally susceptible to the older compounds, such as streptomycin and kanamycin, is now widespread. Resistance to the more clinically important agents such as gentamicin has also increased, but there are marked differences even within countries depending on antibiotic use policies. Resistance rates for gentamicin in North America and Europe have so far generally remained low. However, many strains with plasmid-encoded extended-spectrum β -lactamases (p. 228–231) and other resistances are also aminoglycoside resistant, so outbreaks of infection with such strains may result in an increase in aminoglycoside resistance rates.

Bacterial resistance to the aminoglycosides is usually mediated through one, or more, of the three main mechanisms:

- Alteration in the ribosomal binding of the drug
- Reduced uptake
- Inactivation by specific aminoglycoside-modifying enzymes.

RIBOSOMAL RESISTANCE

Strains of bacteria with ribosomes that have a diminished affinity for streptomycin may emerge during therapy with streptomycin and the MIC is often in excess of 1000 mg/L. Such resistance results from alteration of a single ribosomal protein or rRNA, usually in the *rpsL* gene, and occurs at a natural mutational rate of 10^{-5} per generation in *Escherichia coli*. In contrast, ribosomal resistance to other clinically useful aminoglycosides is not encountered during therapy, as resistance usually requires mutations at two or three ribosomal binding sites. Ribosomal alterations confer high-level resistance to the aminoglycoside against which they were selected (and closely related ones), but not other aminoglycosides. Such resistance is not transferable to other bacteria.

REDUCED UPTAKE

Resistance resulting from a diminished ability to accumulate aminoglycosides occurs as a result of changes in energy metabolism or outer membrane structure, and may be clinically significant. Such resistance is caused by selection of chromosomal mutations at several loci during exposure to the drug and may lead to cross-resistance to other aminoglycosides, including those resistant to aminoglycoside-modifying enzymes. Reversion to wild type occurs rapidly in coliforms in the absence of selective pressure. The isolates often show altered ability to couple oxidative phosphorylation to electron transport and the level of resistance conferred is generally modest; they are frequently slow growing and are of reduced pathogenicity. However, in *Pseudomonas* isolates the changes are relatively stable and generally due to changes in

the MexXY multidrug efflux system. Such isolates are relatively common and are frequently found in isolates from cystic fibrosis patients.

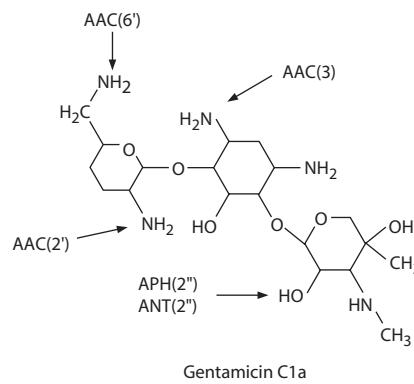

AMINOGLYCOSIDE-MODIFYING ENZYMES

Production of modifying enzymes usually confers a high degree of resistance and is the most common mechanism of resistance. The enzymes are usually plasmid encoded and the resistance conferred is frequently transferable. As with β -lactamase production, the organisms owe their survival to the inactivation of the agent to which they remain intrinsically susceptible and a large number of enzymes have been identified from different bacterial species.

There are three classes of aminoglycoside-modifying enzyme, which differ in the nature of the sites modified:

- *N*-acetyltransferases (AAC) modify amino groups
- *O*-phosphotransferases (APH) modify hydroxyl groups
- *O*-nucleotidyltransferases (ANT) modify hydroxyl groups.

The sites of attack of these enzymes on gentamicin are shown below:

The position of the group attacked and the ring that carries it are indicated by the number of the enzyme: thus AAC(3) is the acetyltransferase that modifies the amino group in the 3-position on the aminocyclitol ring while ANT(2'') modifies the hydroxyl group at the 2''-position on an aminosugar. If two enzymes act at the same position on the molecule, but differ in the aminoglycosides modified, they are distinguished by roman numerals. For example, AAC(3)-I confers resistance to gentamicin alone, whereas AAC(3)-II confers resistance to tobramycin and netilmicin as well as to gentamicin and so on (Table 12.2). Many aminoglycoside-modifying enzymes that are apparently identical in terms of resistance profile have different amino acid sequences. Lower case letters after the roman numeral are used to designate the different subgroups: thus, AAC(6')-Ia and AAC(6')-Ib are two unique proteins conferring identical resistance profiles. Finally, lower case italicized letters are used to indicate the gene responsible, so that the gene coding for the AAC(6')-Ia enzyme is *aac(6')Ia*.

Table 12.2 Range of activity of enzymes that modify 2-deoxystreptamine-containing aminoglycosides

Enzyme	Kanamycin A	Neomycin	Amikacin	Tobramycin	Gentamicin	Netilmicin	Sisomicin
APH(3')-I, II, IV, VII	+	+	-	0	0	0	0
APH(3')-III & VI	+	+	+	0	0	0	0
APH(3')-V	-	+	-	0	0	0	0
APH(2'')	+	0	-	+	+	-	0
ANT(4')	+	+	+	+	0	0	0
ANT(2'')	+	0	-	+	+	-	0
AAC(3)-I & VI	-	-	-	-	+	-	-
AAC(3)-II	±	-	-	+	+	+	-
AAC(3)-III	+	+	-	+	+	-	-
AAC(3)-IV	±	+	-	+	+	+	+
AAC(2')	0	+	0	+	+	+	0
AAC(6')-I	+	+	+	+	Variable ^a	+	0
AAC(6')-II	+	-	-	+	+	+	0

^aGentamicin C_{1a}, C₂ and sisomicin +, gentamicin C₁ ±/-.

+, Modified; ±, poorly modified; -, not modified; 0, substituent necessary for modification absent.

Resistance to aminoglycosides results from the interplay between the rate of drug inactivation by the modifying enzyme and the rate of drug transport. Thus the resistance phenotype of a particular isolate depends on the enzyme kinetics, best defined by the ratio of V_{max} to K_m for a given substrate, and the rate of drug uptake. Consequently, enzymes that poorly inactivate some aminoglycosides, and fail to confer resistance to them, may confer clinically relevant resistance when associated with a change in cell permeability.

The discovery that AAC(6')-Ib-cr can acetylate fluoroquinolones with a piperazinyl moiety (e.g. ciprofloxacin; see Ch. 26) and confer resistance to them has led to the identification of further bifunctional enzymes and is helping to shed light upon the ecological origins of this large family of enzymes, over 50 different types of which are currently known.

DISTRIBUTION OF MODIFYING ENZYMES

Most aminoglycoside-modifying enzymes are encoded by transposable elements in resistant bacteria; however, some are chromosomally determined with the presence of the gene, if not its expression in terms of resistance profile, characteristic of the species. The most notable examples are:

- *aac(2')-Ia*; characteristic of *Providencia stuartii*
- *aac(6')-Ic*; characteristic of *Serratia marcescens*
- *aac(6')-Ii*; present in all *Enterococcus faecium* strains.

The expression of these genes appears to be tightly regulated. Thus, although the chromosomal *aac(6')-Ic* gene is found in

all *Ser. marcescens* strains, most are aminoglycoside susceptible with little or no *aac(6')-Ic* mRNA detectable.

Certain enzymes may be found in a restricted host range, but most are widely distributed throughout clinically important bacterial genera. The prevalence of the individual enzymes within an individual geographic area usually reflects the selective pressure exerted by the aminoglycoside usage there. In many instances there is linkage with other resistance determinants; for example, most gentamicin resistance seen in *Staph. aureus* relates to methicillin-resistant *Staph. aureus* (MRSA) and is a reflection of the transmissibility of these strains rather than the use of gentamicin.

Since the prevalence of the enzymes differs widely with geographic area and over relatively short time periods, reflecting antibiotic prescribing habits and the opportunities for resistant organisms to spread, it is imperative that the local prevalence of resistance to individual agents be established when choosing between aminoglycosides. This is particularly important for the treatment of severe sepsis of undetermined origin. Identification of aminoglycoside-modifying enzymes can often be deduced with varying degrees of confidence from the resistance patterns of the organisms. However, molecular diagnostic products that can be used to identify the most prevalent enzymes are becoming available and it is likely that more accurate identification will soon be within the capacity of many laboratories. Moreover, most of the gene sequences have been published, and departments with appropriate expertise can develop polymerase chain reaction (PCR)-based diagnostic tests for locally troublesome enzymes.

Genome sequences have identified several putative aminoglycoside resistance genes, even in organisms known to be

sensitive to these drugs, suggesting a complex evolutionary history for these enzymes. Most of the genes that have been characterized *in vitro* do not code for bona fide resistance enzymes, but a substantial reservoir of potential aminoglycoside resistance genes may exist within bacterial genomes.

PHARMACOKINETICS

Aminoglycosides are highly polar molecules that carry a net positive charge. Less than 1% of an oral dose is absorbed from the gut, but this may be clinically significant in the presence of renal failure or where gut inflammation leads to increased uptake. Absorption is rapid from intramuscular sites and serous cavities. Plasma protein binding is low (<10%), and aminoglycosides are distributed into the extracellular water and some serous fluids (ascites, pleural fluid), with volumes of distribution of about 0.25 L/kg. Intracellular penetration is low, as is penetration into cerebrospinal fluid (CSF) and aqueous humor, although concentration in these fluids may be higher when inflammation is present. There is extensive binding to tissues, principally renal, which accounts for initial incomplete excretion of aminoglycosides and prolonged excretion after dosing is terminated. The plasma half-lives are typically about 2 h, but this varies between individuals and particularly when renal function is impaired. Excretion is almost entirely as unchanged drug by glomerular filtration, which gives high concentration of active antibiotic in the urine with normal dosages, and no clinically relevant metabolites are known. When renal function is impaired, aminoglycoside excretion is reduced and accumulation can occur.

Because of their low protein binding, relatively small volumes of distribution and small molecular size, aminoglycosides are readily removed by hemodialysis, during which their half-life is reduced to about 4 h from the 50 h typically seen in end-stage renal failure. Some 50% of the drug is removed during a 3–4 h hemodialysis session. Removal by peritoneal dialysis is much less efficient, the half-life being around 36 h.

Aminoglycosides are inactivated by many β -lactam antibiotics with which they combine chemically. This is clinically relevant if the antibiotics are mixed for infusion or, possibly, in renal failure, where the long half-life of both antibiotics may allow time for this interaction.

BLOOD CONCENTRATIONS AND DOSAGE ADJUSTMENTS

Aminoglycosides cause exposure-dependent ototoxicity and nephrotoxicity, with the risk of toxicity increasing with the exposure and, in particular, with sustained rather than transiently high concentrations. Consequently, therapeutic drug monitoring to ensure exposure does not exceed target levels should be used in all patients receiving more than 48 h of systemic therapy. Monitoring is often driven by concerns of toxicity rather than by the need to ensure that adequate

exposure is attained. This is slightly curious, as it has been an improved understanding of the pharmacodynamics of aminoglycosides and the factors driving outcome that has led to the widespread adoption of once daily administration. However, at present almost all approaches to therapeutic drug monitoring of gentamicin are based on detection of elevated concentrations in the pre-dose sample and none adequately detects subtherapeutic concentrations in such a sample.

In both in-vitro and animal models, the measure that most strongly correlates with outcome is the ratio of the maximum serum concentration (C_{\max}) to the MIC, with enhanced killing seen up to $C_{\max}:\text{MIC}$ ratios of 8–10. There is evidence to suggest that the ratio of the area under the time-concentration curve (AUC) to MIC also affects outcome and is important (see Ch. 4). For the assessment of therapeutic concentrations, a post-dose sample is needed, with a satisfactory peak concentration defined as a concentration of 10 \times the MIC. Although it might be expected that a therapeutic concentration should be achieved in most patients, and post dose monitoring is not needed in practice it is often not attained, particularly in critically ill patients with severe sepsis. In such patients, volumes of distribution are increased, due to capillary leakage and fluid loading, and the peak concentration is lowered. Monitoring of post-dose concentrations in this patient group may help to identify subtherapeutic concentrations.

Since aminoglycosides penetrate poorly into adipose tissue, dosage based on total body weight can give excessive plasma concentrations in obese patients. Appropriate dosage adjustment should be made in patients who are 30% or more over ideal body weight. Likewise, in patients with an abnormally low percentage of fat, increased volumes of distribution, and lower peak concentrations, may be seen. These effects occur in children and to a lesser extent in patients with cystic fibrosis, where volumes of distribution may be increased by 50% or more due to body morphology. As a result, peak gentamicin concentrations may be depressed in patients with a high lean body weight and the assay of post-dose samples is helpful in identifying significant underdosing.

Although high clearance leading to low AUC exposure is a known issue in patients with burns, and cystic fibrosis, where abnormally high renal clearances and volume of distribution changes often require increased doses, it is rarely considered in other patient populations. Consequently, in patients with high renal clearances, such as the young and previously fit, lower than expected drug exposure may occur. Unfortunately, the use of a peak sample will fail to identify such patients, as a concentration of 10 \times the MIC will usually be attained, and the only reliable way to identify them is by the use of two post-dose samples, one taken at 1 h post and the other taken 6–14 h post dose.

Alteration in the pharmacokinetics of these drugs requiring dose adjustment may also be anticipated in patients with physiologically (e.g. newborns and the elderly) or pathologically (e.g. patients with oliguria or systemic hypotension) impaired renal function. In children a number of distinct physiological processes occur. At birth, aminoglycoside volumes of distribution approximate to the volume of the extracellular

water at 0.5–0.8 L/kg, and decrease over the first 3 months of life to a value of about 0.4 L/kg during childhood and to a value the same as adults by late childhood (12 years). Similarly, renal function at birth is low at 40 mL/min/1.73 m² but increases rapidly over the first 2 weeks of life and then more slowly to reach, or exceed, adult values of 100 mL/min/1.73 m² by the age of 3 months. Although renal function is much lower in preterm infants, there is considerable interpatient variability, and measures based solely on gestational age often poorly predict actual renal function.

Since patients receiving a course of an aminoglycoside must be subject to blood monitoring, access to a rapid and reliable assay service is essential. Although nomograms have been recommended for initial dosage calculation before and during therapy, because of interindividual variation, continuing therapy needs to be monitored. The size and exact time of all doses must be recorded, as must the exact time of blood samples for assays, since this information is essential to the correct interpretation of the assay results. A laboratory method should be used that gives accurate and rapid (<1 h) results.

TOXICITY AND SIDE EFFECTS

A wide range of adverse effects can occur following the administration of aminoglycosides, ototoxicity and nephrotoxicity being the most important. There are differences in the absolute and relative frequencies of these adverse effects between the various aminoglycosides.

OTOTOXICITY

Aminoglycosides are potentially ototoxic to both the cochlear and vestibular functions of the eighth cranial nerve, with such damage usually being permanent. To damage the hair cells, which are the sensory cells involved, the aminoglycoside must accumulate in the endolymph and possibly the perilymph. Accumulation is caused by persisting and high plasma concentrations, which prevent aminoglycoside from diffusing back into plasma. Consequently, ototoxicity has been associated with impaired renal function. Once damage to the hair cells has occurred it may continue to increase in severity for up to 4 weeks after the drug has been stopped. Vestibulotoxicity is manifest by vertigo, especially on rising out of bed, ataxia and oscillopsia. Cochleotoxicity presents as deafness, particularly to high tones. Ototoxicity is potentiated by previous aminoglycoside exposure, and concomitant exposure to loop diuretics and other drugs, and to noise.

Although ototoxicity can occur in all patients receiving amino-glycosides, an enhanced susceptibility to cochlear toxicity has been linked to an A–G substitution in location 1555 of the mitochondrial ribosomal ribonucleic acid (RNA); a second mutation involving a thymidine deletion in the 12S ribosomal RNA gene can predispose patients to auditory toxicity. These patients may experience ototoxicity at relatively normal drug

exposures. Genetic testing may be useful in prospectively identifying them before starting therapy, but it may be more valuable in the subsequent review of patients who develop ototoxicity.

NEPHROTOXICITY

Aminoglycosides accumulate in the renal cortex to cause nephrotoxicity. The frequency with which this occurs depends on many factors related to the clinical state of the patient, the agent itself, and the way it is administered. Unlike ototoxicity, which is largely specific to aminoglycosides, the diagnosis of nephrotoxicity is made uncertain because of the many causes of diminished renal function.

Nephrotoxicity is associated with poorer outcomes and it is important to detect the onset as soon as practicable in order to decide on the clinical value of continuing aminoglycoside therapy. Serial measurement of plasma creatinine should be made daily or not less than every 3 days, depending on the clinical state of the patient. Since the plasma concentration of creatinine can vary from day to day, measuring the clearance of the aminoglycoside itself may give an earlier indication of the onset of nephrotoxicity. Other indicators of renal damage, such as urinary phospholipid, renal enzymes or β_2 -microglobulin, are currently not in widespread routine use.

Rates of nephrotoxicity vary greatly, but may reach 60% in patients on intensive care. A longer dosage interval lowers the rate by allowing more time for the drug to clear from renal tissue between doses. The problem is more frequently associated with treatment for more than 7 days. Simultaneous exposure to other potentially nephrotoxic drugs, such as vancomycin, amphotericin B, cephalosporins, angiotensin-converting enzyme inhibitors and non-steroidal anti-inflammatory agents, increases the likelihood of nephrotoxicity. Iodinated contrast media have also been implicated. Patient factors increasing the frequency of nephrotoxicity include hypotension, shock, hypovolemia and diabetes.

Renal damage is produced to very different degrees by the various aminoglycosides and is related to the accumulation of high concentrations in the renal cortex. The frequency of nephrotoxicity after systematic administration differs markedly, from around 2% to 60% depending on the patient population, dosage and criteria of renal damage. Gentamicin is generally regarded as more nephrotoxic than netilmicin because of its lower excretion rate and higher degree of net reabsorption. The abnormal persistence of aminoglycosides in the plasma between doses may be the earliest and most sensitive indication of the onset of renal impairment.

If acute tubular necrosis develops it usually does so towards the end of the first week of treatment, while the drugs are accumulated at tissue binding sites. The appearance of brush border membrane fragments in the urine or new cylindruria are strongly correlated with decline of renal function. Restoration of function usually occurs if the drug is discontinued.

Risk factors include dosage and duration of therapy, plasma concentration and renal function. Age has emerged in some

studies as the dominant or even sole independent determinant of toxicity risk. Renal damage is probably more likely and more severe with simultaneous use of other agents that act on the kidney, including some diuretics and cisplatin.

NEUROMUSCULAR BLOCKADE

Aminoglycosides can produce neuromuscular blockade, probably by functioning as membrane stabilizers in the same way as curare. The effect is relatively feeble, and is rarely seen in those with normal neuromuscular function. However, antibiotics are customarily given in much larger amounts than curare, and patients who are also receiving muscle relaxants or anesthetics, or who are suffering from myasthenia gravis, are at special risk. Analogous effects, which can be reversed by calcium, have been described on the gut and uterus.

CLINICAL USE

Aminoglycosides are the mainstay of the treatment of severe sepsis caused by enterobacteria and some other Gram-negative aerobic bacilli. For the treatment of severe sepsis of undetermined cause they are often administered in combination with agents active against Gram-positive or anaerobic bacteria as appropriate. Some are also used for a number of specialized infections, including endocarditis, respiratory infections and tuberculosis.

Gentamicin, tobramycin or amikacin are most commonly used. There is no clear choice on the grounds of toxicity because differences between the various members of the group are of no proven clinical relevance. Differences in *in vitro* activity depend largely on the local prevalence of particular resistance mechanisms.

Gentamicin is a sensible choice for the treatment of suspected or confirmed infections caused by Gram-negative bacilli unless resistance is a major problem. It is often used as first-choice therapy for patients without renal functional deficit. Tobramycin may have some advantage for proven *Ps. aeruginosa* or *Acinetobacter* infections. Amikacin is preferred if there is resistance to other aminoglycosides. These drugs can be combined with a β -lactam antibiotic and metronidazole as appropriate for microbiologically undiagnosed severe infection, unless microbiological or epidemiological evidence indicates a high probability of resistance in any individual case. However, aminoglycoside monotherapy appears to be as effective as combination therapy in areas with a low prevalence of resistance.

GENTAMICIN GROUP

GENTAMICIN

A mixture of fermentation products of *Micromonospora purpurea* supplied as the sulfate. In the commercial product gentamicins C₁, C_{1a}, C₂ and C_{2a} make up the bulk of the antimicrobial activity and are required to be present in certain proportions for therapeutic use. Minute amounts of gentamicin C_{2b} (micronomicin) are also present.

Gentamicin	R ₁	R ₂	Mol. wt.
C ₁	CH ₃	CH ₃	477.6
C ₂	CH ₃	H	463.58
C _{1a}	H	H	449.55

ANTIMICROBIAL ACTIVITY

Activity against common pathogenic bacteria is shown in Table 12.1 (p. 146). It is active against staphylococci, but streptococci are at least moderately resistant. Gram-positive bacilli, including *Actinomyces* and *Listeria* spp., are moderately susceptible, but clostridia and other obligate anaerobes are resistant. There is no clinically useful activity against mycobacteria. It is active against most enterobacteria, including *Citrobacter*, *Enterobacter*, *Proteus*, *Serratia* and *Yersinia* spp., and against some other aerobic Gram-negative bacilli including *Acinetobacter*, *Brucella*, *Francisella* and *Legionella* spp., although its in-vitro activity against intracellular parasites such as *Brucella* spp. is of doubtful usefulness. It is active against *Ps. aeruginosa* and other members of the fluorescens group, but other pseudomonads are often resistant and *Flavobacterium* spp. are always resistant.

The MIC for susceptible strains of *Ps. aeruginosa* can vary more than 300-fold with the Mg²⁺ content of the medium. Activity against *Ps. aeruginosa* is also significantly lower in serum or sputum than in ion-depleted broth, as a result both of binding (more in sputum than in serum) and antagonism by ions.

The action is bactericidal and increases with pH, but to different degrees against different bacterial species. Marked bactericidal synergy is commonly demonstrable with β-lactam antibiotics, notably with ampicillin or benzylpenicillin against *E. faecalis*, and with vancomycin against streptococci and staphylococci. Bactericidal synergy with β-lactam antibiotics can also be demonstrated in vitro against many Gram-negative rods, including *Ps. aeruginosa*. Antagonism with chloramphenicol occurs in vitro, but this is of doubtful clinical significance.

Like other aminoglycosides, gentamicin is degraded in the presence of high concentrations of some β-lactam agents.

ACQUIRED RESISTANCE

Resistant strains of staphylococci, enterobacteria, *Pseudomonas* and *Acinetobacter* spp. have been reported from many centers, often from burns and intensive care units where the agent has

been used extensively. Overall prevalence rates of resistance in various countries range from 3% to around 50% for Gram-negative organisms. Countries in which control of the prescription of antibiotics is lax often have very high rates.

Acquired resistance in Gram-negative organisms is usually caused by aminoglycoside-modifying enzymes. The prevalence of the different enzymes varies geographically. ANT(2") is most common in the USA, but in Europe various forms of AAC(3), particularly AAC(3)-II, are common. ANT(2") is also common in the Far East, usually accompanied by AAC(6'). Strains that owe their resistance to a non-specific decrease in uptake of aminoglycosides have been involved in outbreaks of hospital-acquired infection, and are cross-resistant to all aminoglycosides.

Resistance in staphylococci and high-level resistance in enterococci is usually caused by the bifunctional APH(2")-AAC(6') enzyme. Other aminoglycoside-modifying enzymes do not contribute greatly to gentamicin resistance. Gentamicin-resistant staphylococci began to emerge in the mid-1970s. Rates of resistance in the UK are around 2.5% in methicillin-sensitive *Staph. aureus*, 9% in MRSA and 23–73% in coagulase-negative staphylococci depending on methicillin susceptibility.

High-level resistance to gentamicin (MIC >2000 mg/L) in *E. faecalis* is widespread, accounting for around one-third of blood culture isolates in some places. Penicillin does not exert synergistic bactericidal activity against such strains, although the combination of penicillin with streptomycin may remain active. High-level gentamicin resistance in *E. faecium* is much less common, but has been reported in the UK, the USA and Asia.

PHARMACOKINETICS

C_{\max} 1 mg/kg intramuscular	4–7.6 mg/L after 0.5–1 h
80 mg intramuscular	4–12 mg/L after 0.5–2 h
5 mg/kg infusion	>10 mg/L after 1 h
Plasma half-life (mean)	2 h
Volume of distribution	0.25 L/kg
Plasma protein binding	<10%

Absorption

Gentamicin is almost unabsorbed from the alimentary tract, but well absorbed after intramuscular injection.

Wide variations are observed in the peak plasma concentrations and half-lives of the drug after similar doses, but individual patients tend to behave consistently. Some patients with normal renal function develop unexpectedly high, or unexpectedly low, peak values on conventional doses. Severe sepsis appears to be a significant factor in reducing the peak concentration, and anemia is a significant factor in raising it. The mechanisms involved in these effects seem to be principally related to volume of distribution changes.

Intravenous infusion over 20–30 min achieves concentrations similar to those after intramuscular injection. The peak

plasma concentration increases proportionally with dose and there is dose linearity in the AUC. Despite the very high bronchial concentrations achieved, nebulised administration does not give rise to detectable plasma concentrations.

There is a marked effect of age: in children up to 5 years the peak plasma concentration is about half, and for children between 5 and 10 years about two-thirds, of the concentration produced by the same dose per kg in adults. This difference can be eliminated to a large extent by calculating dosage not on the basis of weight but on surface area, which is more closely related to the volume of the extracellular fluid in which gentamicin is distributed.

Some febrile neutropenic patients do not differ from normal subjects in their pharmacokinetics, but in others, as in patients with cystic fibrosis, gentamicin clearance is enhanced and dosage adjustment is necessary.

Absorption of around half the dose is achieved by addition to the dialysate in patients on continuous ambulatory peritoneal dialysis (CAPD).

Distribution

Gentamicin does not enter cells so intracellular organisms are protected from its action. Fat contains less extracellular fluid than other tissues and pharmacokinetic comparisons indicate that the volume of distribution in obese patients approximates to the lean body mass plus 40% of the adipose mass.

Sputum

Access to the lower respiratory tract is limited. Rapid intravenous infusion produces high but short-lived intrabronchial concentrations, while intramuscular injection produces lower but more sustained concentrations.

CSF

It does not reach the CSF in useful concentrations after systemic administration. In patients receiving 3.5 mg/kg per day plus 4 mg intrathecally, CSF concentrations of 20–25 mg/L have been found. Formulations specifically designed for intrathecal use should be used, owing to issues with the excipients present.

Serous fluids and exudates

Concentrations in pleural, pericardial and synovial fluids are less than half the simultaneous plasma concentrations but may rise in the presence of inflammation. In cirrhotic patients with bacterial peritonitis treated with 3–5 mg/kg per day, concentrations of 4.2 mg/L were found in the peritoneal fluid with a fluid to serum ratio of 0.68. The maximum concentration in inflammatory exudate is less than that in the plasma, partly because it is reversibly bound in purulent exudates, but it persists much longer.

Other tissues

Concentrations in skin and muscle, as judged from assay of decubitus ulcers excised 150 min after patients had received

80 mg intramuscularly, were 5.8 and 6.5 mg/kg, respectively, the serum concentrations at that time being 5.1 and 5.4 mg/L.

Peak concentrations in bone exceed 5 mg/L and closely mirror the pharmacokinetic profile in blood. Penetration varies from 28% to 47% depending on the method used.

Concentrations in fetal blood are about one-third of that in the maternal blood.

Excretion

The initial plasma half-life is about 2 h, but a significant proportion is eliminated much more slowly, the terminal half-life being of the order of 12 days. There is much individual variation.

Gentamicin accumulates in the renal cortical cells, and over the first day or two of treatment only about 40% of the dose is recovered. The renal clearance is around 60 mL/min. Subsequently it is excreted virtually unchanged in the urine, principally by glomerular filtration. In severely oliguric patients some extrarenal elimination by unidentified routes evidently occurs. Urinary concentrations of 16–125 mg/L are found in patients with normal renal function receiving 1.5 mg/kg per day. In the presence of severe renal impairment, urinary concentrations as high as 1000 mg/L may be found. The clearance of the drug is linearly related to that of creatinine, and this relationship is used as the basis of the modified dosage schedules that are required in patients with impaired renal function in order to avoid accumulation of the drug. Concentrations in bile are less than half the simultaneous plasma concentration.

Hemodialysis can remove the drug at about 60% of the rate at which creatinine is cleared, but the efficiency of different dialyzers varies markedly. Peritoneal dialysis removes about 20% of the administered dose over 36 h – a rate that does not add materially to normal elimination (see Ch. 5).

TOXICITY AND SIDE EFFECTS

Ototoxicity

Vestibular function is usually affected, but labyrinthine damage has been reported in about 2% of patients, usually in those with peak plasma concentrations in excess of 8 mg/L. Symptoms range from acute Ménière's disease to tinnitus and are usually permanent. Deafness is unusual but may occur in patients treated with other potentially ototoxic agents. In an extensive study, the overall incidence of ototoxicity was 2%. Vestibular damage accounted for two-thirds of this and impaired renal function was the main determinant.

Nephrotoxicity

Some degree of renal toxicity has been observed in 5–10% of patients. Among 97 patients receiving 102 courses of the drug

in dosages adjusted in relation to renal function, nephrotoxicity was described as definite in 9.8% and possible in 7.8%. In patients treated for 39–48 days, serum creatinine increased initially, but renal function recovered after 3–4 weeks despite continuing treatment. However, many patients are treated for severe sepsis associated with shock or disseminated intravascular coagulopathy, or from other disorders that are themselves associated with renal failure. In critically ill patients with severe sepsis, treatment has been complicated by nephrotoxicity in 23–37%.

Autoradiographic localization indicates that gentamicin is very selectively localized in the proximal convoluted tubules, and a specific effect on potassium excretion may both indicate the site of toxicity and provide an early indication of renal damage. Accumulation of the drug and excretion of proximal tubular enzymes may precede any rise in the serum creatinine.

Alanine aminopeptidase excretion is an unreliable predictor of renal damage. β_2 -Microglobulin excretion may indicate decreased tubular function both before and during treatment. Excretion of the protein has also been shown to parallel increases in elimination half-life in patients on well-controlled therapy in whom reduction of creatinine clearance occurred, although the serum creatinine concentration remained within normal limits.

Other effects

Neuromuscular blockade is possible but unlikely in view of the small amounts of the drug administered. Intrathecal injection may result in radiculitis, fever and persistent pleocytosis. Significant hypomagnesemia may occur, particularly in patients also receiving cytotoxic agents.

CLINICAL USE

In severe sepsis of unknown origin, gentamicin has been traditionally combined with other agents. However, monotherapy has been shown to be as effective as combination therapy. In systemic *Ps. aeruginosa* infections it is advisable to combine gentamicin with an antipseudomonal penicillin or cephalosporin, owing to likelihood of gentamicin resistance.

- Suspected or documented Gram-negative septicemia, particularly when shock or hypotension is present
- Enterococcal endocarditis (with a penicillin)
- Respiratory tract infection caused by Gram-negative bacilli
- Urinary tract infection
- Bone and soft-tissue infections, including peritonitis, burns complicated by sepsis and infected surgical and traumatic wounds
- Serious staphylococcal infection when other conventional antimicrobial therapy is inappropriate

Gentamicin drops are used for conjunctival infections and for infections of the external ear. The drug is also used in orthopedic surgery in bone cements. In these applications systemic concentrations achieved are negligible and toxicities are restricted to local effects.

In the elderly and those with renal impairment the dosage must be suitably modified.

Preparations and dosage

Proprietary names: Genticin, Cidomycin.

Preparations: Injection, various topical.

Dosage: Adult: i.m., i.v. infusion 3–5 mg/kg per day in three divided doses or 5–7 mg/kg infusion in a single dose once daily. 1 mg/kg every 8 h when used with a β -lactam antibiotic in the treatment of endocarditis.

Neonate: i.v. infusion, <32 weeks postmenstrual age, 4–5 mg/kg as a single dose every 36 h; \geq 32 weeks postmenstrual age, 4–5 mg/kg as a single dose every 24 h; or <29 weeks postmenstrual age, 2.5 mg/kg every 24 h; 29–35 weeks postmenstrual age, 2.5 mg/kg every 18 h; $>$ 35 weeks postmenstrual age, 2.5 mg/kg every 12 h.

Child: 1 month–18 years, 7 mg/kg as a single daily dose and adjust dose on the basis of serum concentrations; or 1 month–12 years, 2.5 mg/kg every 8 h; 12–18 years 2 mg/kg every 8 h.

Widely available.

NETILMICIN

Molecular weight (free base): 475.58.

The semisynthetic 1-N-ethyl derivative of sisomicin supplied as the sulfate salt.

ANTIMICROBIAL ACTIVITY

The susceptibility of common pathogenic bacteria is shown in Table 12.1 (p. 146). It is active against a wide range of enterobacteria as well as many *Acinetobacter*, *Pseudomonas*, *Citrobacter*, *Proteus* and *Serratia* spp. *Staphylococci*, including methicillin-resistant and coagulase-negative strains, are usually susceptible. *Nocardiae* are inhibited by 0.04–1 mg/L. *Providencia* spp. and anaerobic bacteria are generally resistant.

It is active against some gentamicin-resistant strains, particularly those that synthesize ANT(2'') or AAC(3)-I. It exhibits typical aminoglycoside properties: bactericidal activity at or close to the MIC; greater activity at alkaline pH; depression of activity against *Pseudomonas* by divalent cations; and synergy with β-lactam antibiotics. Bactericidal synergy can be demonstrated regularly with benzylpenicillin against viridans streptococci and *E. faecalis*, but seldom against *E. faecium*, which characteristically synthesizes AAC(6'), to which netilmicin is susceptible.

The pharmacokinetics are similar to those of gentamicin. In patients receiving 200 mg (2.2–3.6 mg/kg) intramuscularly every 8 h for 10 days, a mean peak plasma concentration of around 14 mg/L was found. Peak concentrations of about 10 mg/L were found in children with pyelonephritis treated with 5 mg/kg per day, compared with peaks of about 5 mg/L in children given 2 mg/kg every 8 h. The serum half-life is linearly inversely related to creatinine clearance in patients with renal impairment. Plasma concentrations decreased by 63% during hemodialysis. In older patients with a mean creatinine clearance of 63 mL/min, the half-life was 6.2 h after a dose of 2 mg/kg.

In the newborn, intramuscular injection of 2.5 mg/kg produced peak plasma concentrations of 1–5 mg/L 1 h after the dose, with a plasma half-life of 4 h. In newborns given 6 mg/kg per day, plasma concentrations were 7.4–13.2 mg/L after 2 h. Half-lives were greater (mean 6.7 h) than in those of >36 weeks postmenstrual age (mean 4.6 h), and pre-dose concentrations were 2.1 and 1.6 mg/L, respectively, suggesting that a lower daily dose (4.5 mg/kg) may be appropriate. Children with cystic fibrosis had a higher total body clearance.

Distribution

Netilmicin is distributed in the extracellular water and in patients with cystic fibrosis the apparent volume of distribution seems not to be increased.

Very little reaches the CSF even in the presence of inflammation. Concentrations of 0.13–0.45 mg/L were found in patients without meningeal inflammation following an intravenous dose of 400 mg. In patients with meningitis, the drug was undetectable, although concentrations of 0.2–5 mg/L could be found later in the course of treatment in some cases.

Excretion

It is excreted unchanged in the urine in the glomerular filtrate, with some tubular reabsorption. Over the first 6 h, about 50% and by 24 h about 80% of the dose appears. No metabolites are known and it is likely that this represents binding to tissues. Clearance on hemodialysis is similar to that reported for gentamicin.

TOXICITY AND SIDE EFFECTS

It is considered to be less nephrotoxic than gentamicin, a difference not easily explained since the renal clearance and renal and medullary concentrations of the drugs appear to be similar. Both vestibular and cochlear toxicity appear to be low and vestibular toxicity without audiometric abnormality is rare. In some patients, plasma concentrations up to 30 mg/L over periods exceeding 1 week have not resulted in ototoxicity. Evidence of some renal toxicity in the excretion of granular casts has occurred fairly frequently in patients

ACQUIRED RESISTANCE

It is resistant to ANT(2''), AAC(3)-I and AAC(3)-III, but sensitive to AAC(6') (Table 12.2, p. 148). AAC(3)-II confers resistance, but generally to a lesser degree than to gentamicin.

Resistance rates are generally about the same as, or a little lower than, those for gentamicin.

PHARMACOKINETICS

C_{max} 1 mg/kg intramuscular	4–6 mg/L after 0.5–1 h
2 mg/kg intravenous 30-min infusion	c. 12 mg/L end infusion
5 mg/kg	>10 mg/L after 1 h
Plasma half-life	2–2.5 h
Volume of distribution	0.25 L/kg
Plasma protein binding	<10%

receiving 7.5 mg/kg per day, and is more likely to occur in the elderly and in those receiving higher doses or longer courses. In patients treated for an average of 35 days with 2.4–6.9 mg/kg per day, there was no effect on initially normal renal function, even in the elderly. Long-term treatment led to an increase in elimination half-life from 1.5 to 1.9 h. Nephrotoxicity has been observed in some diabetic patients. Overall estimates of the frequency of nephrotoxicity have ranged from 1% to 18%. Increases in serum transaminase and alkaline phosphatase concentrations have been seen in some patients without other evidence of hepatic impairment.

Once-daily dosing is thought to be safer than twice or three times daily dosing.

CLINICAL USE

Severe infections (including septicemia, lower respiratory tract infections, urinary tract infections, peritonitis, endometritis) caused by susceptible strains of Gram-negative bacilli and staphylococci

Preparations and dosage

Proprietary names: Netromycin.

Preparation: Injection.

Dosage: Adults: i.m., i.v., i.v. infusion 4–6 mg/kg per day in a single dose or divided doses every 8–12 h. In severe infections up to 7.5 mg/kg per day in divided doses every 8 h, reduced as soon as is clinically indicated, usually within 48 h.

Children: 6–7.5 mg/kg per day, divided into three equal doses and administered every 8 h. This should be reduced to 6 mg/kg per day as soon as clinically indicated.

Infants and neonates (>1 week of age): 7.5–9 mg/kg per day, divided into three equal doses and administered every 8 h. Premature and full-term neonates (<1 week of age): 6 or 4.5 mg/kg per day, as a single daily dose or divided into two equal doses every 12 h.

No longer widely available.

OTHER GENTAMICIN GROUP AMINOGLYCOSIDES

ISEPAMICIN

Hydroxyamino propionyl gentamicin B. A semisynthetic derivative of gentamicin B, modified to render it more resistant to microbial inactivation.

In-vitro activity is comparable to or slightly greater than amikacin against *Staph. aureus* and most enterobacteria; it is much more active against *Ser. marcescens*, *Enterobacter* spp. and *Klebsiella pneumoniae*. It is also active in vitro against the *Mycobacterium avium* complex and *Nocardia asteroides*. It is less susceptible than amikacin or gentamicin to inactivation by β-lactam antibiotics. It retains activity against some strains resistant to most other aminoglycosides.

Pharmacokinetics in neonatal, pediatric, adult, elderly and renally impaired patients are similar to those of other aminoglycosides. In adult volunteers the plasma half-life was 2.1 h. Clearance is reduced in neonates and the elderly. A 7.5 mg/kg once-daily dosage is recommended for children less than 16 days old. No dosage adjustment is required for the elderly unless renal function is impaired. Clearance is proportional to creatinine clearance in patients with chronic renal impairment, and it is eliminated by hemodialysis.

It has been used in respiratory tract infections, urinary tract infections and intra-abdominal infections, in adults and children. It appears to be as effective and well tolerated as amikacin. It is available in Japan.

MICRONOMICIN (SAGAMICIN; GENTAMICIN C_{2b})

Antibacterial and pharmacokinetic properties are similar to those of its precursor gentamicin C_{1a} but it is more resistant to AAC(6'). Dosage is similar to that for gentamicin, and should be controlled by blood level determinations. It is available in Japan.

SISOMICIN (SISSOMICIN; RICKAMICIN)

A fermentation product of *Micromonospora inyoensis*. A dehydro derivative of gentamicin C_{1a}, supplied as the sulfate salt.

It is virtually identical to gentamicin in activity and pharmacokinetic behavior. An intramuscular dose of 1–1.5 mg/kg achieves a peak plasma concentration of 1.5–9.0 mg/L after 0.5–1 h. It is widely distributed in body water, but concentrations in CSF are low, even in the presence of inflammation. The plasma half-life is 2.5 h and protein binding is <10%.

It is eliminated almost completely over 24 h in the glomerular filtrate. Excretion decreases proportionately with renal

impairment and because of the virtual identity of the behavior of the two compounds, a gentamicin nomogram can be used to adjust dosage. About 40% of the dose is eliminated during a 6-h dialysis period, during which the elimination half-life falls to about 8 h.

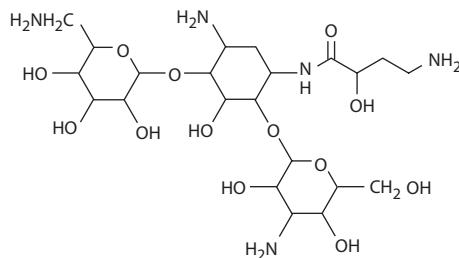

Mild and reversible impairment of renal function occurs in about 5% of patients. Nephrotoxicity is more likely to be seen in those with pre-existing renal disease or treated concurrently with other potentially nephrotoxic drugs. Ototoxicity mainly affecting vestibular function has been found in about 1% of patients. Neuromuscular blockade and other effects common to aminoglycosides including rashes, paresthesiae, eosinophilia and abnormal liver function tests have been described.

Its uses are identical to those of gentamicin, which it closely resembles. It is of limited availability.

KANAMYCIN GROUP

AMIKACIN

Molecular weight: 585.61 (free base); 683.68 (sulfate).

A semisynthetic derivative of kanamycin A, in which the 1-amino group of the deoxystreptamine moiety is replaced by a hydroxyaminobutyric acid group. Supplied as the sulfate.

ANTIMICROBIAL ACTIVITY

The activity against common pathogenic bacteria is shown in Table 12.1 (p. 146). Among other organisms, *Acinetobacter*, *Alkaligenes*, *Campylobacter*, *Citrobacter*, *Hafnia*, *Legionella*, *Pasteurella*, *Providencia*, *Serratia* and *Yersinia* spp. are usually susceptible in vitro. *Stenotrophomonas maltophilia*, many non-aeruginosa pseudomonads and *Flavobacterium* spp. are resistant. *M. tuberculosis* (including most streptomycin-resistant strains) and some other mycobacteria (including *M. fortuitum* and the *M. avium* complex) are susceptible; most other mycobacteria, including *M. kansasi*, are resistant. *Nocardia asteroides* is susceptible.

It exhibits typical aminoglycoside characteristics, including an effect of divalent cations on its activity against *Ps. aeruginosa* analogous to that seen with gentamicin and synergy with β -lactam antibiotics.

ACQUIRED RESISTANCE

Amikacin is unaffected by many of the modifying enzymes that inactivate gentamicin and tobramycin (Table 12.2, p. 148) and is consequently active against staphylococci, enterobacteria and *Pseudomonas* that owe their resistance to the production of those enzymes. However, AAC(6'), ANT(4') and some forms of APH(3') can confer resistance; because these enzymes generally do not confer gentamicin resistance, amikacin-resistant strains can be missed in routine susceptibility tests when gentamicin is used as the representative aminoglycoside.

There have been reports of resistance arising during treatment of infections due to *Serratia* spp. and *Ps. aeruginosa*. Outbreaks of infection with multiresistant strains of enterobacteria and *Ps. aeruginosa* have occurred after extensive use, particularly in burns units. Bacteria that owe their resistance to the expression of ANT(4') have been described in *Staph. aureus*, coagulase-negative staphylococci, *Esch. coli*, *Klebsiella* spp. and *Ps. aeruginosa*. In *E. faecalis*, resistance to penicillin-aminoglycoside synergy has been associated with plasmid-mediated APH(3'). Resistance in Gram-negative organisms is usually caused by either reduced accumulation of the drug or, more commonly, by the aminoglycoside-modifying enzymes AAC(6') or AAC(3)-VI. The latter enzyme is usually found in *Acinetobacter* spp., but has also been found, encoded by a transposon, in *Prov. stuartii*. One type of AAC(6) is chromosomally encoded by *Ser. marcescens*, though not usually expressed.

The prevalence of resistance to amikacin remains low (<5%) in many countries but can change rapidly with increased usage of the drug. However, the spread of extended spectrum β -lactamases belonging to the TEM and SHV families may result in an increase in amikacin resistance that is not associated with use, since most strains that produce such enzymes also produce AAC(6').

PHARMACOKINETICS

C_{\max}	7.5 mg/kg intramuscular	c. 30 mg/L after 1 h
500 mg 30-min infusion		35–50 mg/L end infusion
15 mg/kg 30-min infusion		>50 mg/L after 1 h
Plasma half-life		2.2 h
Volume of distribution		0.25–0.3 L/kg
Plasma protein binding		3–11%

It is readily absorbed after intramuscular administration. Rapid intravenous injection of 7.5 mg/kg produced concentrations in excess of 60 mg/L shortly after injection.

Most pharmacokinetic parameters follow an almost linear correlation when the once-daily doses (15 mg/kg) are compared with the traditional 7.5 mg/kg twice daily. In patients on CAPD, there was no difference in mean peak plasma concentration or volume of distribution whether the drug was given intravenously

or intraperitoneally. However, in patients with significant burn injuries, doses should be increased to 20 mg/kg.

In infants receiving 7.5 mg/kg by intravenous injection, peak plasma concentrations were 17–20 mg/L. No accumulation occurred on 12 mg/kg per day for 5–7 days. There was little change in the plasma concentration or the half-life (1.7 and 1.9 h) on the third and seventh days of a period over which 150 mg/m² was infused over 30 min every 6 h. When the dose was raised to 200 mg/m² the concentration never fell below 8 mg/L. The plasma half-life was longer in babies of lower birth weight and was still 5–5.5 h in babies aged 1 week or older. The importance of dosage control in the neonate is emphasized by the findings that there is an inverse relationship between post-conception age and plasma elimination half-life, though in extremely premature babies the weight of the child is also a significant predictor of half-life.

Distribution

The apparent volume of distribution indicates distribution throughout the extracellular water. Following an intravenous bolus of 0.5 g, peak concentrations in blister fluid were around 12 mg/L, with a mean elimination half-life of 2.3 h. In patients with impaired renal function, penetration and peak concentration increased linearly with decrease in creatinine clearance.

In patients with purulent sputum, a loading dose of 4 mg/kg intravenously plus 8 h infusions of 7–12 mg/kg produced sputum concentrations around 2 mg/L, with a mean sputum:serum ratio of 0.15. With brief infusions over 10 min for 7 days, sputum concentrations of around 9% of the simultaneous serum values have been found.

Concentrations in the CSF of adult volunteers receiving 7.5 mg/kg intramuscularly were less than 0.5 mg/L and virtually the same in patients with meningitis. Rather higher, but variable, concentrations up to 3.8 mg/L have been found in neonatal meningitis.

Amikacin crosses the placenta, and concentrations of 0.5–6 mg/L have been found in the cord blood of women receiving 7.5 mg/kg in labor. Concentrations of 8 mg/L and 16.8 mg/L were reached in the fetal lung and kidney, respectively, after a standard dose of 7.5 mg/kg given to healthy women before therapeutic abortion.

Excretion

Only 1–2% of the administered dose is excreted in the bile, with the remainder excreted in the urine, producing urinary concentrations of 150–3000 mg/L. Renal clearance is 70–84 mL/min, and this, with the ratio of amikacin to creatinine clearance (around 0.7), indicates that it is filtered and tubular reabsorption is insignificant. Accumulation occurs in proportion to reduction in renal function, although there may be some extrarenal elimination in anephric patients. The mean plasma half-life in patients on hemodialysis was around 4 h, while that on peritoneal dialysis was 28 h.

In patients receiving 500 mg/kg preoperatively, concentrations in gallbladder wall reached 34 mg/L and in bile 7.5 mg/L

in some patients. In patients given 500 mg intravenously 12 h before surgery and 12 hourly for four doses thereafter, the mean bile:serum ratio 1 h after the dose was around 0.4.

TOXICITY AND SIDE EFFECTS

Ototoxicity

Neurosensory hearing loss (mainly high-tone deafness) and labyrinthine injury have been detected, but have seldom been severe. High-frequency hearing loss and vestibular impairment have been described in about 5% of patients and conversational loss in about 0.5%; more in patients monitored audiometrically (29%) and by caloric testing (19%).

Patients with high-tone hearing loss have generally received more drug and for longer than patients without; in patients receiving long-term treatment for tuberculosis no other factors were associated with the development of ototoxicity. On multiple daily dosing, over half the patients with peak serum concentrations exceeding 30 mg/L or trough concentrations exceeding 10 mg/L developed cochlear damage; here, the main contributory factor was previous treatment with other aminoglycosides.

Nephrotoxicity

Impairment of renal function, usually mild or transient, has been observed in 3–13% of patients, notably in the elderly or those with pre-existing renal disorders or treated concurrently or previously with other potentially nephrotoxic agents.

Other reactions

Adverse effects common to aminoglycosides occur, including hypersensitivity, gastrointestinal disturbances, headache, drug fever, peripheral nervous manifestations, eosinophilia, mild hematological abnormalities and disturbed liver function tests without other evidence of hepatic derangement.

CLINICAL USES

Severe infection (including septicemia, neonatal sepsis, osteomyelitis, septic arthritis, respiratory tract, urinary tract, intra-abdominal, peritoneal and soft tissue infections) caused by susceptible micro-organisms

Sepsis of unknown origin (combined with a β -lactam or anti-anaerobe agent as appropriate).

Mycobacterial infection

Amikacin is principally used for the treatment of infections caused by organisms resistant to other aminoglycosides because of their ability to degrade them. Peak concentrations on 15 mg/kg once daily administration should exceed 45 mg/L, and trough concentration of <5 mg/L should be maintained to achieve therapeutic effects.

Preparations and dosage

Proprietary name: Amikin.

Preparation: Injection.

Dosage: Adults i.m., i.v., i.v. infusion 15 mg/kg per day in a single dose or in two divided doses.

Neonate: 15 mg/kg per day. Alternatively, an initial loading dose of 10 mg/kg followed by 15 mg/kg per day in two divided doses.

Child: 1 month–18 years, 7.5 mg/kg every 12 h. Alternatively, 1 month–12 years, 7.5 mg/kg every 12 h or 12–18 years, 7.5 mg/kg every 12 h, increasing to every 8 h in serious sepsis. Maximum accumulated dose 15 g.

The dosage must be reduced if renal function is impaired, and in elderly patients.

Widely available.

ANTIMICROBIAL ACTIVITY

The susceptibility of common pathogenic bacteria is shown in Table 12.1 (p. 146). It is active against staphylococci, including methicillin-resistant strains. Other aerobic and anaerobic Gram-positive cocci and most Gram-positive rods are resistant, but *M. tuberculosis* is susceptible. It is widely active against most aerobic Gram-negative rods, except *Burkholderia cepacia* and *Sten. maltophilia*. *Treponema pallidum*, *Leptospira* and *Mycoplasma* spp. are all resistant.

ACQUIRED RESISTANCE

Resistance is usually plasmid borne and due to enzymatic inactivation of the drug by enzymes that also inactivate gentamicin or tobramycin (Table 12.2, p. 148). Resistance due to reduced permeability is also encountered.

PHARMACOKINETICS

C_{max}	500 mg intramuscular	c. 15–20 mg/L after 1 h
Plasma half-life		2.5 h
Volume of distribution		0.3 L/kg
Plasma protein binding		Low

KANAMYCIN

A fermentation product of *Streptomyces kanamyceticus* formulated as the sulfate. Commercial preparations contain a mixture of kanamycins A, B and C, predominantly kanamycin A; the content of kanamycin B is required to be less than 3% (BP) or less than 5% (USP).

Absorption and distribution

Very little is absorbed from the intestinal tract. The peak plasma concentration in the neonate is dose related: concentrations of 8–30 mg/L (mean 18 mg/L) have been found 1 h after a 10 mg/kg dose. The drug is confined to the extracellular fluid. The concentration in serous fluids is said to equal that in the plasma, but it does not enter the CSF in therapeutically useful concentrations even in the presence of meningeal inflammation.

Excretion

It is excreted almost entirely by the kidneys, almost exclusively in the glomerular filtrate. Up to 80% of the dose appears unchanged in the urine over the first 24 h, producing concentrations around 100–500 mg/L. It is retained in proportion to reduction in renal function. Less than 1% of the dose appears in the bile. In patients receiving 500 mg intramuscularly pre-operatively, concentrations of 2–23 mg/L have been found in bile and 8–14 mg/kg in gallbladder wall.

TOXICITY AND SIDE EFFECTS

Intramuscular injections are moderately painful, and minor side effects similar to those encountered with streptomycin have been described. Eosinophilia in the absence of other

manifestations of allergy occurs in up to 10% of patients. Other manifestations of hypersensitivity are rare.

As with other aminoglycosides, the most important toxic effects are on the eighth nerve and much less frequently on the kidney. Renal damage is seen principally in patients with pre-existing renal disease or treated concurrently or sequentially with other potentially nephrotoxic agents. The drug accumulates in the renal cortex, producing cloudy swelling, which may progress to acute necrosis of proximal tubular cells with oliguric renal failure. Less dramatic deterioration of renal function, particularly exaggeration of the potential nephrotoxicity of other drugs or of existing renal disease, is of principal importance because it increases the likelihood of ototoxicity.

Vestibular damage is uncommon but may be severe and prolonged. Hearing damage is usually bilateral, and typically affects frequencies above the conversational range. Acute toxicity is most likely in patients in whom the plasma concentration exceeds 30 mg/L, but chronic toxicity may be seen in patients treated with the drug over long periods. Auditory toxicity may be potentiated by concurrent treatment with potent diuretics like ethacrynic acid. If tinnitus – which usually heralds the onset of auditory injury – develops, the drug should be withdrawn.

Neuromuscular blockade is seen particularly in patients receiving other muscle relaxants or suffering from myasthenia gravis and may be reversed by neostigmine.

CLINICAL USE

Formerly used for severe infection with susceptible organisms, it has largely been superseded by other aminoglycosides.

Preparations and dosage

Proprietary name: Kantrex.

Preparations: Injection, ophthalmic, capsules.

Dosage: Adults, i.m. injection 250 mg every 6 h, or 500 mg every 12 h. Adults and children, i.v. infusion, 15–30 mg/kg per day in 2–4 divided doses. The dosage should be reduced in renal impairment.

Widely available. No longer available in the UK.

TOBRAMYCIN

Nebramycin factor 6; 3'-deoxy kanamycin B. Molecular weight (free base): 467.52.

A natural fermentation product of *Streptomyces tenebraeus*, supplied as the sulfate in various preparations.

ANTIMICROBIAL ACTIVITY

The susceptibility of common pathogenic organisms is shown in Table 12.1 (p. 146). In-vitro activity against *Ps. aeruginosa* is usually somewhat greater than that of gentamicin; against other organisms activity is similar or a little lower. Other *Pseudomonas* species are generally resistant, as are streptococci and most anaerobic bacteria. Other organisms usually susceptible in vitro include *Acinetobacter*, *Legionella* and *Yersinia* spp. *Alkaligenes*, *Flavobacterium* spp. and *Mycobacterium* spp. are resistant. It exhibits bactericidal activity at concentrations close to the MIC and bactericidal synergy typical of aminoglycosides in combination with penicillins or cephalosporins.

ACQUIRED RESISTANCE

It is inactivated by many aminoglycoside-modifying enzymes that inactivate gentamicin (Table 12.2, p. 148). However, AAC(3')-I does not confer tobramycin resistance and AAC(3')-II confers a lower degree of tobramycin resistance than of gentamicin resistance. Conversely, ANT(4') confers tobramycin but not gentamicin resistance, as do some types of AAC(6'). Overproduction of APH(3'), conferring a low degree of resistance to tobramycin (MIC 8 mg/L), but not gentamicin (MIC 2 mg/L), was ascribed to 'trapping' rather than phosphorylation.

Resistance rates are generally similar to those of gentamicin, although they may vary locally because of the prevalence of particular enzyme types.

PHARMACOKINETICS

C_{\max}	80 mg intramuscular	3–4 mg/L after 30 min
1 mg/kg	intravenous	6–7 mg/L after 30 min
5 mg/kg		>10 mg/L after 1 h
Plasma half-life		1.5–3 h
Volume of distribution		c. 0.25 L/kg
Plasma protein binding		<30%

The pharmacokinetic behavior after systemic administration closely resembles that of gentamicin. In patients treated for prolonged periods with 2.5 mg/kg intravenously every 12 h, average peak steady-state values were 6.5 mg/L after 30 weeks and 7.1 mg/L after 40 weeks. Continuous intravenous infusion of 6.6 mg/h and 30 mg/h produced steady-state concentrations of 1 and 3.5–4.5 mg/L, respectively. Higher concentrations (10–12 mg/L) have been obtained by bolus injection over about 3 min. Peak concentrations of around 50 mg/L have been reported in cystic fibrosis patients given 9 mg/kg once daily. Ten minutes after a 300 mg dose of tobramycin solution for inhalation, mean concentration of drug in the sputum of cystic fibrosis patients was 1.2 mg/g and ranged from 0.04 to 1.4 mg/g. The systemic availability of nebulized drug is very variable (6–27%). In general, the concentration found in the sputum of cystic fibrosis patients is high when administered by inhalation, but varies widely depending on individual airway pathology and nebulizer efficiency.

In the neonate, peak plasma concentrations of 4–6 mg/L have been found 0.5–1 h after doses of 2 mg/kg. Mean plasma elimination half-lives of 4.6–8.7 h were inversely proportional to the birth weight and creatinine clearance. The half-life was found to be initially extremely variable (3–17 h) in infants weighing 2.5 kg at birth, but considerably more stable (4–8 h) at the end of therapy 6–9 days later.

β-Lactam inactivation

In common with other aminoglycosides, tobramycin interacts with certain β-lactam agents, but is said to be stable in the presence of ceftazidime, imipenem and aztreonam. Of the penicillins tested, piperacillin caused least inactivation in vitro.

Distribution

The volume of distribution slightly exceeds the extracellular water volume; it increases in patients with ascites, and is relatively smaller in morbidly obese patients. In tracheostomized or intubated patients given a loading dose of 1 mg/kg and then intravenous infusions every 8 h of 2–3.5 mg/kg, average concentrations in the bronchial secretions were 0.7 mg/L with a mean secretion:serum ratio of 0.18. In patients with cystic fibrosis receiving 10 mg/kg of the drug per day, the bronchial secretions may contain 2 mg/L or more.

Concentrations are low in peritoneal fluid but can rise to 60% of the plasma concentration in peritonitis and in synovial fluid. Tobramycin crosses the placenta, and concentrations of 0.5 mg/L have been found in the fetal serum when the mother was receiving a dose of 2 mg/kg. Penetration into the CSF resembles that of gentamicin.

Excretion

It is eliminated in the glomerular filtrate and is unaffected by probenecid. Renal clearance is 90 mL/min. About 60% of the administered dose is recovered from the urine over the first

10 h, producing urinary concentrations after a dose of 80 mg of 90–500 mg/L over the first 3 h. The nature of the extra-renal disposal of the remaining 40% of the drug has not been established. The total body clearance is increased in patients with cystic fibrosis and the plasma half-life is shorter, which may necessitate higher dosage (15 mg/kg per day) for optimum blood concentrations. Renal clearance is increased in younger burn patients. In patients with impaired renal function, urinary concentrations of the drug are depressed and the plasma half-life prolonged in proportion to the rise in serum creatinine, reaching 6–8 h at a creatinine concentration of 350 µmol/L. Dosage in patients with impaired renal function may be based on the procedures used for gentamicin since behavior of the two drugs is virtually identical. About 70% of the drug is removed by hemodialysis over 12 h, but the efficiency of different dialyzers varies markedly.

TOXICITY AND SIDE EFFECTS

Ototoxicity

The effect is predominantly on the auditory branch of the eighth nerve; vestibular function is seldom affected. Experimental evidence suggests that comparable effects on cochlear electrophysiology and histology require doses about twice those of gentamicin. In patients, electrocochleography has shown an immediate and dramatic reduction of cochlear activity when the serum tobramycin concentration exceeded 8–10 mg/L, but there were no associated symptoms and function recovered fully as the drug was eliminated. Clinical ototoxicity is rare and most likely to be seen in patients with renal impairment, or treated concurrently or sequentially with other potentially ototoxic agents.

Nephrotoxicity

Renal impairment with proteinuria, excretion of granular casts, oliguria and rise of serum creatinine have been noted in 1–2% of patients. Some evidence of nephrotoxicity has been found in about 10% of patients, depending on the sensitivity of the tests employed. In patients treated with a 120 mg loading dose and 80 mg every 8 h, renal enzyme excretion increased and there was a small but significant reduction in chrome-EDTA clearance even when the clinical condition improved. It has been suggested that intermittent dosage with large but infrequent plasma peaks may be less toxic than, and as efficacious as, continuous dosing. Tobramycin appears to be less nephrotoxic than gentamicin in critically ill patients.

The likelihood of toxicity is thought to increase with pre-existing renal impairment and higher or more prolonged dosage, but in a comparison of patients treated with 8 mg/kg per day for *Pseudomonas* endocarditis with those treated with 3 mg/kg per day for Gram-negative sepsis there was no evidence of renal impairment in either group. Although there was audiological evidence of high-frequency loss in some

patients receiving the higher dosage, there was no sustained loss of conversational hearing. There seems to be no significant effect of age: in patients aged 20–39 years the mean elimination half-life of the drug at the end of treatment was 2.3 h while in those aged 60–79 years it was 2.4 h. Evidence of renal toxicity may be found in 20% of severely ill patients.

Other reactions

Other toxic manifestations are rare. Local reactions sometimes occur at the site of injection. Rashes and eosinophilia in the absence of other allergic manifestations are seen. Voice alterations and tinnitus were rare in cystic fibrosis patients receiving tobramycin by inhalation. Increased transaminase levels may occur in the absence of other evidence of hepatic derangement.

CLINICAL USE

Severe infections caused by susceptible micro-organisms

Ps. aeruginosa infections, including chronic pulmonary infections in cystic fibrosis (administration by injection or nebulizer)

For practical purposes use is identical to that of gentamicin, except possibly for *Pseudomonas* infection, where it has somewhat greater activity against gentamicin-susceptible and some gentamicin-resistant strains. Its value as a substitute for gentamicin in the speculative treatment of severe undiagnosed infection is offset by its lower activity against other organisms that may be implicated.

It has been used extensively to treat *Ps. aeruginosa* infections in patients with cystic fibrosis.

Preparations and dosage

Proprietary names: Nebcin, Tobradex, Tobiex, TOBI.

Preparations: Injections, topical and inhalation formulations.

Dosage: Adults i.m., i.v. 5 mg/kg per day in a single dose or in three divided doses.

Neonate: i.v. infusion, <32 weeks postmenstrual age, 4–5 mg/kg as a single dose every 36 h; ≥32 weeks postmenstrual age, 4–5 mg/kg as a single dose every 24 h. Alternatively, if <7 days old, 2 mg/kg every 12 h; if 7–28 days old, 2–2.5 mg/kg every 8 h.

Child: 1 month–18 years, 7 mg/kg as a single daily dose and adjust dose on the basis of serum concentrations. Alternatively, 1 month–12 years, 2–2.5 mg/kg every 8 h, or 12–18 years, 1 mg/kg (5 mg/kg in severe cases) every 8 h.

Cystic fibrosis: adults and children, 300 mg inhaled twice daily.

Widely available.

The dosage should be reduced in renal impairment. Dosage should be controlled in all patients by blood level determinations; these should be done at least weekly in patients on long-term treatment.

OTHER KANAMYCIN GROUP AMINOGLYCOSIDES

ARBEKACIN (HABEKACIN)

The 1-N-(4-amino-2-hydroxybutyryl) derivative of dibekacin, to which it bears the same relation as amikacin bears to kanamycin A. Supplied as the sulfate.

Activity and stability to aminoglycoside-modifying enzymes are comparable with those of amikacin. It is active against many strains of methicillin-resistant *Staph. aureus*, either alone or in combination with β-lactam or other agents. Synergy with ampicillin has been observed for high-level gentamicin- and vancomycin-resistant enterococci.

A 3 mg/kg intravenous dose achieved a peak concentration of c. 8 mg/L after 1 h. The plasma half-life is about 2 h and protein binding 3–12%.

About 85% of the dose can be recovered from urine over 48 h. It is retained in renal failure, but moderately well removed by hemodialysis with a plasma half-life of 2–4 h. Peak concentrations of 10.9 mg/L and trough concentrations of 1.7 mg/L have been reported in patients treated for MRSA infection where $C_{\max}:\text{MIC}$ ratios of >25 and $\text{AUC}:\text{MIC}$ ratios of >186 were associated with improved cure rates, and both C_{\min} and AUC were associated with the incidence of nephrotoxicity.

Toxicity and side effects are typical of the aminoglycoside class. It is used in severe infection caused by susceptible micro-organisms, but is not widely available.

DIBEKACIN

3',4'-Dideoxy kanamycin B. A semisynthetic aminoglycoside closely related to the natural compound tobramycin (3'-deoxy kanamycin B). Supplied as the sulfate.

It is active against staphylococci including methicillin-resistant strains, a wide range of enterobacteria, *Acinetobacter* and *Pseudomonas* spp. It is also active against *M. tuberculosis* and the *M. avium* complex (MICs 4–16 mg/L). It exhibits the usual aminoglycoside properties of bactericidal activity at concentrations close to the MIC and bactericidal synergy with selected β-lactam antibiotics.

Absence of hydroxyl groups present in the parent kanamycin B renders dibekacin resistant to phosphorylation by APH(3'). It is also resistant to some forms of ANT(4'). However, the type of this enzyme, ANT(4'), found in some Gram-positive organisms modifies dibekacin at the 2"-hydroxyl group; nevertheless dibekacin has much greater activity than tobramycin against organisms that produce the enzyme.

A 1 mg/kg intravenous bolus dose achieves a peak plasma concentration of around 5 mg/L. The plasma half-life is 2.3 h. Protein binding is 3–12%. It is eliminated principally by the renal route, 75–80% of the dose appearing in the urine in the first 24 h. Elimination is inversely related to renal function. In patients maintained on chronic hemodialysis, the half-life rises to 54 h between dialyses and falls to 6–7 h on dialysis.

Toxic effects are those typical of aminoglycosides with a frequency similar to or less than those of gentamicin.

It is used for severe infections caused by susceptible microorganisms, especially those resistant to established aminoglycosides, but availability is limited.

BEKANAMYCIN (KANAMYCIN B; KANENDOMYCIN)

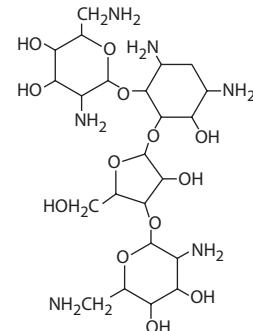

A component of the mixture of kanamycins produced by *Streptomyces kanamyceticus*. It is approximately twice as active as kanamycin A and is twice as toxic. It is not active against amikacin-resistant strains of MRSA. It is poorly active against *Ps. aeruginosa*.

The pharmacokinetics and uses are similar to those of kanamycin. A 0.5% ophthalmic solution has been used to treat gonococcal ophthalmia neonatorum. It is available in Japan.

NEOMYCIN GROUP

NEOMYCIN

Fradiomycin. Molecular weight (sulfate): 711.7; (free base): 614.7.

Neomycins A, B and C are fermentation products of *Streptomyces fradii*. The product marketed as ‘neomycin’ is a mixture of neomycin B and its isomer, neomycin C, supplied as the sulfates. Neomycin B is available alone under the name framycetin for topical use. It is required to contain not more than 3% neomycin C and not more than 1% neomycin A. Buffered aqueous solutions (pH 7) are stable at room temperature.

ANTIMICROBIAL ACTIVITY

The susceptibility of common pathogenic bacteria is shown in Table 12.1 (p. 146). Among other organisms susceptible in vitro (MIC 4–8 mg/L) are *Pasteurella*, *Vibrio*, *Borrelia* and *Leptospira* spp. It is active against *M. tuberculosis*, including streptomycin-resistant strains. Synergy has been reported with polymyxin B. The bactericidal effect is enhanced at alkaline pH.

ACQUIRED RESISTANCE

Resistance is acquired in a stepwise fashion and staphylococci may become resistant as a result of prolonged topical use. The use of neomycin–bacitracin–polymyxin mixtures may contribute to this, as many strains resistant to neomycin are also resistant to bacitracin. Resistant enterobacteria may appear in the feces of patients treated orally and in those treated for prolonged periods; most have been found to possess multiple transferable antibiotic resistance. Cross-resistance with kanamycin is often due to the synthesis of APH(3'), although AAC(6') some forms of AAC(3) and ANT(4') also modify both neomycin and kanamycin. Resistant strains of *Staph. aureus* are usually more resistant to kanamycin than to neomycin. The rare enzyme AAC(1) confers resistance to neomycin and paromomycin, but not to other aminoglycosides.

PHARMACOKINETICS

C_{max} 0.5 g intramuscular	20 mg/L after 1 h
Plasma half-life	2–3 h
Volume of distribution	0.25–0.35 L/kg
Plasma protein binding	Low

Very little is absorbed after oral administration and more than 95% is eliminated unchanged in the feces. Peak plasma concentrations of less than 4 mg/L have been found after an oral dose of 3 g. Distribution and excretion resemble that of streptomycin, but the toxicity of neomycin precludes systemic administration except in the most extreme cases.

TOXICITY AND SIDE EFFECTS

Neomycin is the most likely of all the aminoglycosides to damage the kidneys and the auditory branch of the eighth nerve (Table 12.3). This has almost entirely restricted it to topical and oral use.

Irreversible deafness may develop even if the drug is stopped at the first sign of damage. Loss of hearing may occur as a result of topical applications to wounds or other denuded areas, particularly if renal excretion is impaired. Instillation of ear drops containing neomycin can result in deafness. This generally develops in the second week of treatment and is usually reversible.

Rashes have been described in 6–8% of patients treated topically and these patients may be rendered allergic to other aminoglycosides. Nausea and protracted diarrhea may follow oral administration. Sufficient drug may be absorbed from the gut on prolonged oral administration to produce deafness but not renal damage. Intestinal malabsorption and superinfection have been seen in patients receiving 4–9 g per day and may develop in patients receiving as little as 3 g of the drug per day. Precipitation of bile salts by the drug may impair the hydrolysis of long-chain triglycerides. Large doses instilled into the peritoneal cavity at operation may be

Table 12.3 Relative toxicity index^a of aminoglycosides

	Vestibular	Auditory	Renal
Streptomycin	4	1	<1
Neomycin	1	4	4
Kanamycin	1	2	1
Gentamicin	3	2	2
Tobramycin	2	2	2

^a1–4: least to most toxic.

Based on Price KE, Godfrey JC, Kawaguchi H 1974 *Advances in Applied Microbiology* 18: 191–307.

absorbed, with resultant systemic toxicity, and patients currently exposed to anesthetics and muscle relaxants are liable to suffer neuromuscular blockade, which is reversible by neostigmine.

CLINICAL USE

Superficial infections with staphylococci and Gram-negative bacilli (topical; alone or in combination with bacitracin, chlorhexidine or polymyxin)

Treatment of staphylococcal nasal carriers (topical, in combination with chlorhexidine or bacitracin)

Eye infections (topical; alone or in combination)

Otitis externa (alone or with a corticosteroid)

Gut decontamination before abdominal surgery (oral)

Prophylaxis after urinary tract instrumentation (instillation)

Use is discouraged because of the possibility of promoting the appearance of aminoglycoside-resistant strains, and because of the risk of absorption with the consequent danger of systemic toxicity or neuromuscular blockade.

Preparations and dosage

Neomycin

Proprietary names: Mycifradin, Nivemycin.

Preparations: Tablets, elixir, topical.

Dosage: Adults, oral, 1 g every 4 h for a maximum of 72 h.

Children 6–12 years, 250–500 mg every 4 h.

Widely available.

Framycetin (neomycin B)

Proprietary name: Soframycin.

Preparations: Tablets, topical ophthalmic, aural.

Dosage: Adult, oral, 2–4 g per day in divided doses.

Widely available in topical preparations.

PAROMOMYCIN

Aminosidine, catenulin, crestomycin, hydroxymycin, estomycin, monomycin A, neomycin E, paucimycin. Molecular weight (free base): 615.63.

A fermentation product of *Streptomyces rimosus* var. *paromomycinus*, supplied as the sulfate. The commercial product is a mixture of the two isomeric paromomycins I and II, which are closely related to neomycin.

The antibacterial activity is almost identical to that of neomycin. Since it differs from neomycin in having a hydroxyl rather than an amino group at the 6'-position it is not sensitive to AAC(6') modifying enzymes. It is active against *M. tuberculosis*, including multidrug-resistant strains, and the *M. avium* complex.

Unlike other aminoglycosides, paromomycin is active against some protozoa, including *Entamoeba histolytica*, *Cryptosporidium parvum*, *Leishmania* spp., *Giardia lamblia* and *Trichomonas vaginalis*. It also exhibits activity against the tape-worms *Taenia saginata*, *Taenia solium*, *Diphyllobothrium latum* and *Hymenolepis nana*.

It closely resembles neomycin in pharmacokinetic behavior and liability to produce deafness and intestinal malabsorption.

CLINICAL USE

Intestinal amebiasis (oral)

Cutaneous leishmaniasis (topical) and visceral leishmaniasis (intramuscular)

Nitroimidazole-resistant trichomoniasis (topical)

Its antiprotozoal activity has attracted some attention, but it has largely been superseded by more active and less toxic compounds. Success in treating nitroimidazole-resistant trichomoniasis with topical paromomycin has been reported. Trials in India and East Africa of parenteral paromomycin alone, or in combination with sodium stibogluconate, for treatment of visceral leishmaniasis have shown promising results.

Preparations and dosage

Proprietary names: Gabbroral.

Preparations: Capsules, syrup, topical.

Dosage: Adult, oral dosage, 25–35 mg/kg per day in three divided doses with meals for 5–10 days; adult, i.m. dosage, 16–20 mg/kg per day for 21 days.

Limited availability. Available in the USA and continental Europe, but not in the UK.

OTHER AMINOGLYCOSIDES AND AMINOCYCLITOLS

STREPTOMYCIN

Molecular weight (free base): 581.58.

A fermentation product of *Streptomyces griseus*. It is available in some countries as the calcium chloride or as the hydrochloride, but usually supplied as the sulfate. Solutions are stable for long periods if refrigerated.

ANTIMICROBIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 12.1 (p. 146). It is less active than gentamicin group compounds against most micro-organisms within the spectrum,

but it is particularly active against mycobacteria, including *M. kansasii* and most strains of *M. ulcerans*. *Brucella* (MIC 0.5 mg/L), *Francisella*, *Pasteurella* spp. and *Yersinia pestis* are susceptible.

It is actively bactericidal, the speed of killing increasing progressively with concentration. The antibacterial activity is greatest in a slightly alkaline medium (pH 7.8) and is considerably reduced below pH 6.0. It is so sensitive to the effect of pH that the natural acidity of a solution of streptomycin sulfate may be sufficient to depress its antibacterial activity.

ACQUIRED RESISTANCE

In contrast to most other aminoglycosides, high level resistance can result from a single-step mutation in the gene encoding ribosomal protein S12 (*rpsL*), which alters the protein so that binding is reduced. Resistance in some clinical isolates of *M. tuberculosis* is associated either with missense mutations in the *rpsL* gene, or with base substitutions at position 904 in the 16S rRNA.

Resistance can also be caused by aminoglycoside-modifying enzymes: phosphotransferases that modify the 3"-hydroxyl group in both Gram-negative and Gram-positive organisms; a phosphotransferase that modifies the 6-hydroxyl group in *Pseudomonas* spp.; and a nucleotidyltransferase that modifies the 3"-hydroxyl group in Gram-negative organisms.

Increase in resistance often occurs within a few days (for *M. tuberculosis* a few weeks) of the beginning of treatment, and resistance of many species is now common. Primary streptomycin resistance in *M. tuberculosis* is much more common in the Far East and less developed countries than in the UK and USA. However, several clusters of multidrug-resistant tuberculosis have been identified among hospital patients with AIDS in the USA.

Strains of streptococci and enterococci showing moderate resistance (MIC 6–500 mg/L) exhibit synergy with penicillin, but strains showing high levels of resistance (MIC >500 mg/L) have ribosomes that are resistant to streptomycin and simultaneous treatment with penicillin is without effect.

It is not uncommon to find strains of bacteria, including *M. tuberculosis*, that are actually favored by the presence of the antibiotic or completely dependent on it. Isolated ribosomes from streptomycin-dependent *Esch. coli* show a change in the same single ribosomal protein that determines resistance and synthesize peptides only in the presence of the drug.

Streptomycin-resistant bacteria usually remain sensitive to other aminoglycosides. Enterococci with high-level resistance to gentamicin, and consequent resistance to gentamicin-β-lactam synergy, may show synergy between the β-lactam and streptomycin.

PHARMACOKINETICS

C_{max}	1 g intramuscular	26–58 mg/L after 0.5–1.5 h
Plasma half-life		2.4–2.7 h
Volume of distribution		0.3 L/kg
Plasma protein binding		35%

Absorption

Absorption from the intestinal tract is negligible. In patients treated for tuberculosis considerable interindividual variability of C_{max} has been observed following both intramuscular and intravenous administration due to differences in distribution volume and, in the case of intramuscular administration, rate of absorption. In patients over the age of 40 years, excretion is delayed and in older subjects commonly incomplete at 24 h. In such patients a dose of 0.75 g intramuscularly produces peak plasma concentrations around 25–60 mg/L with a half-life up to 9 h.

Distribution

Streptomycin diffuses fairly rapidly into most body tissues, but is distributed only in the extracellular fluid. It appears in the peritoneal fluid in concentrations of about one-quarter to one-half those present in the blood, and in pleural fluid the concentrations may equal those in the blood. It does not penetrate into the CSF or thick-walled abscesses, but significant amounts are usually present in tuberculous cavities. Concentrations in cord blood are similar to those in maternal blood.

Excretion

It is rapidly excreted by glomerular filtration and is unaffected by agents that block tubular secretion. The renal clearance is 1.8–4.2 L/h and 30–90% of the dose is usually excreted in the first 24 h. Concentrations in the urine often reach 400 mg/L after doses of 0.5 g. In oliguria, the plasma half-life is prolonged and dosage must be reduced if toxic concentrations are to be avoided. Plasma half-life during hemodialysis approaches that in normal renal function.

TOXICITY AND SIDE EFFECTS

Pain and irritation at the site of injection are common, and sterile inflammatory reactions or peripheral neuritis from direct involvement of a nerve sometimes occur. Many patients experience circumoral paresthesia, vertigo and ataxia, headaches, lassitude and 'muzziness in the head'. Renal dysfunction is rare but has been described in patients receiving 3–4 g per day.

Ototoxicity

The most common serious toxic effect is vestibular disturbance, which is related to total dosage and excessive blood concentrations, and hence to the age of the patient and the state of renal function. In older patients the risk of damage is higher and compensation is less than in young patients. Persistence of the drug in the perilymph after the plasma concentration has fallen may play an important part in such ototoxicity. There is no significant relation between incidence of dizziness and peak streptomycin concentration, but a highly significant relation to plasma concentrations exceeding 5 mg/L at 24 h. The risk to hearing is much less, but damage sometimes occurs after only a few doses. Congenital hearing loss or abnormalities in the caloric test or audiogram have been described several times in children born to women treated with streptomycin in pregnancy. There is considerable individual variation in susceptibility to its toxic effects, which may be partly genetically determined.

Allergy

In addition to eosinophilia unassociated with other allergic manifestations, rashes and drug fever occur in about 5% of treated patients. These are usually trivial and respond to anti-histamine treatment, so that in most cases therapy can be continued, although this should be done with caution, since occasionally severe and even fatal exfoliative dermatitis may develop. Skin sensitization is also common in nurses and dispensers who handle streptomycin and may lead to severe dermatitis, sometimes associated with periorbital swelling and conjunctivitis. Reactions most frequently develop between 4 and 6 weeks, but may appear after the first dose or after 6 months' treatment. Patients who develop hypersensitivity during prolonged therapy can generally be desensitized by giving 20 mg prednisolone daily plus 10 daily increments from 0.1 to 1.0 g streptomycin when normal dosage will usually be tolerated, or by giving increased doses of streptomycin every 6 h.

Neuromuscular blockade

It is rare for neuromuscular blockade to develop in those whose neuromuscular mechanisms are normal, but patients who are also receiving muscle relaxants or anesthetics, or are suffering from myasthenia gravis are at special risk.

Other effects

Rare neurological manifestations include peripheral neuritis and optic neuritis with scotoma. Other rare effects have been aplastic anemia, agranulocytosis, hemolytic anemia, thrombocytopenia, hypocalcemia and severe bleeding associated with a circulating factor V antagonist.

CLINICAL USE

Tuberculosis (in combination with other antituberculosis drugs)

Infections caused by *M. kansasii* (in combination with other antimycobacterial agents)

Plague and tularemia, including tularemia pneumonia

Bacterial endocarditis (in combination with a penicillin)

Brucellosis

Whipple's disease (in combination with other antibiotics)

The most important use of streptomycin is in the treatment of tuberculosis (see Ch. 58). Depression of vestibular function by streptomycin has been used in the treatment of patients suffering from Ménière's disease.

Preparations and dosage

Proprietary names: Many generic forms.

Preparation: Injection.

Dosage: Tuberculosis: Adults, i.m., 1 g per day (750 mg per day for adults >40 years of age or <50 kg body weight). Children, i.m., 15 mg/kg per day (maximum 1 g). Can also be given intravenously.

Widely available.

SPECTINOMYCIN

Aminospectacin; actinospectacin. Molecular weight (free base): 332.35.

An aminocyclitol that lacks an aminoglycosidic function and which is a fermentation product of *Streptomyces spectabilis* and *Streptomyces flavopersicus*. It is supplied as the dihydrochloride and the sulfate.

ANTIMICROBIAL ACTIVITY

Its activity is modest (Table 12.1, p. 146) and markedly affected by medium composition and pH. It exerts only moderate activity against Gram-positive organisms. It is widely active against enterobacteria, but *Providencia* spp. are resistant. Anaerobic bacteria are also resistant.

Of particular interest is its activity against *N. gonorrhoeae*, including β -lactamase-producing strains. Among other sexually acquired organisms, *Ureaplasma urealyticum* is susceptible, but *Chlamydia trachomatis* and *T. pallidum* are resistant.

For most organisms, the minimum bactericidal concentration (MBC) is at least four times the MIC and it is regarded as essentially bacteriostatic. In contrast, it is bactericidal for gonococci at concentrations close to the MIC, which is of the order of 2–16 mg/L for both penicillin-susceptible and resistant strains.

ACQUIRED RESISTANCE

N. gonorrhoeae strains resistant to spectinomycin have emerged in South East Asia, the USA and the UK; the resistance of UK isolates was not attributable to aminoglycoside-modifying enzymes. In most countries where its use remains low the prevalence of resistance in gonorrhea is also low.

Acquired resistance in enterobacteria, enterococci and staphylococci can be caused by nucleotidyltransferases that modify the drug at position 9. The enzyme from Gram-negative organisms ANT(3") (9) also modifies streptomycin at position 3", thus conferring cross-resistance to the two drugs. There is no enzymatic cross-resistance with 2-deoxystreptamine-containing aminoglycosides.

PHARMACOKINETICS

C_{max}	25 mg/kg intramuscular	60–80 mg/L after 1 h
Plasma half-life		2–3 h
Volume of distribution		10–13.4 L
Plasma protein binding		<10%

It is poorly absorbed on oral administration. It is almost completely excreted unchanged in the urine over 48 h, concentrations on conventional dosage reaching 1 g/L. Excretion

is prolonged in renal impairment, and is unaffected by probenecid.

TOXICITY AND SIDE EFFECTS

Transient headache, dizziness, pain at the site of injection and occasional fever have been described. No evidence of ototoxicity or renal toxicity has been found in volunteers receiving doses of 2 g every 6 h for 3 weeks, amounts much in excess of those used therapeutically.

CLINICAL USE

Gonorrhoea in penicillin-allergic patients or due to penicillin-resistant strains (single-dose treatment)

Preparations and dosage

Proprietary names: Trobicin, Trobicine.

Preparation: Injection.

Dosage: Deep i.m. injection adults, 2 g as a single dose, or 4 g in two separate i.m. sites in those difficult to treat and in areas of resistance. Children, i.m., 40 mg/kg as a single dose (maximum dose, 2 g per day). Widely available.

ASTROMICIN

A pseudodisaccharide aminoglycoside produced by *Micromonospora olivoasterospora*. Formulated as the sulfate.

Intrinsic activity is similar to that of amikacin for most groups of organisms, but activity against *Ps. aeruginosa* is relatively poor. It is resistant to many aminoglycoside-modifying enzymes, but is sensitive to AAC(3') and the APH(2")/AAC(6') bifunctional enzyme.

Peak concentrations of 10–12 mg/L were found in the blood following 200 mg intravenous or intramuscular administration to volunteers. The plasma half-life was 1.5–2 h. Over 85% of the drug was recovered in urine during the 8 h following administration.

Toxicity and side effects are similar to those observed with other aminoglycosides. Where the drug is available it is used instead of amikacin in the treatment of infections caused by susceptible organisms.

13 β-Lactam antibiotics: cephalosporins

David Greenwood

All cephalosporins are based on cephalosporin C, which was discovered by Edward Abraham and his colleagues in Oxford as a minor component of the antibiotic complex produced by *Cephalosporium acremonium*, a mold cultivated from a Sardinian sewage outfall by Giuseppe Brotzu in 1948. Interest in cephalosporin C was fuelled by its stability to staphylococcal β-lactamase (shared by all subsequent cephalosporins), which was causing concern at the time, and they probably owe their continued development to this property. Over 100 semisynthetic cephalosporins have since been marketed, although not all have survived into present-day use.

In all cephalosporins the β-lactam ring is fused to a six-membered dihydrothiazine ring in place of the five-membered thiazolidine ring of penicillins (see pp. 226–227). The basic 7-aminocephalosporanic acid skeleton can be modified at a number of positions.

- Alterations at the C-3 position tend to affect the pharmacokinetic and metabolic properties.
- Introduction of a methoxy group at C-7 yields a cephemycin with enhanced stability to β-lactamases, including the cephalosporinases of certain *Bacteroides* spp.
- Changes at the 7-amino position alter, in general, the antibacterial activity or β-lactamase stability or both.

Other compounds conveniently considered alongside the cephalosporins, since their properties are very similar, include:

- the oxacephems, in which the sulfur of the dihydrothiazine ring is replaced by oxygen
- the carbacephems, in which the sulfur is replaced by carbon.

CLASSIFICATION

As new cephalosporins have become available they have been loosely classified into ‘generations’, but these descriptions are too simplistic, and are to be discouraged. The following grouping is adopted here:

- *Group 1:* Parenteral compounds of moderate antimicrobial activity and susceptible to hydrolysis by a wide variety of enterobacterial β-lactamases.
- *Group 2:* Oral compounds of moderate antimicrobial activity and moderately resistant to some enterobacterial β-lactamases.
- *Group 3:* Parenteral compounds of moderate antimicrobial activity resistant to a wide range of β-lactamases. Some are available as esters for oral administration.
- *Group 4:* Parenteral compounds with potent antimicrobial activity and resistance to a wide range of β-lactamases.
- *Group 5:* Oral compounds (often achieved by esterification) resistant to a wide range of β-lactamases. Most exhibit potent activity against enterobacteria; activity against Gram-positive cocci is variable.
- *Group 6:* Parenteral compounds with activity against *Pseudomonas aeruginosa*. They vary widely in their spectrum of activity against other bacterial species.
- *Group 7:* Compounds characterized by activity against methicillin-resistant staphylococci.

Although the ‘generation’ categories often used are imprecise, ‘first-generation’ compounds roughly correspond to Groups 1 and 2; ‘second-generation’ to group 3; ‘third-generation’ to groups 4–6. Certain group 6 and 7 compounds are sometimes allocated to so-called ‘fourth and fifth generations’.

Some cephalosporins, including cefalonium and cefaloram (group 1) and cefquinone and ceftiofur (group 4) are used only in veterinary medicine and are not discussed further here.

Group 1	Group 2	Group 3	Group 4	Group 5	Group 6	Group 7
Cefacetile	Cefaclor	Cefbuperazone*	Cefmenoxime	Cefcapene	Cefepime	Ceftaroline
Cefaloridine	Cefadroxil	Cefmetazole*	Cefodizime	Cefdinir	Cefoperazone	Ceftobiprole
Cefalotin	Cefalexin	Cefminox*	Cefotaxime	Cefditoren	Cefozopran	
Cefamandole	Cefatrizine	Cefotetan*	Ceftizoxime	Cefetamet	Cefpimizole	
Cefapirin	Cefprozil	Cefotiam	Ceftriaxone	Cefixime	Cefpiramide	
Cefazolin	Cefradine	Cefoxitin*	Flomoxef [†]	Cefpodoxime	Cefpirome	
Cefonicid	Cefroxadine	Cefuroxime	Latamoxef [†]	Ceferam	Cefsulodin	
Ceforanide	Loracarbef [‡]			Ceftibuten	Ceftazidime	

*7-Methoxycephalosporin (cephamycin).

[†]7-Methoxyxacephem.

[‡]1-Carbacephem.

ANTIMICROBIAL ACTIVITY

Most cephalosporins are active against staphylococci other than methicillin-resistant strains, including those producing β -lactamase. The degree of activity varies among different members of the group. Streptococci, including pneumococci, are susceptible but *Enterococcus faecalis*, *Ent. faecium* and *L. monocytogenes* are virtually completely resistant. *Streptococcus pneumoniae* strains with reduced susceptibility to penicillins are also less susceptible to the cephalosporins. Many Gram-negative species including *neisseriae*, *Haemophilus influenzae*, *Escherichia coli*, *salmonellae*, some *klebsiellae* and *Proteus mirabilis* are sensitive to varying degrees. Inoculum-related effects are common, particularly when compounds of groups 1 and 2 are tested against Gram-negative bacilli. *Ps. aeruginosa* is sensitive only to group 6 compounds. Except for cephamycins, activity against many anaerobes is unreliable. Mycobacteria, mycoplasmas, chlamydiae and fungi are resistant.

Cephalosporins are usually bactericidal at concentrations above the minimum inhibitory concentration (MIC) and bactericidal synergy is commonly demonstrable with aminoglycosides and a number of other agents.

ACQUIRED RESISTANCE

The most important form of resistance is that due to the elaboration of β -lactamases (pp. 228–231). All cephalosporins are relatively stable to staphylococcal β -lactamase, but resistance among Gram-negative genera is a good deal more complicated. The chromosomal β -lactamase of *Esch. coli*, which has virtually no hydrolytic activity against ampicillin, slowly degrades some group 1 cephalosporins and is responsible for the inoculum effect observed with *Esch. coli*. Chromosomal β -lactamases of *Bacteroides fragilis* are also more active against cephalosporins than against penicillins, but cephamycins and

oxacephems are unusual in their stability to these enzymes. Cephalosporins exhibit considerable variation in stability to the enzymes of genera with an inducible, or derepressible, chromosomal β -lactamase and to plasmid-mediated enzymes of Gram-negative bacilli (pp. 230–231).

The resistance of Gram-negative bacilli does not depend solely on β -lactamase formation. It varies also with the extent to which the antibiotic can penetrate the outer cell membrane and reach the site of enzyme formation. This property, known as crypticity, can be measured by comparing the enzyme activity of intact and disrupted cells. Resistance may also result from a change in the biochemical target of the antibiotic (i.e. the penicillin-binding proteins).

PHARMACOKINETICS

Group 2 agents are well absorbed, with bioavailability often exceeding 85%. The bioavailability of some of the agents in other groups is enhanced by prodrug formulation. These agents tend to have improved absorption following food, whereas food has little or a deleterious effect on the absorption of group 2 compounds.

Cephalosporins are usually well distributed, achieving high concentrations in the interstitial fluid of tissues and in serous cavities. Penetration into the eye and the cerebrospinal fluid (CSF) is poor, though some cephalosporins achieve adequate levels in the CSF in the presence of meningeal inflammation. They cross the placenta.

Compounds that carry an acetoxyethyl group at C-3, such as cefalotin and cefotaxime, are susceptible to mammalian esterases that remove the acetyl group to form the corresponding hydroxymethyl derivative with reduced antibacterial activity. The relevance (if any) of deacetylation to therapy has not been established.

Cephalosporins are generally excreted into urine by glomerular filtration and tubular secretion; elimination is depressed by

probencid and renal failure. Most are rapidly eliminated with plasma half-lives of 1–2 h but some are more persistent. The less active metabolites resulting from removal of acetoxyethyl groups at C-3 are also excreted in the urine. Some excretion is via the bile, and certain compounds, notably cefoperazone and cefpiramide, are preferentially excreted by this route.

TOXICITY AND SIDE EFFECTS

HYPERSENSITIVITY

Hypersensitivity occurs in 0.5–10% of patients, mostly in the form of rashes, eosinophilia, drug fever and serum sickness. In addition to immediate reactions, a maculopapular rash with or without fever, lymphadenopathy and eosinophilia may appear after several days' treatment. As with penicillins, allergy to cephalosporins is probably based on major and minor antigenic determinants, but they are less well characterized than with penicillins. Clinical reactions to cephalosporins in penicillin-allergic patients are uncommon and severe reactions are very rare. About 10% of such reactions are said to occur, generally in patients who react to a variety of drugs. Nonetheless, the generally accepted advice is that cephalosporins should not be given to patients who have previously suffered a well-documented severe reaction to penicillins. Specific allergy to cephalosporins also occurs, but there is no evidence that the compounds differ markedly in allergenicity.

HEMATOLOGIC TOXICITY

Rare reversible abnormalities of platelet function and coagulation resulting from several different mechanisms have been described. Thrombocytopenia and neutropenia are occasionally seen.

Although penicillins have long been associated with clotting abnormalities, it was cephalosporins that brought bleeding associated with β -lactam antibiotics into prominence when cefamandole, cefoperazone, latamoxef and other compounds with a methylthiotetrazole side chain at the C-3 position were found to induce severe hypoprothrombinemia, especially in patients who were malnourished, had renal failure or were treated for prolonged periods. The deficiency is readily reversed by vitamin K₁.

OTHER ADVERSE REACTIONS

Pain at the site of intramuscular injection and phlebitis at the site of intravenous administration is fairly common. *Candida* overgrowth with vaginitis has been a feature of some studies.

Diarrhea occurs in about 5% of patients and pseudomembranous colitis has been described. Changes in bowel flora, accompanied by emergence of resistant organisms, including *Clostridium difficile*, are particularly likely with those agents

which are extensively excreted in the bile and because of their non-absorption achieve substantial fecal concentrations.

Rare disturbances of renal function appear to have the direct toxic or allergic origins described for penicillins. Claims that the nephrotoxicity of cephalosporins is potentiated by aminoglycosides have been disputed.

As with other β -lactam antibiotics, central nervous system (CNS) disturbances may occur if they are given in excessive doses, particularly to patients with renal failure. Transient abnormalities of liver function tests without other evidence of hepatotoxicity and gastrointestinal disturbances also occur.

In addition to hypoprothrombinemia (see above) cephalosporins with a methylthiotetrazole side chain may cause a disulfiram-like reaction, evidently due to inhibition of aldehyde dehydrogenase. Patients should be advised to avoid alcohol during and 3 days after treatment with these agents.

CLINICAL USE

GROUP 1

Group 1 cephalosporins are no longer widely used. They are not reliable for the treatment of severe respiratory tract infection, severe undiagnosed sepsis or meningitis. They should be avoided in the treatment of diseases where *H. influenzae* or enterococci may be implicated.

GROUP 2

The older oral agents have had widespread use for the treatment of upper respiratory, urinary, soft tissue and various other infections. They are possible alternatives to benzylpenicillin in allergic patients for the treatment of streptococcal, pneumococcal and staphylococcal infections.

GROUPS 3 AND 4

The properties of the β -lactamase-stable cephalosporins strongly commend them for the treatment of severe sepsis of unknown or mixed bacterial origin. It is not established that the superior activity in vitro of group 4 over group 3 compounds is reflected in greater clinical efficacy. Despite the difference in potency, it is customary to give similar doses of compounds in both groups, partly because the very high activity seen against enterobacteria is not exhibited against staphylococci. They have been successfully used in hospital-acquired pneumonia, particularly that due to enterobacteria. They are inactive against *Legionella pneumophila*, *Mycoplasma pneumoniae* and *Coxiella burnetii*.

Group 4 agents now have an established place in the treatment of meningitis due to many enterobacteria, β -lactamase-producing *H. influenzae* and penicillin-resistant pneumococci. They are not effective in the treatment of meningitis due to

L. monocytogenes, *Enterobacter*, *Ps. aeruginosa* or *Serratia* spp. Despite their in-vitro potency, they do not appear to offer any advantage over established therapy in the treatment of meningitis due to *Neisseria meningitidis*. Their activity and resistance to β -lactamases has led to their successful use for the treatment of infection due to β -lactamase-producing gonococci.

GROUP 5

Those oral compounds may replace the group 2 agents if resistance to the earlier compounds becomes significant. The relatively lower activity of cefixime and ceftibuten against Gram-positive cocci suggests they should be used with caution in infections with these organisms.

GROUPS 6 AND 7

Ceftazidime has been widely used in serious infection due to *Ps. aeruginosa*. Cefsulodin and cefoperazone are indicated only in proven or highly suspected pseudomonas infection and in combination with an appropriate aminoglycoside. Other group 6 compounds are appropriate for use in patients with severe infections caused by bacteria with plasmid and chromosomally mediated β -lactamases. Their main use is in hospital-acquired infections or in serious problems in the neutropenic patient.

The newer group 7 compounds have been specifically developed for their action against methicillin-resistant staphylococci.

GROUP 1 CEPHALOSPORINS

CEFALOTIN

Cephalothin. Molecular weight (sodium salt): 418.4.

A semisynthetic cephalosporin supplied as the sodium salt.

ANTIMICROBIAL ACTIVITY

Its activity against common pathogenic bacteria is shown in Table 13.1. Cefalotin is active against staphylococci, including β -lactamase-producing strains. Streptococci, including penicillin-sensitive pneumococci, but not enterococci, are highly susceptible. It is active against a range of enterobacteria, but is hydrolyzed by many enterobacterial β -lactamases. *Pasteurella* and *Vibrio* spp., *H. influenzae*, *Bordetella* and *Brucella* spp. are moderately resistant. *Campylobacter*, *Citrobacter*, *Enterobacter*, *Pseudomonas* and *Listeria* spp. are resistant. Most anaerobes, with the exception of *B. fragilis*, are susceptible: *Treponema pallidum* and *Leptospira* spp. are susceptible, but mycobacteria and mycoplasma are resistant.

PHARMACOKINETICS

C_{max}	1 g intravenous	30 mg/L after 15 min
	1 g intramuscular	15–20 mg/L after 0.5–1 h
Plasma half-life		c. 0.8 h
Volume of distribution		0.26 L
Plasma protein binding		60–70%

Distribution

Intramuscular administration is commonly painful and it is normally given intravenously. Continuous infusion of 12 g per day produces steady-state plasma levels of 10–30 mg/L. Penetration into the CSF is very poor, rising in the presence of inflammation to less than 2 mg/L after a 2 g intravenous dose.

Table 13.1 Activity of group 1 cephalosporins against common pathogenic bacteria: MIC (mg/L)

	Cefamandole	Cefalotin	Cefazolin
<i>Staphylococcus aureus</i>	0.5–1	0.25–0.5	0.25–0.5
<i>Streptococcus pyogenes</i>	0.06–1	0.1	0.1–0.25
<i>Str. pneumoniae</i>	0.06–16	0.06–0.1	0.1
<i>Enterococcus faecalis</i>	32–R	32	R
<i>Neisseria gonorrhoeae</i>	0.06	0.25–2	0.1–0.5
<i>N. meningitidis</i>	0.1–0.5	0.5	
<i>Haemophilus influenzae</i>	0.25–2	4–8	2–8
<i>Escherichia coli</i>	0.5–4	4–8	0.5–4
<i>Klebsiella pneumoniae</i>	0.5–2	4	1–4
<i>Pseudomonas aeruginosa</i>	R	R	R
<i>Bacteroides fragilis</i>	R	32–64	16–32

R, resistant (MIC >64 mg/L).

Concentrations in sputum are 10–25% of the corresponding serum levels. An intravenous dose of 1 g produces a concentration in bone around 4 mg/kg.

Metabolism and excretion

It is deacetylated by hepatic esterases. The metabolite has about 20% of the activity of the parent compound and accounts for 20–30% of concentrations in serum and urine.

Urinary concentrations of 500–2000 mg/L are achieved during the first 6 h after a 1 g dose. Excretion is depressed by probenecid, indicating significant tubular secretion, and by renal failure although, because of metabolism, the plasma half-life of the drug is only moderately prolonged to about 3 h, while that of the principal metabolite rises to 12 h or more. Impaired tubular secretion is responsible for the elevated levels of the drug found in newborn and premature infants. Biliary excretion is trivial and liver disease has little effect on its half-life or plasma protein binding.

TOXICITY AND SIDE EFFECTS

In volunteers receiving very large doses (8 g per day for 2–4 weeks) a serum-sickness-like illness developed. Positive Coombs' reactions associated with red cell agglutination, but very seldom with hemolysis, are common. Thrombocytopenia and leukopenia have been described. Coagulopathy with prolonged prothrombin time has been encountered in patients with renal failure or very high plasma levels resulting from excessive dosage. Evidence has been cited of exaggeration of pre-existing renal disease or renal damage, perhaps enhanced by simultaneous administration of aminoglycosides or furosemide (frusemide), in which direct tubular injury or allergic nephritis may have been involved.

CLINICAL USE

It has been used in staphylococcal and streptococcal infections in penicillin-allergic patients, but is no longer recommended.

Preparations and dosage

Proprietary name: Keflin.

Preparation: Injection.

Dosage: Adults, i.m., i.v. 0.5–1 g every 4–6 h; up to 12 g per day in severe infections. Children, 50–150 mg/kg per day in divided doses.

No longer widely available.

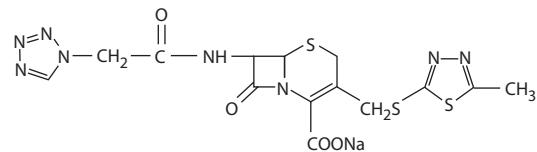

Further information

Anonymous. Cephalothin (sodium). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C147–C149.

CEFAZOLIN

Cephazolin. Molecular weight (sodium salt): 476.5.

A semisynthetic cephalosporin supplied as the sodium salt.

ANTIMICROBIAL ACTIVITY

Activity against common pathogenic bacteria is shown in Table 13.1. *Enterobacter*, *Klebsiella*, *Providencia*, *Serratia* spp. and *Pr. vulgaris* are all resistant. *B. fragilis* is resistant, but other anaerobes are susceptible.

PHARMACOKINETICS

C_{\max}	1 g intramuscular	65–70 mg/L at 1 h
	1 g intravenous bolus	180–200 mg/L end infusion
Plasma half-life		1.5–2.0 h
Volume of distribution		c. 10 L
Plasma protein binding		75–85%

Distribution

The volume of distribution is the smallest of the cephalosporins in group 1, perhaps an indication of relative confinement to the plasma space. It crosses inflamed synovial membranes, but the levels achieved are well below those of the simultaneous serum levels and entry to the CSF is poor. In patients receiving 10 mg/kg by intravenous bolus, mean concentrations in cancellous bone were 3.0 mg/kg when the mean serum concentration was 33 mg/L, giving a bone:serum ratio of 0.09. Some crosses the placenta, but the concentrations found in the fetus and membranes are low.

Metabolism and excretion

It is not metabolized. Around 60% of the dose is excreted in the urine within the first 6 h, producing concentrations in excess of 1 g/L. Excretion is depressed by probenecid. The renal clearance is around 65 mL/min and declines in renal failure, when the half-life may rise to 40 h, although levels in the urine sufficient to inhibit most urinary pathogens are still found. It is moderately well removed by hemodialysis and less well by peritoneal dialysis.

Levels sufficient to inhibit a number of enteric organisms likely to infect the biliary tract are found in T-tube bile (17–31 mg/L after a 1 g intravenous dose), but this is principally due to the high serum levels of the drug and the total amounts excreted via the bile are small.

TOXICITY AND SIDE EFFECTS

protein. Penetration into the CSF is limited. About 80% of the drug is excreted in the urine, producing concentrations in excess of 1 g/L, 25% of which is in the desacetylated form. Clearance is depressed by probenecid and in renal failure. Little is excreted in the bile.

Manifestations of hypersensitivity in patients not known to be allergic to β -lactam antibiotics are common. It is no longer used.

Side effects are those common to other cephalosporins (p. 172), including rare bleeding disorders and encephalopathy in patients in whom impaired excretion or direct instillation leads to very high CSF levels. Neutropenia has been described and hypoprothrombinemic bleeding has been attributed to the side chain.

CLINICAL USE

Cefazolin has been widely used in surgical prophylaxis, especially in biliary tract (because of the moderately high concentrations achieved in bile), orthopedic, cardiac and gynecological surgery.

CEFALORIDINE (CEPHALORIDINE)

Its activity and spectrum are similar to those of cefalotin. A 1 g intramuscular dose produces peak plasma levels of 20–40 mg/L at 1 h. The plasma half-life is 1.5 h. It is about 20% bound to plasma protein. In the presence of inflammation, CSF concentrations are around 25% of simultaneous plasma levels.

It is excreted unchanged in the urine, mainly in the glomerular filtrate. Moderate doses produce many hyaline casts in the urine and large doses sometimes cause proximal tubular necrosis, occasionally leading to oliguria and renal failure. Renal toxicity is enhanced by furosemide and ethacrynic acid. It is no longer used.

Preparations and dosage

Proprietary name: Kefzol.

Preparation: Injection.

Dosage: Adults, i.m., i.v., i.v. infusion 0.5–2 g every 6–12 h, up to 12 g per day in severe infections. Children, 25 mg/kg per day in divided doses, increasing to 100 mg/kg per day in severe infection.

Widely available.

CEFAMANDOLE

A semisynthetic cephalosporin supplied as the nafate, an antibacterially inactive ester hydrolyzed in the body to cefamandole. It is active against common pathogenic bacteria (Table 13.1), but there is considerable strain variation in susceptibility. It is somewhat more stable than other group 1 agents to enterobacterial β -lactamases. *Acinetobacter*, *Serratia* and *Pseudomonas* spp. are often resistant. Some anaerobic Gram-negative rods are susceptible but *B. fragilis* is resistant.

A 1 g intramuscular dose achieves a plasma concentration of 20–35 mg/L after 1 h. It is widely distributed in body tissues. CSF levels are poor in the absence of meningeal inflammation. Therapeutically effective concentrations (c. 9 mg/kg) are found in bone after an intravenous dose of 2 g. Protein binding is 65–80%.

Renal excretion with a plasma half-life of around 50 min is mainly by both glomerular and tubular routes. A small amount is excreted in the bile and concentrations around 150–250 mg/L are found in T-tube bile following a 1 g intravenous dose. Only about 5% is removed by hemodialysis.

Cefamandole is one of the analogs containing the methylthiotetrazole side chain associated with bleeding (p. 172). Rare renal damage or enhancement of existing renal damage has been described. Thrombophlebitis on intravenous administration is relatively common.

OTHER GROUP 1 CEPHALOSPORINS

CEFACETRILE

Its spectrum resembles that of cefalotin. Following an intramuscular dose of 1 g, a peak plasma concentration around 15 mg/L is achieved at 1 h. About 25% is bound to plasma

Experience in the treatment of a variety of infections and for surgical prophylaxis has been mixed and it is no longer recommended.

Further information

Anonymous. Cefamandole (nafate). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C86–C88.

CEFAPIRIN

Its antibacterial spectrum is almost identical to that of cefalotin, but it is more labile to staphylococcal β -lactamase. Intramuscular injections can be painful. A peak plasma concentration of 15–25 mg/L is obtained 0.5 h after intramuscular injection of 1 g. The plasma half-life is 0.4–0.8 h. It is c. 50% plasma protein bound and metabolized to the desacetyl form. The metabolite accounts for almost half the drug in the urine. Less than 1% of the dose appears in the bile.

A serum-sickness-like illness analogous to that seen with cefalotin has been observed. It is no longer used.

CEFONICID

Activity against Gram-positive and Gram-negative organisms in vitro is depressed by the presence of 50% serum. It is highly bound to plasma protein (98%) and has an extended plasma half-life of 4.5–5 h. A 1 g intramuscular dose achieves a mean peak plasma concentration of around 83 mg/L. Following a 1 g intravenous bolus dose, mean peak plasma concentrations of 130–300 mg/L have been reported. In patients treated for community-acquired pneumonia, concentrations of 2–4 mg/L have been found in sputum.

It is predominantly excreted by renal secretion, 83–89% being recovered unchanged in the urine over 24 h. Plasma half-life is linearly related to creatinine clearance. As a result of its high protein binding it is not removed by hemodialysis.

It is generally well tolerated; pain on injection, rash and positive Coombs' test are reported in some patients. It has been used to treat respiratory, soft tissue and urinary infections. Available in Italy.

Further information

Saltier E, Brogden RN. Cefonicid. A review of its antibacterial activity, pharmacological properties and therapeutic use. *Drugs*. 1986;32:222–259.

CEFORANIDE

A semisynthetic parenteral cephalosporin with activity broadly similar to that of cefalotin. Its activity in vitro is significantly reduced in the presence of serum. A 1 g intravenous dose

achieves a concentration of c. 135 mg/L at the end of infusion. The response after 0.25, 0.5 and 1 g intravenous doses is essentially linear. A 1 g intramuscular dose produces mean peak values of around 70 mg/L. Plasma protein binding is around 85%.

It is almost entirely eliminated in the urine with a half-life of about 2.5 h, 80–95% being recovered in the first 12 h. The half-life is inversely related to renal function, rising to around 20 h when the creatinine clearance falls below 5 mL/min. About half the dose is removed by hemodialysis over 6 h.

It is generally well tolerated; phlebitis and pain at the site of injection are reported in some patients with occasional transient neutropenia and increased transaminase levels. It has been used principally for the treatment of infections due to Gram-positive cocci, including staphylococcal and streptococcal soft-tissue infections, but is no longer widely available.

GROUP 2 CEPHALOSPORINS

CEFACLOR

Molecular weight (monohydrate): 385.8.

A semisynthetic oral cephalosporin available as the monohydrate. Aqueous solutions are stable at room temperature and 4°C for 72 h at pH 2.5 but rapidly lose activity at pH 7. A delayed-release formulation is available.

ANTIMICROBIAL ACTIVITY

Its activity against common pathogenic bacteria is shown in Table 13.2. It is less resistant than other group 2 cephalosporins to staphylococcal β -lactamase. It is active against *N. gonorrhoeae* and *H. influenzae* and against most enterobacteria, but it is susceptible to common enterobacterial β -lactamases. *Pr. vulgaris* and *Providencia*, *Acinetobacter* and *Serratia* spp. are resistant. *B. fragilis* and clostridia are resistant but other anaerobes are commonly susceptible.

Table 13.2 Activity of group 2 cephalosporins against common pathogenic bacteria: MIC (mg/L)

	Cefaclor	Cefadroxil	Cefatrizine	Cefalexin^a	Cefprozil	Loracarbef
<i>Staphylococcus aureus</i>	2–4	2–4	0.5–1	2–4	0.25–4	1–8
<i>Streptococcus pyogenes</i>	0.25	0.1–0.5	0.03–0.1	0.5–2	0.06–0.25	0.12–1
<i>Str. pneumoniae</i>	0.5–1	1	0.25–0.5	2	0.06–0.25	0.5–2
<i>Enterococcus faecalis</i>	R	R	R	R	16	R
<i>Neisseria gonorrhoeae</i>	0.1–0.5	4	0.25–0.5	0.5–4	0.12–0.25	0.004–1
<i>Haemophilus influenzae</i>	1–2	16–32	2–8	8–32	0.006–8	0.5–2
<i>Escherichia coli</i>	2–8	8–16	2–8	8	1–4	1–2
<i>Klebsiella pneumoniae</i>	4–8	8–16	8	8	1–64	1–8
<i>Pseudomonas aeruginosa</i>	R	R	R	R	R	R
<i>Bacteroides fragilis</i>	R	R	R	R	R	R

^aCefadrine and cefroxadine have almost identical activity. R, resistant (MIC >64 mg/L).

PHARMACOKINETICS

Oral absorption	c. 90%
C_{\max} 250 mg oral	c. 6–7 mg/L after 50 min
Plasma half-life	0.5–1 h
Volume of distribution	0.37 L
Plasma protein binding	25%

Absorption

Food intake increases the time taken to reach peak plasma levels and reduces the peak by 25–50%. The actual amount absorbed is unaffected. In children receiving 15 mg/kg per day (maximum daily dose 1 g) the mean peak serum level was 16.8 mg/L at 0.5–1 h. There is no accumulation of the drug during repeated administration.

Distribution

In patients receiving 500 mg every 8 h for 10 days, concentrations were 0–1.7 (mean 0.5) mg/L in mucoid sputum and 0–2.8 (mean 1.0) mg/L in purulent sputum. In children with chronic serous otitis media receiving 15 mg/kg per day, the mean peak concentration in middle ear secretion was 3.8 mg/L within 30 min of the dose when the mean simultaneous serum concentration was 12.8 mg/L.

Metabolism and excretion

No metabolites have been identified, but the drug probably chemically degrades in serum. About half of the dose is recovered from the urine in the first 6 h and 70% in 24 h. Probenecid prolongs the plasma levels but in renal insufficiency the plasma half-life is only moderately increased. In patients with creatinine clearance values of 5–15 mL/min the mean plasma elimination half-life rose to 2.3 h and the 24 h urinary excretion fell

to less than 10%. In patients requiring intermittent hemodialysis and receiving 500 mg every 8 h for 10 days, the half-life rose to 2.9 h. Dialysis removed 34% of the dose.

TOXICITY AND SIDE EFFECTS

Apart from mild gastrointestinal disturbance, the drug is well tolerated. Transiently increased transaminase levels and symptomatic vaginal candidosis have been noted. Clusters of a serum sickness-like illness have been described in children.

CLINICAL USE

Uses are similar to those of other group 2 cephalosporins. It is among the few suitable for use in respiratory infections because of its activity against *H. influenzae*.

Preparations and dosage

Proprietary name: Distaclor.

Preparations: Tablets, suspension, capsules.

Dosage: Adults, oral, 250–500 mg every 8 h, depending on severity of infection (maximum dose, 4 g per day). Children >1 month, 20 mg/kg per day in divided doses every 8 h. In more severe infections, 40 mg/kg per day in divided doses (maximum dose, 1 g per day).

Widely available.

Further information

CEFADROXIL

Molecular weight (monohydrate): 381.4.

p-Hydroxycephalexin, available as the mono- and trihydrate.

ANTIMICROBIAL ACTIVITY

Resembles closely that of cefalexin (Table 13.2).

PHARMACOKINETICS

Oral absorption	>90%
C_{\max} 250 mg oral	c. 9 mg/L after 1.2 h
500 mg oral	c. 18 mg/L after 1.2 h
Plasma half-life	1–1.5 h
Plasma protein binding	20%

Absorption is little affected by administration with food. Distribution is similar to that of cefalexin. It is eliminated unchanged by glomerular filtration and tubular secretion; 90% of the dose appears in the urine over 24 h, most in the first 6 h, producing concentrations exceeding 500 mg/L.

TOXICITY AND SIDE EFFECTS

Side effects described are those common to oral cephalosporins.

CLINICAL USE

It has been used for various community-acquired infections for which oral cephalosporins are appropriate.

Preparations and dosage

Proprietary name: Baxan.

Preparations: Capsules, suspension, tablets.

Dosage: Adults, oral, ≥ 40 kg, 0.5–1 g every 12 h. Children <1 year, 25 mg/kg per day in divided doses; children 1–6 years, 250 mg every 12 h; children >6 years, 500 mg every 12 h.

Widely available.

Tanrisever B, Santella PJ. Cefadroxil. A review of its antibacterial, pharmacokinetic and therapeutic properties in comparison with cephalexin and cephradine. *Drugs*. 1986;32(suppl 3):1–16.

CEFALEXIN

Cephalexin. Molecular weight (monohydrate): 365.4.

ANTIMICROBIAL ACTIVITY

Activity against common pathogens is shown in Table 13.2. It is resistant to staphylococcal β -lactamase. Gram-positive rods and fastidious Gram-negative bacilli, such as *Bordetella* spp. and *H. influenzae*, are relatively resistant. It is active against a range of enterobacteria, but it is degraded by many enterobacterial β -lactamases. *Citrobacter*, *Edwardsiella*, *Enterobacter*, *Hafnia*, *Providencia* and *Serratia* spp. are all resistant. Gram-negative anaerobes other than *B. fragilis* are susceptible. Because of its mode of action (p. 13) it is only slowly bactericidal to Gram-negative bacilli.

PHARMACOKINETICS

Oral absorption	>90%
C_{\max} 500 mg oral	c. 10–20 mg/L after 1 h
Plasma half-life	0.5–1 h
Volume of distribution	15 L
Plasma protein binding	10–15%

Absorption and distribution

It is almost completely absorbed when given by mouth, the peak concentration being delayed by food. Intramuscular preparations are not available: injection is painful and produces delayed peak plasma concentrations considerably lower than those obtained by oral administration.

In synovial fluid, levels of 6–38 mg/L have been described after a 4 g oral dose, but penetration into the CSF is poor. Useful levels are achieved in bone (9–44 mg/kg after 1 g orally) and in purulent sputum. Concentrations of 10–20 mg/L have been found in breast milk. Concentrations in cord blood following a maternal oral dose of 0.25 g were minimal.

Metabolism and excretion

It is not metabolized. Almost all the dose is recoverable from the urine within the first 6 h, producing urinary concentrations exceeding 1 g/L. The involvement of tubular secretion is indicated by the increased plasma peak concentration and reduced urinary excretion produced by probenecid. Renal clearance is around 200 mL/min and is depressed in renal failure, although a therapeutic concentration is still obtained in the urine. It is removed by peritoneal and hemodialysis. Some is excreted in the bile, in which therapeutic concentrations may be achieved.

TOXICITY AND SIDE EFFECTS

Nausea, vomiting and abdominal discomfort are relatively common. Pseudomembranous colitis has been described and overgrowth of *Candida* with vaginitis may be troublesome. Otherwise, mild hypersensitivity reactions and biochemical changes common to cephalosporins occur. Very rare neurological disturbances have been described, particularly in patients in whom very high plasma levels have been achieved. There are rare reports of Stevens–Johnson syndrome and toxic epidermal necrolysis.

CLINICAL USE

As for group 2 cephalosporins (p. 172). It should not be used in infections in which *H. influenzae* is, or is likely to be, implicated. It should not be used as an alternative to penicillin in syphilis.

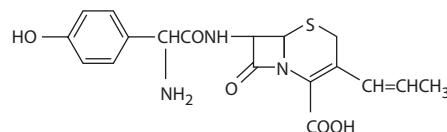

Preparations and dosage

Proprietary names: Keflex, Ceporex.

Preparations: Capsules, tablets, suspension.

Dosage: Adults, oral, 1–2 g per day in divided doses; for severe infections, increase dose to 1 g every 8 h or 3 g every 12 h. Children, 25–50 mg/kg per day in 2–3 divided doses, for severe infection increase dose to 100 mg/kg per day in 4 divided doses (maximum dose, 4 g per day).

Widely available.

A semisynthetic oral cephalosporin formulated as the monohydrate.

ANTIMICROBIAL ACTIVITY

Activity against Gram-positive cocci and Gram-negative bacilli is better than that of cefadroxil (which it structurally resembles) but is not as good as that of group 5 agents (Tables 13.2 and 13.5). It is moderately stable to hydrolysis by the common plasmid-mediated β -lactamases, but is hydrolyzed by the chromosomal enzymes of Gram-negative bacilli (p. 230).

PHARMACOKINETICS

Oral absorption	>90%
C_{max} 250 mg oral	5–7 mg/L after 1 h
500 mg oral	10 mg/L after 1
Plasma half-life	1–1.4 h
Volume of distribution	15–20 L
Plasma protein binding	35–45%

Absorption and distribution

It is almost completely absorbed and well distributed, penetrating well into tonsillar and other tissues and inflammatory exudate. Absorption is unaffected by food or antacids and there is no accumulation on multiple dosing regimens.

Metabolism and excretion

Most of the dose is excreted unchanged in urine, though about 20% is found in feces. Urinary concentrations after a 500 mg oral dose usually exceed 1 g/L. The elimination half-life is prolonged in patients with renal impairment, reaching 6 h in anuric patients. About half the drug is removed in 3 h by hemodialysis.

TOXICITY AND SIDE EFFECTS

It is well tolerated. Diarrhea and gastrointestinal discomfort may occur. There have been a few reports of pseudomembranous colitis and serum sickness-like reactions.

CEFPROZIL

Molecular weight (monohydrate): 407.5.

CLINICAL USE

It has been used for various infections for which oral cephalosporins are appropriate.

Preparations and dosage

Proprietary name: Cefzil.

Preparations: Tablets, suspension.

Dosage: Adults, oral, 250–500 mg every 12–24 h depending on infection being treated. Children, 7.5–15 mg/kg every 12 h.

Available in the UK, USA and continental Europe.

Further information

OTHER GROUP 2 CEPHALOSPORINS

CEFATRIZINE

A semisynthetic cephalosporin formulated for oral use. The spectrum is similar to that of cefalexin but it is more active against *H. influenzae* (Table 13.2). Wide strain variations in susceptibility have been reported.

It is only partially absorbed when given by mouth. A 500 mg oral dose achieves a concentration of *c.* 6 mg/L after 1–2 h. The normal half-life of 2.5 h is extended to 5.5 h in end-stage renal failure. Distribution resembles that of cefalexin. It crosses the placenta readily. Plasma protein binding is 40–60%.

Urinary recovery in 6 h is 35% of an oral dose, producing urinary levels of 50–1500 mg/L. It is presumed that the remainder is metabolized, but no metabolites have been identified.

Apart from some mild diarrhea, it is well tolerated. It is available in Japan.

Further information

Santella PJ, Tanrisever B. Cefatrizine: a clinical overview. *Drugs Exp Clin Res*. 1985;11:441–445.

CEFRADINE

Cefradine. A semisynthetic cephalosporin available in both oral and injectable forms. The antibacterial spectrum and susceptibility to β -lactamases are almost identical to those of cefalexin (Table 13.2).

It is almost completely absorbed when given by mouth. A 500 mg oral dose achieves a concentration of about 18–20 mg/L after 1 h. The peak is delayed and reduced by food, but the half-life is not altered. Intramuscular administration of 1 g results a plasma concentration of 10–12 mg/L within 2 h. The plasma half-life is around 1 h and protein binding low.

Concentrations of up to 40% of those simultaneously found in the serum have been demonstrated in lung tissue. Penetration into the CSF is poor. Levels in sputum were about 20% of those simultaneously present in the plasma following a 1 g oral dose and similar levels have been found in bone. Breast milk concentrations approaching 1 mg/L have been found after 500 mg orally every 6 h and similar concentrations have been found in amniotic fluid. Cord blood concentration is said to be similar to that in the maternal blood.

It is excreted unchanged in the urine mostly in the first 6 h, achieving concentrations exceeding 1 g/L. Probenecid markedly increases the plasma concentration and delays the peak. There is some biliary excretion.

The parenteral forms may give rise to local pain or thrombophlebitis. Other side effects common to cephalosporins have been described. In some patients *Candida vaginitis* has been troublesome.

Clinical use is similar to that of cefalexin, but it has been largely superseded by later cephalosporins.

Preparations and dosage

Proprietary name: Velosef.

Preparations: Capsules, syrup, injection.

Dosage: Adults, oral, 250–500 mg every 6 h, or 0.5–1 g every 12 h (maximum dose, 4 g per day). Children, 25–100 mg/kg per day in 2–4 divided doses.

Adults, i.m., i.v., 2–8 g per day in divided doses depending on severity of infection. Children, 50–100 mg/kg per day in four divided doses; more serious illnesses may require 200–300 mg/kg per day.

Widely available.

Further information

Anonymous. Cefradine. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C150–C152.

CEFROXADINE

Cefroxadine is closely related to cefradine, the structure differing only by the presence of a methoxy group replacing methyl

at the C-3 position. The antimicrobial spectrum is identical to that of cefradine and cefalexin (Table 13.2). A dose of 1 g as film-coated tablets produced mean peak plasma levels of 25 mg/L at 1 h. Absorption is depressed and delayed by administration with food. The plasma elimination half-life is 0.8 h, rising to 40 h in end-stage renal failure and falling to 3.4 h during hemodialysis. Around 85% of an oral dose is excreted unchanged in the urine. It is available in Japan.

Further information

LORACARBEF

An oral carbacephem, with carbon replacing sulfur in the fused ring structure. Its structure and properties are otherwise closely related to those of cefaclor, but it has improved chemical stability. Activity and stability to β -lactamases correspond closely to those of cefaclor (Table 13.2).

It is almost completely absorbed by the oral route, but food delays absorption. A 500 mg oral dose achieves a serum concentration of around 16 mg/L after 1.3 h. Adequate concentrations are achieved for the treatment of upper respiratory tract infection. Sputum concentrations have been found to be around 2% of the corresponding plasma level. The plasma half-life is about 1 h and protein binding is 25%.

Most of the dose is excreted unchanged in the urine, 60% within 12 h. The elimination half-life is increased in patients with impaired renal function. Probenecid delays excretion.

Table 13.3 Activity of group 3 cephalosporins against common pathogenic bacteria: MIC (mg/L)

	Cefoperazone	Cefmetazole	Cefminox	Cefotetan	Cefotiam	Cefoxitin	Cefuroxime
<i>Staphylococcus aureus</i>	8	1	8–16	8–16	1	2–8	1–4
<i>Streptococcus pyogenes</i>	2–8	0.5	4–8	1	0.03	0.25–1	0.03–0.1
<i>Str. pneumoniae</i>	2–4	0.5	0.5–2	2	0.25	1–2	0.03–0.1
<i>Enterococcus faecalis</i>	R	R	R	R	R	R	R
<i>Neisseria gonorrhoeae</i>		0.5	0.5–1	0.5–1	0.1	0.1–0.5	0.06–0.1
<i>N. meningitidis</i>		0.25		0.1	0.06	0.25	0.06
<i>Haemophilus influenzae</i>	1	4–8	0.25–2	1–4	0.5	2–4	0.5
<i>Escherichia coli</i>	0.25	1–2	0.25–2	0.1–0.5	0.1	2–8	1–4
<i>Klebsiella pneumoniae</i>	0.5	1–2	0.5–1	0.1–0.5	0.5	2–8	2–4
<i>Pseudomonas aeruginosa</i>	R	R	R	R	R	R	R
<i>Bacteroides fragilis</i>	2	4–R	0.5–4	4–32	R	4–32	4–64

R, resistant (MIC >64 mg/L).

Diarrhea is the most prominent side effect, occurring in about 4% of patients. Other gastrointestinal upsets are also reported. It has been used for the oral treatment of upper respiratory tract infection, skin and soft-tissue infections, and uncomplicated urinary tract infection caused by sensitive organisms, but is not widely available.

GROUP 3 CEPHALOSPORINS

CEFOXITIN

Molecular weight (sodium salt): 449.4.

A semisynthetic cephamycin available as the sodium salt for intramuscular or intravenous injection.

ANTIMICROBIAL ACTIVITY

Its activity against common pathogenic bacteria is shown in Table 13.3. Most Gram-positive bacilli are susceptible, but

L. monocytogenes is resistant. It is resistant to many Gram-negative β -lactamases and is active against organisms elaborating them, including some *Citrobacter*, *Providencia*, *Serratia* and *Acinetobacter* spp. *Enterobacter* spp. are resistant. It is moderately active against *Bacteroides* spp., but considerable strain variation in susceptibility occurs.

ACQUIRED RESISTANCE

Resistant strains of *Bacteroides*, some of which produce β -lactamases that hydrolyze cefoxitin, have been described. Resistance may be transferable to other *Bacteroides* spp. It is a potent inducer of chromosomal cephalosporinases of certain Gram-negative bacilli (p. 230) and can antagonize the effect of cefotaxime and other β -lactam agents.

PHARMACOKINETICS

C_{max} 500 mg intramuscular	11 mg/L after 20 min
1 g intravenous	c. 150 mg/L end injection
Plasma half-life	0.7–1 h
Volume of distribution	c. 10 L
Plasma protein binding	65–80%

Absorption

It is not absorbed when given orally, but is very rapidly absorbed from intramuscular sites. Doubling the dose approximately doubles the plasma level. It is absorbed from suppositories to varying degrees depending on the adjuvants: peak serum levels around 9.8 mg/L have been obtained after a dose of 1 g, giving a bioavailability of around 20%. In infants and children treated with 150 mg/kg per day, mean serum concentrations 15 min after intravenous and intramuscular administration were 81.9 and 68.5 mg/L, with elimination half-lives of 0.70 and 0.67 h, respectively.

Distribution

About 20% of the corresponding serum levels are found in sputum. In patients given 1 g by intravenous bolus preoperatively, concentrations in lung tissue at 1 h were around 13 mg/g. Penetration into normal CSF is very poor; even in patients with purulent meningitis CSF concentrations seldom exceed 6 mg/L. In children with meningitis receiving 75 mg/kg every 6 h, peak concentrations of 5–6 mg/L were found around 1 h after the dose. In patients receiving 2 g intravenously before surgery, the mean penetrance into peritoneal fluid was 86%. In patients receiving 2 g intramuscularly before hysterectomy, mean concentrations in pelvic tissue were 7.8 mg/g. Breast milk contained 5–6 mg/L after a 1 g intravenous dose. Concentrations up to 230 mg/L have been found in bile after 2 g intravenously.

Metabolism and excretion

Less than 5% of the drug is desacylated and in a few subjects deacylation of 1 or 2% of the dose to the antibacterially inactive descarbamyl form also occurs.

It is almost entirely excreted in the urine by both glomerular filtration and tubular secretion, 80–90% being found in the first 12 h after a parenteral dose, producing concentrations in excess of 1 g/L. Furosemide, in doses of 40–160 mg, had no effect on the elimination half-life of doses of 1 or 2 g. Probenecid delays the plasma peak and decreases the renal clearance and urine concentration. The renal clearance has been calculated variously to lie between 225 and 330 mL/min. The plasma half-life increases inversely with creatinine clearance to reach 24 h in oliguric patients, with corresponding reduction in total body clearance. In patients on peritoneal dialysis, peritoneal clearance accounted for only 7.5% of mean plasma clearance and the mean plasma half-life during 6 h dialysis was 7.8 h.

TOXICITY AND SIDE EFFECTS

Reactions are those common to cephalosporins. Pain on intramuscular, and thrombophlebitis on intravenous, injection occur. Substantial changes can occur in the fecal flora, with virtual eradication of susceptible enterobacteria and non-*fragilis* *Bacteroides*, and appearance of, or increase in, yeasts, enterococci and other resistant bacteria including *C. difficile*. Development of meningitis due to *H. influenzae* and *Str. pneumoniae* in patients treated for other infections has been observed.

CLINICAL USE

As for other group 3 cephalosporins, with particular emphasis on mixed infections including anaerobes, notably abdominal and pelvic sepsis. In considering its use, its low activity against aerobic Gram-positive cocci should be noted.

Preparations and dosage

Proprietary name: Mefoxin.

Preparation: Injection.

Dosage: Adults, i.m., i.v., 1–2 g every 6–8 h (maximum dose, 12 g per day in 4–6 divided doses). Children <1 week, 20–40 mg/kg every 12 h; children 1–4 weeks, 20–40 mg/kg every 8 h; children >1 month, 20–40 mg/kg every 6–8 h (maximum dose, 200 mg/kg per day).

Widely available.

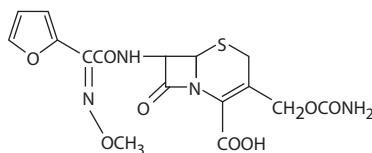

Further information

Anonymous. Cefoxitin. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C106–C109.

Brogden RN, Heel RC, Speight TM, Avery GS. Cefoxitin: a review of its antibacterial activity, pharmacological properties and therapeutic use. *Drugs*. 1979;17:1–37.
Goodwin CS. Cefoxitin 20 years on: is it still useful? *Rev Med Microbiol*. 1995;6:146–153.

CEFUROXIME

Molecular weight (sodium salt): 446.4.

A semisynthetic cephalosporin supplied as the sodium salt, or as the acetoxyethyl ester (cefuroxime axetil).

ANTIMICROBIAL ACTIVITY

Activity against common pathogenic bacteria is shown in Table 13.3. The methoximino side chain provides stability to most Gram-negative β -lactamases and it is active against most enterobacteria, including many multiresistant strains. *Acinetobacter* spp., *S. marcescens* and *Ps. aeruginosa* are resistant, although some *Burkholderia cepacia* strains are susceptible. Some anaerobic Gram-negative rods are susceptible, but *B. fragilis* is resistant. The minimum immobilizing concentration for the Nichol's strain of *T. pallidum* is 0.01 mg/L.

PHARMACOKINETICS

Oral absorption (axetil)	40–50%
C_{\max} 500 mg intramuscular	c. 18–25 mg/L after 0.5–1 h
0.75 g intravenous infusion	c. 50 mg/L end infusion
500 mg oral (axetil)	6–9 mg/L after 1.8–2.5 h
Plasma half-life	1.1–1.4 h
Volume of distribution	11–15 L
Plasma protein binding	30%

Absorption

The acetoxyethyl ester (cefuroxime axetil) is rapidly hydrolyzed on passage through the intestinal mucosa and in the portal circulation to liberate cefuroxime, acetaldehyde and acetic acid. No unchanged ester is detectable in the systemic circulation. Absorption is independent of dose in the range 0.25–1 g, and there is no accumulation on repeated dosing.

Bioavailability is improved after food to around 50%. In elderly subjects receiving doses of 500 mg every 8–12 h, peak plasma levels were 5.5 mg/L after 1.5–2 h in the fasting state, rising to 7.6 mg/L after 20 min when the dose was administered with food.

Distribution

In patients with severe meningeal inflammation, the mean CSF concentration after a 1.5 g intravenous dose was in the range 1.5–3.7 mg/L. In about one-third of patients with normal CSF, no drug could be detected and in the remainder concentrations were 0.2–1 mg/L. In children treated for meningitis with 50 or 75 mg/kg, the CSF:serum ratios were 0.07 and 0.10, respectively. Concentrations in pleural drain fluid after thoracic surgery approximated to serum levels at 2 h after doses of 1 or 1.5 g and exceeded serum levels at 4 h, when they were still around 10 mg/L. Levels in pericardial fluid were similar, with fluid:serum ratios of 0.44 between 0.5 and 2 h. In patients receiving 1.5 g by intravenous bolus preoperatively, concentrations around 22 mg/g were found in subcutaneous tissue at about 5 h with an elimination half-life of about 1.5 h.

Mean bone:serum ratios in the femoral head after 750 mg intramuscular and 1.5 g intravenous bolus injections were 0.14 and 0.23, respectively. In patients with chronic otitis media treated with 0.75 g every 8 h for 6–8 days, peak concentrations in the middle ear of 0.7–1.7 mg/L were reached about 2 h after the dose. In patients given 750 mg intramuscularly on five consecutive days the mean sputum concentration rose from 0.57 mg/L on the first day to 1.15 mg/L on the third.

Excretion

The drug is excreted unchanged in the urine mostly within 6 h of administration, producing concentrations exceeding 1 g/L. About 45–55% of the drug is excreted by tubular secretion, so that the administration of probenecid increases the serum peak and prolongs the plasma half-life. Renal clearance is slightly affected by the route of administration but lies between 95 and 180 L/min. The plasma half-life is prolonged in the elderly up to 2.4 h.

TOXICITY AND SIDE EFFECTS

It is well tolerated with little pain or phlebitis on injection. Minor hypersensitivity reactions and biochemical changes common to cephalosporins are described.

The axetil ester may cause diarrhea and, in some cases, vomiting. Changes in the bowel flora, sometimes with the appearance of *C. difficile*, have been reported in about 15% of patients. Vaginitis is reported in about 2% of female patients.

CLINICAL USE

It has been used successfully to treat urinary, soft-tissue and pulmonary infections, as well as septicemia, and as a single-dose treatment (with probenecid) of gonorrhea due to β -lactamase-producing strains. It has been widely used for surgical prophylaxis.

Preparations and dosage

Cefuroxime

Proprietary name: Zinacef.

Preparation: Injection.

Dosage: Adults, i.m., i.v., 750 mg every 6–8 h; 1.5 g every 6–8 h in severe infections. Children, 30–100 mg/kg per day in 3–4 divided doses; 50–60 mg/kg every 8 h for severe infections. Neonates, 30–100 mg/kg per day in 2–3 divided doses.

Widely available.

Cefuroxime axetil

Proprietary name: Zinnat.

Preparations: Tablets, suspension, sachets.

Dosage: Adults, oral, 250–500 mg every 12 h depending on severity of infection. Children 3 months to 2 years, 10 mg/kg (maximum 125 mg) twice daily; >2 years 15 mg/kg (maximum 250 mg) twice daily.

Widely available.

OTHER GROUP 3 CEPHALOSPORINS

CEFBUPERAZONE

A semisynthetic cephamycin antibiotic with properties similar to those of cefoxitin, but somewhat more active against *B. fragilis* and enterobacteria. It is not hydrolyzed by common β-lactamases and as a result its activity is not affected by inoculum size. Its activity against common pathogenic bacteria is shown in Table 13.3. It is not active against cefoxitin-resistant strains. It is available in Japan.

Further information

- Del Bene VE, Carek PJ, Twitty JA, Burkey LI. In vitro activity of cefbuperazone compared with that of other new β-lactam agents against anaerobic Gram-negative bacilli and contribution of β-lactamase to resistance. *Antimicrob Agents Chemother*. 1985;27:817–820.

CEFMETAZOLE

A semisynthetic cephamycin antibiotic. Activity against common pathogenic bacteria is shown in Table 13.3. It is active against *Pr. mirabilis*, *Pr. vulgaris*, *Morganella morganii*, *Yersinia* spp.

and most anaerobes. *S. marcescens* is moderately susceptible, but *Ps. aeruginosa* and *E. faecalis* are resistant. It is active against *Mycobacterium fortuitum* and some strains of *M. chelonei*. It is resistant to a wide range of β-lactamases.

The serum concentration at the end of a 1 g intravenous infusion is around 77 mg/L. Plasma protein binding is 68%. It is principally excreted in the urine with a plasma half-life of c. 1.3 h; 70% is recovered over the first 6 h. In patients whose creatinine clearance is less than 10 mL/min, plasma levels are elevated and the plasma half-life is increased to around 15 h.

Side effects associated with the methylthiotetrazole group at position C-3 have been reported. Uses are similar to those of cefoxitin, but it is not widely available.

Further information

- Schentag JJ. Cefmetazole sodium: pharmacology, pharmacokinetics, and clinical trials. *Pharmacotherapy*. 1991;11:2–19.

CEFMINOX

A semisynthetic cephamycin. Activity is similar to that of cefoxitin and cefotetan, but the activity against enterobacteria and *B. fragilis* is somewhat better (Table 13.3). *C. difficile* is inhibited by 4–16 mg/L. It is stable to the common β-lactamases of enterobacteria and *Bacteroides* spp.

A 15-min intravenous infusion of 1 g achieves a serum concentration of 30 mg/L after 1 h. The plasma half-life is c. 2 h and around 68% is protein bound.

Its safety profile and uses are similar to those of other cephamycins. It is available in Japan.

Further information

- Watanabe S, Omoto S. Pharmacology of cefminox, a new bactericidal cephamycin. *Drugs Exp Clin Res*. 1990;16:461–467.

CEFOTETAN

A semisynthetic cephamycin formulated as the disodium salt for intravenous administration. The activity is similar to that of cefoxitin, but cefotetan exhibits more potent activity against enterobacteria and more modest activity against *Staph. aureus* (Table 13.3).

A 1 g intravenous dose achieves a serum concentration of 140–180 mg/L. There is no evidence of accumulation on a dosage of 1 g every 12 h. Tissue fluid concentrations are about 30% of the simultaneous serum level. The plasma half-life is about 3 h and protein binding is around 88%.

About 85% of the drug is eliminated in the urine over 24 h. Accumulation in renal failure is inversely related to the creatinine clearance, the plasma half-life rising to 20 h in patients requiring hemodialysis. During hemodialysis the half-life falls to around 7.5 h and on peritoneal dialysis it falls to 15.5 h, 5–10% of the dose being recovered in the dialysate over 24 h.

Side effects are those typical of the group. Anaphylaxis has been described. Because of the methylthiotetrazole side chain there is some risk of hypoprothrombinemia, and disulfiram-like reactions can occur. Marked changes in the bowel flora, with appearance of *C. difficile*, have been reported. Uses are similar to those of other cephemycins, but it is not widely available.

Further information

Ward A, Richards DM. Cefotetan. A review of its antibacterial activity, pharmacokinetic properties and therapeutic use. *Drugs*. 1985;30:382–426.

CEFOTIAM

A semisynthetic cephalosporin formulated as the dihydrochloride for injection and as a prodrug ester, cefotiam hexetil, for oral administration. Activity is similar to that of cefuroxime, but it is somewhat more active against a range of enterobacteria (Table 13.3).

A 30-min intravenous infusion of the dihydrochloride produces a peak serum concentration of 35 mg/L; the corresponding concentration after a 1 g intramuscular dose is 17 mg/L. Oral absorption of the hexetil ester is around 65%. Food delays absorption of the ester. The plasma half-life is 0.6–1.1 h. Around 40% is bound to plasma protein.

Urinary excretion is almost complete 4 h after the end of intravenous infusion, but only 50–67% is recovered unchanged; there is substantial non-renal elimination and some evidence of saturation of renal tubular excretion at doses above 2 g. In anuria the plasma elimination half-life rises to 13 h and plasma and renal clearances parallel creatinine clearance. A small amount is excreted in bile. In patients with cholelithiasis given 0.5 or 1 g intravenously, mean concentrations in gallbladder bile and gallbladder wall 30 min after the dose were around 17 and 32 mg/L, respectively. In patients with normal liver function, hepatic bile concentrations can exceed 1 g/L.

It is generally well tolerated and has been used successfully to treat lower respiratory infections, skin and soft-tissue infection. It is not widely used, but is available in Japan and some other countries.

GROUP 4 CEPHALOSPORINS

CEFOTAXIME

Molecular weight (sodium salt): 478.5.

A semisynthetic cephalosporin available as the sodium salt for parenteral administration.

ANTIMICROBIAL ACTIVITY

The aminothiazoyl and methoximino groups at the 7-amino position confer, respectively, potent activity against many Gram-negative rods and cocci (Table 13.4) and stability to most β -lactamases. *Ps. aeruginosa*, *Sten. maltophilia* and other pseudomonads are often resistant. *Brucella melitensis* and some strains of *Nocardia asteroides* are susceptible. Activity against *L. monocytogenes* and *B. fragilis* is poor.

ACQUIRED RESISTANCE

Many enterobacteria resistant to other β -lactam agents are susceptible, but selection of resistant strains with derepressed chromosomal molecular class C cephalosporinases (see p. 230) may occur. Gram-negative bacilli producing variants of the TEM enzymes (pp. 230–231) are resistant.

PHARMACOKINETICS

C_{max} 500 mg intramuscular	10–15 mg/L after 0.5–1 h
1 g intravenous (15-min infusion)	90 mg/L end infusion
Plasma half-life	c. 1 h
Volume of distribution	32–37 L
Plasma protein binding	c. 40%

Distribution

It is widely distributed, achieving therapeutic concentrations in sputum, lung tissue, pleural fluid, peritoneal fluid, prostatic tissue and cortical bone. In patients receiving 2 g every 8 h, mean CSF concentrations in aseptic meningitis were

Table 13.4 Activity of group 4 cephalosporins against common pathogenic bacteria: MIC (mg/L)

<i>Bacteroides fragilis</i>	8–64	8–R	2–32	8–64	16–64	0.5–4

^a Penicillin-resistant strains are often less susceptible. R, resistant (MIC >64 mg/L).

0.8 mg/L. Levels of 2–15 mg/L can be found in the CSF in the presence of inflammation after doses of 50 mg/kg by intravenous infusion over 30 min. A single intraventricular dose of 40 mg/kg produced levels at 2, 4 and 6 h of 6.4, 5.7 and 4.5 mg/L, respectively.

Metabolism

About 15–25% of a dose is metabolized by hepatic esterases to the desacetyl form, which may have some clinical importance because of its concentration in bile and accumulation in renal failure. Desacetylcefotaxime has about 10% of the activity of the parent against enterobacteria, less against *Staph. aureus*. Its half-life in normal subjects is around 1.5 h.

Excretion

Elimination is predominantly by the renal route, more than half the dose being recovered in the urine over the first 24 h, about 25% as the desacetyl derivative. Excretion is depressed by probenecid and declines in renal failure with accumulation of the metabolite. In patients with creatinine clearances in the range 3–10 mL/min, the plasma half-life rose to 2.6 h while that of the metabolite rose to 10 h.

TOXICITY AND SIDE EFFECTS

Minor hematological and dermatological side effects common to group 4 cephalosporins have been described. Superinfection with *Ps. aeruginosa* in the course of treatment has occurred. Occasional cases of pseudomembranous colitis have been reported.

CLINICAL USES

Cefotaxime is widely used in neutropenic patients, respiratory infection, meningitis, intra-abdominal sepsis, osteomyelitis, typhoid fever, urinary tract infection, neonatal sepsis and gonorrhea.

Preparations and dosage

Proprietary name: Claforan.

Preparation: Injection.

Dosage: Adults, i.m., i.v., 1–2 g every 8–12 h depending on severity of infection (maximum dose, 12 g per day). Neonates, <7 days, 25 mg/kg every 12 h; 7–21 days, 25 mg/kg every 8 h; 21–28 days, 25 mg/kg every 6–8 h; children >1 month, 50 mg/kg every 8–12 h (every 6 h in severe infections and meningitis; maximum 12 g daily).

Widely available.

CEFTRIAXONE

Molecular weight (disodium salt) 600.6.

A semisynthetic cephalosporin supplied as the disodium salt.

ANTIMICROBIAL ACTIVITY

Activity is almost identical to that of cefotaxime (Table 13.4). Most β -lactamase-producing enterobacteria are highly susceptible, as are streptococci (but not enterococci) and fastidious Gram-negative bacilli, although brucellae are less sensitive (MIC 0.25–2 mg/L). Treatment failure has been reported in tularemia. *Ps. aeruginosa*, mycoplasmas, mycobacteria and *L. monocytogenes* are resistant.

ACQUIRED RESISTANCE

It is hydrolyzed by some chromosomal enzymes, including those of *Enterobacter* spp. and *B. fragilis*. Derepression of chromosomal β -lactamase production can cause resistance in some species of Gram-negative bacilli in vitro and has been observed in patients.

PHARMACOKINETICS

C_{max} 500 mg/L intramuscular 1 g intravenous (15–30-min infusion)	c. 40 mg/L after 2 h c. 120–150 mg/L end infusion
Plasma half-life	6–9 h
Volume of distribution	0.15 L/kg
Plasma protein binding	95%

Distribution

It penetrates well into normal body fluids and natural and experimental exudates. In children treated for meningitis with 50 or 75 mg/kg intravenously over 10–15 min, mean peak CSF concentrations ranged from 3.2 to 10.4 mg/L, with lower values later in the disease. In patients receiving 2 g before surgery, concentrations in cerebral tissue reached 0.3–12 mg/L. In patients with pleural effusions of variable etiology given a 1 g intravenous bolus, concentrations of 7–8.7 mg/L were found at 4–6 h. In patients with exacerbations of rheumatoid arthritis receiving the same dose, joint fluid contained concentrations close to those in the serum, but with wide individual

variation. Tissue fluid:serum ratios have varied from around 0.05 in bone and muscle to 0.39 in cantharides blister fluid. The apparent volume of distribution is increased in patients with cirrhosis where the drug rapidly enters the ascitic fluid, but its elimination kinetics are unaffected.

It rapidly crosses the placenta, maternal doses of 2 g intravenously over 2–5 min producing mean concentrations in cord blood of 19.5 mg/L, a mean cord:maternal serum ratio of 0.18; and in amniotic fluid 3.8 mg/L, a fluid:maternal serum ratio of 0.04. The plasma elimination half-life appears to be somewhat shortened in pregnancy (5–6 h). Some appear in the breast milk, the milk:serum ratio being about 0.03–0.04, secretion persisting over a long period with a half-life of 12–17 h.

Metabolism and excretion

It is not metabolized. Biliary excretion is unusually high, 10–20% of the drug appearing in the bile in unchanged form, with concentrations up to 130 mg/g in biopsied liver tissue from patients receiving 1 g intravenously over 30 min. The insoluble calcium salt may precipitate in the bile leading to pseudolithiasis. About half the dose appears in the urine over the first 48 h, somewhat more (c. 70%) in neonates. Excretion is almost entirely by glomerular filtration, since there is only a small effect of probenecid on the excretion of the drug. The half-life is not linearly correlated with creatinine clearance in renal failure and, in keeping with the low free plasma fraction, it is not significantly removed by hemodialysis. The volume of distribution is not affected by renal failure.

TOXICITY AND SIDE EFFECTS

Reactions are those common to other cephalosporins. Mention has been made of thrombocytopenia, thrombocytosis, leukopenia, eosinophilia, abdominal pain, phlebitis, rash, fever and increased values in liver function tests. Diarrhea is common and suppression of the aerobic and anaerobic fecal flora has been associated with the appearance of resistant bacteria and yeasts.

Biliary pseudolithiasis due to concretions of insoluble calcium salt has been described in adults but principally in children. The precipitates can be detected in a high proportion of patients by ultrasonography and can occasionally cause pain, but resolve on cessation of treatment. The drug is better avoided in patients with pre-existing biliary disease, but the principal hazard appears to be misdiagnosis of gallbladder disease and unnecessary surgery.

CLINICAL USES

Uses are similar to those of cefotaxime, the long half-life offering the advantage of once-daily administration. It is used in the treatment of acute bacterial meningitis and as an alternative to rifampicin (rifampin) in the prophylaxis of meningo-coccal disease.

 Preparations and dosage
<p>Proprietary name: Rocephin.</p> <p>Preparation: Injection.</p> <p>Dosage: Adults, i.m., i.v., 1 g per day as a single dose, 2–4 g once or twice each day in severe infections. Neonates, i.v. infusion, 20–50 mg/kg once daily; children >1 month, 50 mg/kg once daily, increased up to 80 mg/kg in severe infections and meningitis; older children weighing >50 kg, 1 g daily, increased to 2–4 g daily in severe infections and meningitis.</p> <p>Widely available.</p>

OTHER GROUP 4 CEPHALOSPORINS

 CEFMENOXIME
<p>A semisynthetic cephalosporin supplied as the hydrochloride. Its activity is very similar to that of cefotaxime (Table 13.4). A 500 mg intramuscular injection achieves a plasma concentration of 15 mg/L after 40 min. A concentration of 200 mg/L is attained after intravenous administration of 1 g. The plasma half-life is c. 1 h. Around 77% is protein bound. Probenecid increases peak plasma levels and extends the plasma half-life to 1.8 h. Therapeutic concentrations are achieved in CSF. There is a degradation product with a long half-life (around 40 h), but 80–92% of the drug is recovered unchanged from the urine. In patients with renal insufficiency, no significant relation was found between creatinine clearance and peak serum concentrations but there was a linear relationship with plasma half-life and total body clearance. About 10% of the dose appears in the feces, mostly extensively degraded, possibly by the fecal flora.</p>

Toxicity, side effects and clinical use are those common to group 4 cephalosporins.

 Further information
<p>Campoli-Richards DM, Todd PA. Cefmenoxime. A review of its antibacterial activity, pharmacokinetic properties and therapeutic use. <i>Drugs</i>. 1987;34:188–221.</p>

 CEFODIZIME

Activity is typical of the group (Table 13.4) but its overall activity is somewhat less than that of cefotaxime against enterobacteria. There has been some interest in its immunomodulating properties, which affect a number of functions.

A 1 g intramuscular dose achieves a plasma concentration of 55–60 mg/L after about 1.5 h. The plasma half-life is around 3.5 h. Protein binding is c. 88%. It penetrates into lung, sputum, serous fluids and prostate. Excretion is mainly renal with about 60% of the dose appearing in the urine over 12 h in adults and 80–90% in children. Elimination is inversely correlated with creatinine clearance.

It is well tolerated apart from some pain at the site of injection, mild gastrointestinal upset and rash in a few patients. It has been used mainly to treat respiratory and urinary tract infection.

 Further information

Anonymous. Cefodizime (sodium). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C96–C100.

Barradell LB, Brogden RN. Cefodizime: a review of its antibacterial activity, pharmacokinetic properties and therapeutic use. *Drugs*. 1992;44:800–834.

 CEFTIZOXIME

A semisynthetic cephalosporin supplied as the sodium salt. The properties are very similar to those of cefotaxime, but it lacks the acetoxyethyl group at position C-4 and is therefore not subject to deacetylation. Activity against common pathogenic bacteria (Table 13.4) is very similar to that of cefotaxime.

A 500 mg intramuscular injection achieves a plasma concentration of around 14 mg/L. A concentration of 85–90 mg/L is produced 30 min at the end of a 30-min intravenous infusion. The plasma half-life is 1.3–1.9 h. Protein binding is 30%. It is well distributed. In children with meningitis receiving 200–250 mg/kg per day in four equally divided doses for 14–21 days, mean CSF concentrations 2 h after a dose were 6.4 mg/L on day 2 and 3.6 mg/L on day 14.

About 70–90% of the dose is recovered in the urine in the first 24 h, principally by glomerular filtration. Probenecid increases the plasma half-life by about 50%. In patients receiving 1 g intravenously over 30 min, the plasma elimination half-life rose to 35 h when the corrected creatinine clearance was <10 mL/min. It is partly removed by peritoneal and hemodialysis.

Adverse reactions and clinical use are similar to those of cefotaxime.

 Further information

Anonymous. Ceftizoxime sodium. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C125–C130.

Richards DM, Heel RC. Ceftizoxime. A review of its antibacterial activity, pharmacokinetic properties and therapeutic use. *Drugs*. 1985;29:281–329.

FLOMOXEF

An oxa-cephem which differs from latamoxef in the side chains carried at the 7-amino and C-3 positions, but which retains the 7-methoxy group that confers β -lactamase stability. The methyl group of the methylthiotetrazole side chain of latamoxef has been modified to hydroxymethyl in an attempt to avoid the undesirable side effects, while the side chain at the 7-amino position is $\text{F}_2\text{-CH-S-CH}_2^-$.

Activity is similar to that of latamoxef, but activity against *Staph. aureus* is improved and it is claimed to be a poor inducer of penicillin-binding protein 2', which is associated with resistance in methicillin-resistant strains.

Intravenous injection of 2 g achieves a peak plasma concentration of around 50 mg/L, falling to 2.6 mg/L after 6 h. The plasma half-life is about 50 min. It appears to be well distributed and penetrates moderately well into lung, mucosal tissue of the middle ear and bone.

Flomoxef does not seem to be prone to the effects on platelet function of latamoxef and it has a less marked effect on vitamin K metabolism. It does not cause a disulfiram-like reaction with alcohol.

It is available in Japan, where it appears safe and effective in a wide range of infections.

LATAMOXEF

Moxalactam. A semisynthetic 7-methoxyoxacephem, supplied as the disodium salt. Activity against common pathogenic bacteria is shown in Table 13.4. It is generally slightly less active than cefotaxime, especially against *Staph. aureus*, but unlike other group 4 cephalosporins it exhibits fairly good activity against *B. fragilis*. Other *Bacteroides* spp. are generally less susceptible. The 7-methoxy substitution, also found in cephamycins such as cefoxitin, confers resistance to hydrolysis by a wide range of β -lactamases including those of *Staph. aureus*, various enterobacteria and *B. fragilis*. Resistance, predominantly in *Enterobacter* spp., *Ps. aeruginosa* and *Ser. marcescens* due to induction of chromosomal enzymes (p. 230), has been found in vitro and in some patients.

A 500 mg intramuscular injection achieves a serum concentration of 12–22 mg/L after 1.2 h. Infusion of 1 g over 30 min results in a concentration of 60 mg/L. The plasma half-life is c. 2 h and plasma protein binding 40–50%. There is

reasonably good penetration into serous fluids, the concentration in ascitic fluid reaching 75% and in pleural fluid 50% of the concentration simultaneously present in the serum. Levels of 5–35 mg/L have been obtained in inflamed meninges. Sputum levels are of the order of 2 mg/L following 1 g of the drug intravenously.

Renal elimination accounts for 90% of the clearance, but significant concentrations are found in the feces. Excretion is depressed in renal failure. Hemodialysis removes 48–51% of the drug in 4 h; peritoneal dialysis has little or no effect.

Increased bleeding and decreases in platelet function associated with the methylthiotetrazole side chain are sufficiently common to have been cited as reasons for restricting use of the agent. Use is contraindicated in patients on anticoagulant therapy. Uses are similar to those of group 4 cephalosporins. It is generally less successful in the treatment of infections due to Gram-positive organisms.

GROUP 5 CEPHALOSPORINS

CEFDITOREN

Molecular weight (pivoxil ester): 620.73

A semisynthetic cephalosporin formulated for oral use as the pivoxiloyloxymethyl ester, cefditoren pivoxil.

ANTIMICROBIAL ACTIVITY

Activity against common pathogens is shown in Table 13.5. It exhibits good activity against staphylococci, streptococci (but not enterococci), *H. influenzae* and *M. catarrhalis*, including β -lactamase-producing strains. Isolates of *Str. pneumoniae* exhibiting reduced susceptibility to penicillin are less susceptible (MIC 0.125–2 mg/L). Most enterobacteria, including many *Enterobacter*, *Citrobacter*, *Serratia* and *Proteus* spp., are susceptible. It is not active against *Ps. aeruginosa*, *Sten. maltophilia* or atypical respiratory pathogens such as *Chlamydophila pneumoniae* and *M. pneumoniae*. It is stable to staphylococcal and common enterobacterial β -lactamases.

Table 13.5 Activity of group 5 cephalosporins against common pathogenic bacteria: MIC (mg/L)

	Cefdinir	Cefditoren	Cefixime	Cefpodoxime	Ceftibuten
<i>Staphylococcus aureus</i>	0.002–1	1	4–16	0.5	32
<i>Streptococcus pyogenes</i>	<0.06–0.25	\leq 0.01	0.01–0.25	0.06	8–16

<i>Pseudomonas aeruginosa</i>	R	R	2–32	R	R
<i>Bacteroides fragilis</i>	R	4–32	R	R	R

R, resistant (MIC >64 mg/L).

PHARMACOKINETICS

Oral absorption	c. 70%
C_{\max} 200 mg oral	c. 1.8 mg/L after 1.5–3 h
Plasma half-life	0.8–1.3 h
Volume of distribution	9.3 L
Plasma protein binding	88%

After oral administration the pivaloyl ester is rapidly cleaved by esterases in the gut wall. Ingestion with food improves the bioavailability. Plasma concentrations are raised in elderly patients. There is no accumulation on repeated dosing.

It is excreted unchanged in the urine with a half-life of around 1.5 h, achieving a concentration of 150–200 mg/L within 4 h. Dosage adjustment is recommended in patients with deteriorating renal function.

TOXICITY AND SIDE EFFECTS

In common with other pivoxil esters it may cause carnitine deficiency. Other side effects are those common to cephalosporins, mainly gastrointestinal disturbance.

CLINICAL USE

It has been advocated for community-acquired upper and lower respiratory tract infections and skin infections.

Preparations and dosage

Proprietary name: Spectacef.

Preparation: 200 mg tablets.

Dosage: 400 mg every 12 h for 10 days.

Available in USA and Japan; not available in the UK.

CEFIXIME

Molecular weight (anhydrous): 453.4; (trihydrate): 507.5.

An oral cephalosporin formulated as the anhydrous compound or the trihydrate.

ANTIMICROBIAL ACTIVITY

Activity against common pathogenic bacteria is shown in Table 13.5. It is active against *N. gonorrhoeae*, *M. catarrhalis*, *H. influenzae* and a wide range of enterobacteria, including most strains of *Citrobacter*, *Enterobacter* and *Serratia* spp. Its antistaphylococcal activity is poor. It is not active against *Acinetobacter* spp., *Ps. aeruginosa* or *B. fragilis*. It is resistant to hydrolysis by common β -lactamases.

Preparations and dosage

Proprietary name: Suprax.

Preparations: Tablets, suspension.

Dosage: Adults, oral, 200–400 mg per day as a single dose or in two divided doses. Children >6 months, 8 mg/kg per day (maximum 400 mg) as a single dose or in two divided doses.

Widely available.

PHARMACOKINETICS

Oral absorption	c. 50%
C_{\max} 400 mg oral	4–5.5 mg/L after 4 h
Plasma half-life	3–4 h
Volume of distribution	0.1 L/kg
Plasma protein binding	60–70%

Absorption and distribution

Oral absorption is slow and incomplete, but is unaffected by aluminum magnesium hydroxide. Penetration into cantharides blister fluid was very slow but exceeded the plasma level. CSF concentrations are poor even in the presence of meningeal inflammation, reaching an average of around 0.22 mg/L in children with meningitis.

Metabolism and excretion

It is not metabolized and is excreted unchanged in urine (mainly by glomerular filtration) and in bile, in which concentrations exceeding 100 mg/L have been found. Less than 20% of an oral dose is recovered from the urine over 24 h, falling to less than 5% in patients with severe renal impairment, with a corresponding increase in plasma concentration. It is not removed by peritoneal or hemodialysis.

TOXICITY AND SIDE EFFECTS

It is well tolerated, but diarrhea is fairly common and pseudomembranous colitis has been reported. Other side effects common to cephalosporins are occasionally seen.

CLINICAL USE

Cefixime has been used successfully in uncomplicated cystitis, upper and lower respiratory tract infections and various other infections. Its failure to provide adequate cover for staphylococci should be noted.

CEFPODOXIME

Molecular weight (proxetil ester): 557.6.

A semisynthetic cephalosporin supplied as the prodrug ester, cefpodoxime proxetil.

ANTIMICROBIAL ACTIVITY

The hydrolysis product is very similar to cefotaxime and it shares its potent, broad-spectrum activity (Table 13.5). It is stable to a wide range of plasmid-mediated β -lactamases. It induces the chromosomal β -lactamases of *Ps. aeruginosa*, *Enterobacter* spp., *S. marcescens* and *Citrobacter* spp., but is a less potent inducer than cefoxitin.

PHARMACOKINETICS

Oral absorption	c. 50%
C_{max} 200 mg oral	2.1 mg/L after 3 h
Plasma half-life	c. 2.2 h
Volume of distribution	c. 35 L
Plasma protein binding	20–30%

Absorption and distribution

The ester is rapidly hydrolyzed to the parent compound in the small intestine. Bioavailability increases to 65% if taken with food, but antacids and H₂-receptor antagonists reduce absorption. Unabsorbed drug is hydrolyzed and excreted in the feces.

It is well distributed and penetrates well into tissues (including lung tissue) and inflammatory exudate to achieve concentrations inhibitory to common pathogens.

Metabolism and excretion

The hydrolyzed prodrug is not subject to further metabolism. About 80% of the absorbed compound (30–40% of the original dose) appears in the urine over 24 h. Excretion is by glomerular filtration and tubular secretion; probenecid delays secretion and increases the peak plasma concentration.

TOXICITY AND SIDE EFFECTS

The drug is well tolerated, but gastrointestinal disturbance with diarrhea is common. Pseudomembranous colitis has been reported occasionally. Other side effects are those common to cephalosporins.

CLINICAL USE

Cefpodoxime has been used principally for the treatment of upper and lower respiratory tract infections in children and adults.

Preparations and dosage

Proprietary name: Orelox, Vantin.

Preparations: Tablets, suspension.

Dosage: Adults, oral, 200–400 mg every 12 h depending on infection being treated. Children, 8 mg/kg per day in two divided doses.

Widely available.

OTHER GROUP 5 CEPHALOSPORINS

CEFCAPENE

A semisynthetic cephalosporin formulated for oral administration as the prodrug ester, cefcapene pivoxil. Activity and uses are similar to those of cefditoren.

Available in Japan.

CEFDINIR

An oral cephalosporin similar in structure to cefixime, but with a slightly modified side chain at the 7-amino position. Activity is similar to that of cefixime, but it is more active, especially against staphylococci (Table 13.5). It is not hydrolyzed by staphylococcal or the common plasmid-mediated enterobacterial β -lactamases. An enhancing effect on phagocytosis has been demonstrated in vitro.

Oral absorption is about 35%. A 200 mg oral dose achieves a plasma concentration of 1 mg/L after c. 3 h. Absorption is reduced after a fatty meal. Concentrations equal to or higher than corresponding plasma levels were present in blister fluid 6–12 h after administration of an oral dose. The plasma half-life is 1.5 h. Protein binding is 60–70%. A total of 12–20% of the dose was excreted in the urine within 12 h, the renal elimination declining with increasing dose. The elimination half-life and peak plasma concentration are increased in renal failure. About 60% of the drug is removed by hemodialysis.

Side effects and uses are those common to oral cephalosporins.

Further information

Guay DR. Cefdinir: an expanded-spectrum oral cephalosporin. *Ann Pharmacother*. 2000;34:1469–1477.

Perry CM, Scott LJ. Cefdinir: a review of its use in the management of mild-to-moderate bacterial infections. *Drugs*. 2004;64:1433–1464.

CEFETAMET

A semisynthetic cephalosporin formulated for oral use as the prodrug ester, cefetamet pivoxyl. It is less active than cefaclor and cefadroxil against *Staph. aureus*, but as active against streptococci and more active against enterobacteria, *H. influenzae* and *N. gonorrhoeae*, including β -lactamase-producing strains. *L. monocytogenes*, *C. difficile*, *Sten. maltophilia* and *Burk. cepacia* are all resistant. It is resistant to hydrolysis by common plasmid-mediated enzymes.

The absolute bioavailability is about 50%. The plasma peak is delayed by food. Binding to plasma protein is about 20%. The volume of distribution approximates to the extracellular water. It is excreted into urine with a half-life of 2–2.5 h, principally in the glomerular filtrate. Elimination is linearly related to creatinine clearance. Side effects and uses are similar to those of other group 5 cephalosporins.

Further information

Bryson HM, Brogden RN. Cefetamet pivoxyl: a review of its antibacterial activity, pharmacokinetic properties and therapeutic use. *Drugs*. 1993;45:589–621.

CEFTERAM

A semisynthetic cephalosporin formulated for oral administration as the prodrug ester, ceftoram pivoxil. Activity is similar to that of cefixime, but with slightly better activity against staphylococci and some Gram-negative rods.

Available in Japan.

CEFTIBUTEN

A semisynthetic cephalosporin formulated as the dihydrate for oral administration.

Activity against common pathogens is shown in Table 13.5. It exhibits good activity against many Gram-negative bacilli, but its activity against Gram-positive cocci is very poor. It is stable to hydrolysis by the common plasmid-mediated β -lactamases, but not derepressed chromosomal enzymes (see p. 230).

It is rapidly and almost completely absorbed by mouth and is excreted in the urine with a half-life of 1.5–3 h. An oral dose of 400 mg achieves a peak plasma concentration of around 15 mg/L. Binding to plasma proteins is 65–77%.

Side effects mostly consist of mild gastrointestinal symptoms and mild liver function test changes. Clinical trials have mainly been conducted in urinary tract and respiratory tract infections which, despite the poor in-vitro activity against *Str. pneumoniae*, have shown ceftibuten to be as efficacious as comparator agents.

Preparations and dosage

Proprietary name: Cedax.

Preparations: Capsules, suspension.

Dosage: Adults and children >10 years (>45 kg), oral, 400 mg per day as a single dose. Children >6 months, 9 mg/kg per day as a single dose.

Available in USA and Japan; not available in the UK.

Further information

GROUP 6 CEPHALOSPORINS

CEFEPIME

Molecular weight (dihydrochloride monohydrate): 571.5.

A semisynthetic parenteral cephalosporin formulated as the hydrochloride with arginine as a pH stabilizer.

ANTIMICROBIAL ACTIVITY

Its activity against common pathogens (Table 13.6) is comparable to that of group 4 cephalosporins, but it is somewhat more active against *Ps. aeruginosa*. Like cefpirome it has low affinity for the molecular class C cephalosporinases of many Gram-negative rods (p. 230) and is consequently active against most strains of *Citrobacter* spp., *Enterobacter* spp., *Serratia* spp. and *Ps. aeruginosa* that are resistant to cefotaxime and ceftazidime. It has poor activity against *L. monocytogenes* and against anaerobic organisms.

PHARMACOKINETICS

C_{max} 2 g intravenous (30-min infusion)

c. 160 mg/L end infusion

Plasma half-life

c. 2 h

Volume of distribution

14–20 L

Plasma protein binding

10–19%

Table 13.6 Activity of group 6 cephalosporins against common pathogenic bacteria: MIC (mg/L)

	Cefoperazone	Cefpiramide	Cefsulodin	Ceftazidime	Cefepime	Cefpirome
<i>Staphylococcus aureus</i>	1–4	1	2–4	4–8	2–4	0.5–1
<i>Streptococcus pyogenes</i>	0.1	0.1	2	0.1–0.25	0.1	0.03
<i>Str. pneumoniae</i> ^a	0.1–0.25	0.1	4–8	0.25	<0.05	<0.05
<i>Enterococcus faecalis</i>	64–R	R	R	R	R	4–R
<i>Neisseria gonorrhoeae</i>	0.06		4–8	0.06–0.1	0.1	0.03
<i>N. meningitidis</i>	0.06		4–8	<0.01		
<i>Haemophilus influenzae</i>	0.1	0.5	32	0.1		0.1
<i>Escherichia coli</i>	0.1–2	0.5	64–R	0.1	0.1–0.5	0.1–0.5
<i>Klebsiella pneumoniae</i>	0.5–8	2	64–R	0.1	0.1–0.5	0.1–0.5
<i>Pseudomonas aeruginosa</i>	4–8	2	2	1–4	8–16	2–8
<i>Bacteroides fragilis</i>	16–32	R	R	16–64	R	R

^aPenicillin-resistant strains are often less susceptible. R, resistant (MIC >64 mg/L).

It is well distributed. Penetration into tissues, including lung, appears to be similar to that of other aminothiazoyl cephalosporins. Very low concentrations are achieved in CSF in the absence of meningeal inflammation. It is secreted in breast milk.

It is partially metabolized, but 85% of the dose is excreted unchanged in the urine, achieving a concentration approaching 1 g/L within 4 h of a 1 g intravenous dose. Dosage adjustment is required in patients with impaired renal function, but hepatic impairment does not affect the pharmacokinetic properties.

TOXICITY AND SIDE EFFECTS

It is generally well tolerated, adverse events being those typical of the group.

CLINICAL USE

It is used in the treatment of serious infections, particularly those in which resistant Gram-negative pathogens are known or suspected to be involved.

Preparations and dosage

Proprietary name: Maxipime.

Preparation: Injection.

Dosage: Adult, i.m., i.v., 1–6 g per day in 2–3 divided doses.

Available in USA, most of Europe and Japan; not available in the UK.

CEFTAZIDIME

Molecular weight (anhydrous): 546.6; (pentahydrate): 636.7.

A semisynthetic parenteral cephalosporin formulated as the pentahydrate.

ANTIMICROBIAL ACTIVITY

Its activity against common pathogenic bacteria is shown in Table 13.6. Its activity is comparable to that of cefotaxime and ceftizoxime, but it is more active against *Ps. aeruginosa*, including almost all gentamicin-resistant strains, and *Burk. cepacia*. It is, however, less active against *Staph. aureus*. It is

stable to a wide range of β -lactamases, but is hydrolyzed by some TEM variants (see pp. 230–231).

PHARMACOKINETICS

C_{max} 500 mg intramuscular	18–20 mg/L
2 g intravenous (20-min infusion)	185 mg/L end infusion
Plasma half-life	1.5–2 h
Volume of distribution	16 L
Plasma protein binding	c. 10%

No accumulation was seen in subjects receiving 2 g every 12 h over 8 days. In premature infants given 25 mg/kg every 12 h, mean peak plasma concentrations were 77 mg/L after intravenous and 56 mg/L after intramuscular administration, with plasma elimination half-lives of 7.3 and 14.2 h, respectively. Postnatal age was the most important determinant of elimination rate, which was halved after 5 days. In newborn infants given 50 mg/kg intravenously over 20 min, mean peak plasma concentrations varied inversely with gestational age from 102 to 124 mg/L, with half-lives of 2.9–6.7 h.

Distribution

The concentration into serous fluids reaches 50% or more of the simultaneous serum level. In patients given 1 g intravenously during abdominal surgery, detectable concentrations appeared within a few minutes in the peritoneal fluid, reaching a peak around 67 mg/L with a half-life of 0.9 h. Following a similar intravenous dose, a mean peak of 9.4 mg/L was reached at 2 h in ascitic fluid. Concentrations in middle ear fluid after 1 g intravenously were broadly comparable to those of the plasma.

In patients with meningitis, CSF concentrations of 2–30 mg/L have been found 2–3 h after doses of 2 g intravenously over 30 min given every 8 h for four doses. Concentrations are substantially less in the absence of meningitis. Concentrations of 3–27 mg/g were found in patients with intracranial abscesses treated with 0.5–2 g every 8 h. Concentrations around 0.4 mg/g in skin, 0.6 mg/g in muscle and 0.2 mg/g in fatty tissue have been found in patients given 2 g intravenously over 5 min preoperatively. A similar dose has produced mean prostate tissue:serum ratios of around 0.14. Effective concentrations are achieved in bone: in patients given 1 g intravenously mean bone concentrations were 14.4 mg/kg 35–40 min after the dose. There is secretion in breast milk, peak concentrations being around 5 mg/L at about 1 h in patients receiving 2 g intravenously every 8 h.

Metabolism and excretion

No metabolites have been detected. Elimination is almost exclusively renal, predominantly via the glomerular filtrate, with 80–90% of the dose appearing in the urine in the first

24 h. Elimination half-life is inversely correlated with creatinine clearance: as the values fall to 2–12 mL/min, the mean plasma half-life rises to 16 h. In patients maintained on hemodialysis the half-life fell to 2.8 h on dialysis. No accumulation occurred over 10 days in severe renal impairment on a daily dose of 0.5–1 g.

Concentrations of 6.6–58 mg/L have been found in bile 25–160 min after the dose at times when the mean serum concentration was 77.4 mg/L. In T-tube bile there was considerable interpatient variation, with mean concentrations of 34 mg/L at 1–2 h after the dose. No accumulation occurs in patients with impaired hepatic function, but the presence of ascites, low plasma albumin and accumulation of protein-binding inhibitors may increase the volume of distribution.

TOXICITY AND SIDE EFFECTS

It is generally well tolerated. Preparations containing arginine have replaced those with sodium carbonate, which causes pain on intramuscular injection. Reactions common to cephalosporins have been observed in some patients, including positive antiglobulin tests without hemolysis, raised liver function test values, eosinophilia, rashes, leukopenia, thrombocytopenia and diarrhea, occasionally associated with toxigenic *C. difficile*.

Failure of therapy has been associated with superinfection with resistant organisms, including *Staph. aureus*, enterococci and *Candida*. Resistance caused by induction of chromosomal β -lactamases may emerge in *Ps. aeruginosa*, *Ser. marcescens* or *Enterobacter* spp.

CLINICAL USE

It is used, often combined with an aminoglycoside, to treat a wide range of severe urinary, respiratory and wound infections, mostly due to enterobacteria or *Ps. aeruginosa*. Reference is made to its use in pneumonia, septicemia, meningitis (especially if caused by *Ps. aeruginosa*), peritonitis, osteomyelitis, neonatal sepsis, burns and melioidosis. Concern has been expressed at the relative frequency with which failure is associated with superinfection or the emergence of resistance.

Preparations and dosage

Proprietary names: Fortum, Kefadim, Ceptaz, Fortaz.

Preparation: Injection.

Dosage: Adults, i.m., i.v., 1–6 g per day in divided doses, depending on severity of infection. Neonates and children 25 mg/kg (neonates <7 days every 24 h; 7–21 days, every 12 h, older infants and children, every 8 h). The dose may be doubled in severe infection to a maximum of 6 g/day in children >1 month (9 g in cystic fibrosis). Widely available.

OTHER GROUP 6 CEPHALOSPORINS

CEFOPERAZONE

A semisynthetic parenteral cephalosporin. It is unstable, losing activity on storage even at –20°C. A formulation with sulbactam is available in some countries (see p. 241). Activity against common pathogenic bacteria is shown in Table 13.6. It exhibits moderate activity against carbenicillin-sensitive strains of *Ps. aeruginosa*. Activity against *Burk. cepacia* and *Sten. maltophilia* is unreliable. It is much less stable to enterobacterial β -lactamases than most other cephalosporins of groups 4–6 and consequently has unreliable activity against many species, including β -lactamase-producing strains of *H. influenzae* and *N. gonorrhoeae*. It is active against *Achromobacter*, *Flavobacterium*, *Aeromonas* and associated non-fermenters. *Past. multocida* is extremely susceptible (MIC <0.01–0.02 mg/L). It exhibits modest activity against most Gram-negative anaerobes, but not *B. fragilis*. Sulbactam increases activity against many, but not all, enterobacteria and non-fermenters, and almost all *B. fragilis*.

A 2 g intravenous infusion achieves a peak plasma concentration of 250 mg/L. The plasma half-life is 1.5–2 h. Over 85% is bound to plasma proteins. It achieves therapeutic concentrations in tissue and inflammatory exudates. Variable low levels are found in the sputum up to 1.5% of simultaneous serum levels. Penetration into CSF is unreliable even in the presence of meningeal inflammation.

The bile is a major route of excretion, accounting for almost 20% of the dose. About 20–30% is eliminated in urine, almost entirely by glomerular filtration. Clearance is effectively unchanged by renal failure or dialysis.

Side effects associated with the methylthiotetrazole side chain have been reported. Diarrhea has been notable in some studies. Marked suppression of fecal flora, with the appearance of *C. difficile*, has occasionally been found. There is a 5–10% incidence of mild transient increases in liver function tests.

Its potential toxicity and the availability of compounds with better β -lactamase stability and more reliable anti-pseudomonal activity have undermined its popularity.

- Symposium. Evaluation of cefoperazone. *Rev Infect Dis*. 1983;5(suppl 1):S108–S209.

CEFOZOPRAN

An aminothiazole cephalosporin formulated as the hydrochloride. Activity is similar to that of ceftazidime, but it is more active against methicillin-susceptible staphylococci (MIC 1 mg/L). Representative MICs against Gram-negative species are: *Esch. coli* 0.25 mg/L; *K. pneumoniae* 1 mg/L; *Ps. aeruginosa* 1–8 mg/L. Activity against *Acinetobacter* spp., *Sten. maltophilia* and *B. fragilis* group is poor.

A 20-min infusion of 1.5 g achieved a plasma concentration of around 125 mg/L at the end of infusion. Almost 90% of the dose was excreted in the urine over 24 h. The mean terminal half-life was around 2 h. Adverse reactions appear to be typical of those of other group 6 cephalosporins.

It is available in Japan.

Further information

- Iwah I, Okonogi K, Yamazaki T, et al. In vitro and in vivo activities of SCE-2787, a new parenteral cephalosporin with a broad antibacterial spectrum. *Antimicrob Agents Chemother*. 1992;36:1358–1366.
- Paulfeuerborn W, Muller HJ, Borner K, Koeppe P, Lode H. Comparative pharmacokinetics and serum bactericidal activities of SCE-2787 and ceftazidime. *Antimicrob Agents Chemother*. 1993;37:1835–1841.

CEFPIMIZOLE

A semisynthetic parenteral cephalosporin. It exhibits modest activity compared to other antipseudomonal cephalosporins. Like cefoperazone, it is susceptible to many enterobacterial β -lactamases. In volunteers receiving 0.1–1 g intramuscularly, mean peak plasma concentrations reached 15–20 and 35–40 mg/L, respectively. There was no accumulation when the dose was repeated every 8 h for 7 days. No metabolites have been detected. The plasma elimination half-life is 1.8–2.1 h. The principal route of elimination is renal, 70–80% being recovered unchanged in the urine.

Significant pain at the site of infection has been a prominent adverse event. It is no longer widely available.

CEPPIRAMIDE

A semisynthetic parenteral cephalosporin. It exhibits a broad range of activity, which includes *Ps. aeruginosa*, though the

overall activity is rather modest (Table 13.6). It is moderately stable to most β -lactamases but less so than ceftazidime or cefpirome.

In volunteers given 0.5 or 1 g by intravenous bolus, the mean plasma concentration shortly after injection was around 150 or 300 mg/L, respectively. There was no accumulation when the same doses were repeated every 12 h for 11 doses. It is highly bound to plasma protein (*c.* 95%). The mean plasma half-life is around 5 h. Less than one-quarter of the dose appears in the urine over 24 h; the rest is excreted in bile and high concentrations are found in feces. Renal impairment has little effect on elimination in patients with normal liver function.

Diarrhea may be associated with marked suppression of gut flora resulting from biliary excretion of the drug. The molecule includes a C-3 methylthiotetrazole side chain and side effects associated with that substituent are to be expected.

It is available in Japan.

Nakagawa K, Koyama M, Matsui H, et al. Pharmacokinetics of cefpiramide (SM-1652) in humans. *Antimicrob Agents Chemother*. 1984;25:221–225.

CEFPIROME

A semisynthetic aminothiazoyl cephalosporin formulated as the sulfate for parenteral administration. Activity against common pathogens (Table 13.6) is similar to that of cefotaxime and ceftriaxone, but it is more active against *Ps. aeruginosa*. Unlike other cephalosporins it exhibits activity against some strains of enterococci (MIC 4–16 mg/L), but this is of doubtful clinical benefit. It is generally very stable to β -lactamases. It is active against strains of *Enterobacter* spp., *Citrobacter* spp., *Hafnia* spp., *Providencia* spp., *Ser. marcescens* and *Pr. vulgaris* producing molecular class C cephalosporinases (*see p. 230*). *Sten. maltophilia* is resistant.

A 1 g intramuscular injection produces a plasma concentration of 25 mg/L after 1.6–2.3 h. A similar intravenous dose achieves a peak concentration of 97 mg/L. The plasma half-life is 1.4–2.3 h and protein binding is around 10%. It is well distributed, achieving therapeutic concentrations in tissues and exudates. It penetrates poorly into CSF in the absence of meningeal inflammation, but concentrations around 2–4 mg/L have been found in patients with purulent meningitis.

Little, if any, of the drug is metabolized and most is excreted unchanged in the urine within 12 h, mainly by glomerular filtration. Clearance declines in proportion to renal function. Around 60% of the drug is removed in 3 h by hemodialysis. Low concentrations are found in breast milk.

Side effects are those common to other cephalosporins. Diarrhea is common and occasional cases of pseudomembranous colitis have been reported.

It is mainly used in the treatment of serious sepsis, particularly nosocomial infections in which resistant Gram-negative pathogens are known or suspected to be involved. It is not widely available, but is marketed in Japan.

Further information

Anonymous. Cefpirome. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C109–C113.

Wiseman LR, Lamb HM. Cefpirome. A review of its antibacterial activity, pharmacokinetic properties and clinical efficacy in the treatment of severe nosocomial infections and febrile neutropenia. *Drugs*. 1997;54:117–140.

CEFSULODIN

A semisynthetic parenteral cephalosporin supplied as the sodium salt. Activity against *Ps. aeruginosa* contrasts strikingly with poor activity against many other organisms (Table 13.6). Anaerobic Gram-negative rods, Gram-positive rods and cocci are all resistant. It is stable to many β -lactamases, including the *Ps. aeruginosa* chromosomal enzyme, and is a poor substrate for the enzymes of *Enterobacter* spp. and *Morg. morganii*. It is slowly hydrolyzed by TEM β -lactamases and more rapidly by the enzymes of some carbenicillin-resistant strains of *Ps. aeruginosa*, with which distinct inoculum effects may be seen.

A 500 mg intravenous bolus dose achieves a plasma concentration of *c.* 70 mg/L at the end of the injection; the corresponding intramuscular dose achieves a peak concentration of around 15 mg/L. The plasma half-life is 1.5 h. About 15–30% is protein bound.

There is some metabolism of the drug, but the main route of excretion is via the kidneys, most appearing in the urine in the first 6 h. The plasma half-life is linearly related to creatinine clearance, rising to a mean of 10–13 h in patients where clearance was <10 mL/min, falling to around 2 h on hemodialysis.

It is well tolerated, apart from nausea and vomiting in some subjects. It has been used in severe pseudomonas infections, usually in combination with an aminoglycoside, but treatment has been complicated on a number of occasions by the emergence of resistance or superinfection.

It is available in Japan.

GROUP 7 CEPHALOSPORINS

CEFTOBIPROLE

Molecular weight: 534.57 (base); 712.64 (medocaril ester).

A semisynthetic cephalosporin formulated as the water-soluble medocaril prodrug for intravenous administration.

ANTIMICROBIAL ACTIVITY

The most important property distinguishing it from older cephalosporins is activity against methicillin-resistant staphylococci, a property conferred by a high affinity for penicillin-binding protein 2' (2a). MICs for methicillin-resistant strains are nevertheless somewhat higher than those seen with fully susceptible strains. A similar situation exists with coagulase-negative staphylococci and with *Str. pneumoniae*, for which strains with reduced susceptibility to penicillin are less susceptible than fully resistant strains, while remaining within therapeutically achievable levels.

Otherwise activity approximates to that of cephalosporins of group 4 (Table 13.7). Activity against *Ps. aeruginosa* is modest and much reduced against ceftazidime-resistant strains.

ACQUIRED RESISTANCE

It is hydrolyzed by extended spectrum β -lactamases of enterobacteria (see p. 230), which are therefore resistant. The prospects for the emergence of resistance during extensive clinical use are presently unclear, though increased resistance in *Staph. aureus* appears to be difficult to induce under laboratory conditions.

PHARMACOKINETICS

C_{max} 500 mg (667 mg prodrug) intravenous (30-min infusion)	c. 35 mg/L end infusion
Plasma half-life	c. 3 h
Volume of distribution	18.4 L
Plasma protein binding	16%

The prodrug is rapidly hydrolyzed in plasma to release the active form together with diacetyl (2,3-butanediol) and CO₂. Distribution approximates to the extracellular fluid volume in adults. There is no accumulation on repeat dosing in subjects with normal renal function.

Table 13.7 Activity of group 7 cephalosporins against common pathogenic bacteria: MIC (mg/L)

	Ceftobiprole	Ceftaroline
<i>Staphylococcus aureus</i> (methicillin-sensitive)	0.25–0.5	0.25
<i>Staph. aureus</i> (methicillin-resistant)	1–2	0.5–1
<i>Streptococcus pyogenes</i>	0.06	0.008–0.03
<i>Str. pneumoniae</i>	0.015–0.25	0.008–0.12
<i>Enterococcus faecalis</i>	4	2–4
<i>Neisseria gonorrhoeae</i>	0.06	No data
<i>Haemophilus influenzae</i>	0.06	0.015–0.03
<i>Escherichia coli</i>	0.03–0.06	0.06–0.5
<i>Klebsiella pneumoniae</i>	0.03–0.12	0.06–0.25
<i>Pseudomonas aeruginosa</i>	2–8	0.5–R
<i>Bacteroides fragilis</i>	R	No data
R, resistant (MIC >64 mg/L).		

It is chiefly excreted in urine by glomerular filtration. A urinary concentration exceeding 1 g/L is achieved within the first 2 h of a 500 mg (active drug equivalent) dose and 80–90% of active drug can be recovered within 24 h.

TOXICITY AND SIDE EFFECTS

Limited studies have so far revealed no unexpected side effects. Nausea, vomiting and altered taste sensation appear to be the most common.

CLINICAL USE

In countries in which approval has been granted, use is presently limited to complicated infections of skin and skin structures.

Preparations and dosage

Proprietary names: Zeftera, Zevtera.

Preparation: Infusion.

Dosage: i.v. infusion (1–2 h), 500 mg (667 mg medocaril prodrug) every 12 h.

Limited availability. Available in Canada.

active against Amp-C derepressed strains of Gram-negative bacilli (see p. 230).

C_{max}	600 mg intravenous (1-h infusion)	19 mg/L end infusion
Plasma half-life		2.6 h
Volume of distribution		0.37 L/kg
Plasma protein binding		<20%

Like ceftobiprole, ceftaroline fosamil is rapidly hydrolyzed in plasma after intravenous infusion and excreted principally in urine. In preliminary clinical studies it appears to be well tolerated.

OTHER GROUP 7 CEPHALOSPORINS

CEFTAROLINE

A semisynthetic cephalosporin formulated as the water-soluble fosamil acetate prodrug for intravenous administration.

Its properties are similar to those of ceftobiprole, with which it shares an enhanced affinity for penicillin-binding protein 2' (2a) of methicillin-resistant *Staph. aureus*. Activity against common bacterial pathogens is shown in Table 13.7. It is hydrolyzed by extended-spectrum β -lactamases and is not

14 β-Lactam antibiotics: penicillins

Karen Bush

The penicillin class of antibiotics comprises a large group of bicyclic penam compounds (pp. 226–227) differing in the nature of the acyl side chain attached to the fused β -lactam-thiazolidine ring system. Most are semisynthetic derivatives of the penicillin nucleus, 6-aminopenicillanic acid (6-APA), prepared synthetically by the addition of acyl side chains at the 6-amino group.

Fleming reported the discovery of penicillin as the compound responsible for the antibacterial activity displayed by the mold *Penicillium notatum* in 1929, but it was not until 1940 that Florey and his collaborators at Oxford produced enough crude penicillin to start therapeutic tests in mice. Preliminary human trials followed in 1941. Later studies showed that the product derived from industrial fermentations of *Penicillium chrysogenum* was a family of closely related compounds differing only in the nature of the acyl side chain. These natural penicillins consisted of penicillins F (pentenylpenicillin), G (benzylpenicillin), K (heptylpenicillin) and X (*p*-hydroxybenzylpenicillin). From this family, benzylpenicillin (penicillin G) was selected as the penicillin most suitable for clinical development based on biological properties and ease of commercial production.

The limitations of benzylpenicillin as an antibacterial agent soon led to efforts to produce novel penicillins with superior properties. In early work acidic side-chain precursors that could be incorporated during biosynthesis were added during the fermentation. However, only a limited number of side chains could be introduced; the only penicillin produced by this process with any advantage over penicillin G was phenoxyethylpenicillin (penicillin V), the product of fermentations to which phenoxyacetic acid had been added as a precursor. This change conferred stability to gastric acid, allowing it to be administered orally.

The first semisynthetic penicillins, prepared by chemical substitution of the *p*-hydroxy group of the naturally occurring penicillin X (*p*-hydroxybenzylpenicillin) were, unfortunately, no better than penicillin G. A similar approach to modify the amino group of *p*-aminobenzylpenicillin was also unsuccessful, but research on this compound led to the important identification in 1957 of the penicillin nucleus, 6-aminopenicillanic acid (6-APA). It was later obtained more easily by removal of the benzylpenicillin side chain by microbial enzymes or by chemical modification, the process now used for commercial production.

The significance of the identification of 6-APA is that numerous semisynthetic penicillins can be prepared by adding acyl side-chain structures to the 6-amino group of the molecule. With the exceptions of penicillin G and penicillin V, the penicillins in clinical use are all derived from 6-APA, and display advantages over benzylpenicillin in antibacterial activity, stability to bacterial β -lactamases or pharmacokinetic properties. Attempts to further modify the penicillin nucleus have been disappointing. Only two clinically useful compounds resulted: mecillinam (amdinocillin), in which the side chain is joined in an amidino linkage; and temocillin, in which a 6-methoxy group has been incorporated in the β -lactam ring. After the late 1970s, research emphasis in the β -lactam field switched from penicillins to other β -lactam agents, notably the cephalosporins, cephams, carbapenems, penems, monobactams and penicillanic acid sulfones (Ch. 15), and the development of novel penams appears to have come to a halt.

CLASSIFICATION

Following the isolation of 6-APA, objectives in penicillin research were:

- synthesis of narrow-spectrum penicillins similar to benzylpenicillin in activity but with superior oral absorption
- preparation of penicillins stable to staphylococcal β -lactamase and active against benzylpenicillin-resistant staphylococci (excluding methicillin-resistant staphylococci)
- development of penicillins with broader spectra of antibacterial activity than benzylpenicillin and stability to plasmid-encoded class A β -lactamases (p. 230).

The first two objectives were achieved with some success but with the third there was less success, in that the extended-spectrum penicillins (with the exception of temocillin) are largely inactive against β -lactamase-producing bacteria, although some have achieved clinical success when combined with β -lactamase inhibitors (pp. 239–244).

The penicillins in clinical use may be divided into six major groups:

- *Group 1:* Benzylpenicillin and its long-acting parenteral forms.
- *Group 2:* Orally absorbed penicillins similar to benzylpenicillin.
- *Group 3:* Penicillins that are relatively stable to staphylococcal β -lactamase, but which have no useful activity against Gram-negative bacilli. Several are structurally related isoxazolypenicillins.
- *Group 4:* Compounds with enhanced activity against certain Gram-negative bacilli, including many

enterobacteria and *Haemophilus influenzae*, but which are inactivated by staphylococcal and many enterobacterial β -lactamases. They include several aminopenicillins, such as ampicillin and amoxicillin, and the amidinopenicillin mecillinam. Esters and condensates of ampicillin and a mecillinam ester, pivmecillinam, have been developed to improve oral absorption of the parent compounds.

- *Group 5:* Penicillins active against *Pseudomonas aeruginosa*. These include carboxypenicillins (and their orally absorbed esters) and acyl or acylureido derivatives of ampicillin.
- *Group 6:* Penicillins resistant to enterobacterial β -lactamase.

Group 1	Group 2	Group 3	Group 4	Group 5	Group 6
Benzylpenicillin	Azidocillin ^a	Cloxacillin ^b	Amoxicillin	Apalcillin ^a	Temocillin
Benzathine penicillin	Phenethicillin ^a	Dicloxacillin ^b	Ampicillin	Aspoxicillin	
Clemizole penicillin ^a	Phenoxyethyl penicillin	Flucloxacillin ^b	Cyclacillin	Azlocillin ^{a,c}	
Procaine penicillin	Propicillin ^a	Methicillin ^a	Epicillin ^a	Carbenicillin ^{a,d}	
		Nafcillin	Mecillinam	Mezlocillin ^{a,c}	
		Oxacillin ^b		Piperacillin ^c	
				Ticarcillin ^d	

^aNo longer available ^bisoxazolypenicillins ^cacyureidopenicillins ^dcarboxypenicillins.

MODE OF ACTION

Penicillins and other β -lactam antibiotics prevent synthesis of the bacterial cell wall (pp. 12–13), a structure that is not found in mammalian cells – a feature responsible for the low toxicity and the consequent clinical popularity of this class of antibiotics.

ACQUIRED RESISTANCE

Bacteria may exhibit resistance to penicillins and other β -lactam antibiotics by several mechanisms (*see also* Ch. 3):

- Acquisition of penicillin-binding proteins (PBPs) with reduced affinity for penicillin. This is a frequent cause of resistance in Gram-positive bacteria such as staphylococci, pneumococci and enterococci. This mechanism may also be responsible for low-level penicillin resistance in *H. influenzae* and viridans streptococci.
- The production of a bacterial enzyme, β -lactamase, that opens the β -lactam ring, causing inactivation of the antibiotic.
- Modification of outer membrane proteins (porins) in Gram-negative bacteria, preventing passage of penicillins into the bacterial cell. Efflux mechanisms have been described in which bacteria pump out β -lactam antibiotics. Bacteria frequently display more than one resistance mechanism – for example, methicillin-resistant staphylococci typically produce β -lactamase but demonstrate resistance

primarily due to altered PBPs; Gram-negative bacteria may produce β -lactamases in organisms with efflux mechanisms or altered outer membrane proteins.

Methicillin-resistant strains of *Staphylococcus aureus* (MRSA) are considered to be resistant to all β -lactam antibiotics, with the exception of some newer cephalosporins, and are frequently multiresistant. The prevalence of MRSA is variable, with very low incidence in some countries of northern Europe, but high incidence in Japan and other countries. In the USA the frequency increased from 2.4% in 1975 to 64% in 2007. Although largely confined to hospitals, MRSA is increasingly seen in community settings.

When benzylpenicillin was introduced, all streptococci were sensitive to its action, and this situation remains largely unchanged. However, pneumococci exhibiting reduced susceptibility are now common, although the criteria for penicillin resistance differ in the USA and Europe (Table 14.1).

The interpretive criteria for non-meningitis isolates defined by the FDA in 2008 is based on clinical experience showing that high doses of penicillin provide efficacious drug concentrations, except in cerebrospinal fluid (CSF). The EUCAST or FDA pre-2008 definitions are generally used for epidemiological purposes.

Until the 1980s, clinical isolates of *Streptococcus pneumoniae* were uniformly susceptible to penicillin, except for a few reports from South Africa and elsewhere. By 1998, 24% of invasive pneumococci isolated in the USA displayed reduced susceptibility to penicillin and often to other classes of antibiotics. The frequency of isolation of penicillin-resistant pneumococci in Europe was 51% in Hungary (1990) and 9% in

Table 14.1 Interpretive criteria for susceptibility of *Str. pneumoniae* to penicillin

Organization	Source of isolate	MIC (mg/L)		
		Susceptible	Intermediate	Resistant
FDA (pre-2008) (post-2008)	Any	≤0.06	0.12–1	≥2
	Meningitis	≤0.06	Not defined	≥0.12
	Non-meningitis	≤2	4	>8
EUCAST	Any	≤0.06	0.12–2	≥4

FDA, United States Food and Drug Administration; EUCAST, European Committee on Antimicrobial Susceptibility Testing; MIC, minimum inhibitory concentration.

the UK (1998). Introduction of the heptavalent pneumococcal vaccine in 2000 caused a dramatic decrease in isolates of pneumococci insusceptible to penicillin, especially in the elderly and young children, in countries with effective vaccination programs.

As with pneumococci, enterococci were initially perceived always to be susceptible to ampicillin and benzylpenicillin, but resistant strains are now common. Resistance is less prevalent among the most common species, *Enterococcus faecalis*, in which β-lactamase has been reported at a low frequency. In *Enterococcus faecium*, the next most common enterococcal species, high-level penicillin resistance due to modified PBPs is usual.

IMPERMEABILITY RESISTANCE

β-Lactam antibiotics cross the outer membrane to reach PBPs in Gram-negative bacteria through porin proteins (p. 27; see also Figure 2.1, p.11). Alterations in porin production can lead to decreased permeability and concomitant β-lactam resistance. Porin deficiencies coupled with high β-lactamase production have been reported in clinical isolates of Enterobacteriaceae such as *Enterobacter cloacae* and *Serratia marcescens* that produce cephalosporinases. Resistance due to decreased permeability is also important among *Ps. aeruginosa* strains, which possess a less permeable membrane and contain efflux pump mechanisms for β-lactam antibiotics, coupled with production of chromosomally mediated β-lactamase activity. Because Gram-positive bacteria lack an outer membrane, this mechanism of resistance does not apply.

EFFLUX-MEDIATED RESISTANCE

Efflux mechanisms for β-lactam-containing antimicrobial agents were described in the 1990s. These multidrug, active efflux mechanisms have been best studied in *Ps. aeruginosa*, where an operon consisting of *mexA–mexB–oprM* is involved in an energy-dependent pumping out of diverse agents such as tetracyclines, fluoroquinolones and chloramphenicol, as well as penicillins. Related pumps have also been identified in the pseudomonads and Gram-negative bacteria.

TOXICITY AND SIDE EFFECTS

HYPERSENSITIVITY REACTIONS

Penicillins and other β-lactam agents are among the safest antibacterial agents used therapeutically. The most important untoward reactions are those resulting from hypersensitivity. Although serious or life-threatening reactions are rare, allergic reactions present a more serious problem with benzylpenicillin than with other antibiotics. There is cross-reaction among penicillins, and the agent to which the patient reacts is not necessarily the sensitizing agent.

The most dangerous form of drug allergy is acute anaphylactic shock, which may develop between a few minutes and 30 minutes after administration. It is characterized by profound circulatory collapse, nausea, vomiting, abdominal pain, severe bronchospasm and coma, and may be rapidly fatal. Anaphylaxis is said to occur in 0.005–0.05% of treated patients, with a mortality rate of approximately 10%.

The most common manifestations of hypersensitivity are various skin eruptions, usually maculopapular with itching but sometimes urticarial or mixed, and occasionally purpuric. Penicillins should not be applied to the skin as topical preparations are likely to lead to contact dermatitis or local swelling. Rashes occur in 1–7% of patient courses of penicillin. Although reactions can occur after any route of administration, the severe forms are much more common after injections than after oral administration. A serum sickness form of allergy can arise 7–10 days after treatment (earlier in previously sensitized patients).

Some patients develop allergic reactions only after repeated administration of penicillin but in others reactions develop after the initial treatment, often as a result of non-medicinal exposure to penicillin in the environment.

Anaphylaxis is much less common with penicillins other than benzylpenicillin. Ampicillin, however, is much more likely to produce rashes (9.5%), which may be severe, especially in patients with coexisting viral infections caused by cytomegalovirus or Epstein–Barr virus, notably infectious mononucleosis. It has been claimed that this propensity is not exhibited to the same degree by amoxicillin, ciclacillin or mecillinam.

ALLERGENS

The principal antigen responsible for these reactions is generated by opening the β -lactam ring, allowing the carbonyl group to react with the amino groups of proteins. This benzylpenicilloyl hapten, accounting for 95% of tissue-bound penicillin, is the major determinant for hypersensitivity. A number of other reactions within and between the molecules can occur, leading to the ‘minor determinants’ – minor components of the complex mixtures, but potentially important determinants of penicillin allergy. Penicillins with different side chains have different sensitizing capacities and may lead to different populations of antibodies in treated patients.

DETECTION AND CONTROL

Many patients without a history of penicillin allergy have circulating antibodies to the drug, and their presence is of no prognostic value. Skin testing for cutaneous reactivity to specific IgE is the most widely accepted test used to detect patients likely to suffer immediate hypersensitivity reactions to penicillins. Only about 10% of the patients who claim to have a history of penicillin hypersensitivity respond positively to the determinants used in skin testing. This testing, currently the most accepted and reliable testing method, uses all relevant antigens, including both major and minor determinants.

The use of benzylpenicillin itself for testing is generally regarded as hazardous because it may lead to a severe reaction in the highly susceptible patient and may sensitize the previously non-allergic individual. For this reason, agents such as penicilloyl-polylysine, in which the amino groups of an artificial peptide are virtually saturated with penicilloyl residues, are used. As there are other antigens involved, excellent predictive performance has been claimed for penicilloyl-polylysine plus a ‘minor determinant’ mixture. A positive penicillin skin test indicates that a patient is at risk for immediate hypersensitivity; a negative test cannot preclude a future hypersensitivity reaction upon subsequent therapy with penicillin. It is extremely rare, however, that life-threatening reactions occur in patients with a negative skin test.

The management of penicillin reactions relies on the use of antihistamines, corticosteroids and, in anaphylaxis or dangerous angioedema, adrenaline (epinephrine). It has sometimes been recommended that allergic patients may be successfully treated with the co-administration of corticosteroids or antihistamines, together with penicillin, where that is the most appropriate agent. However, this has major risks, as it is possible that any allergic reaction to the penicillin would be masked by the action of these agents.

CROSS-REACTIONS WITH CEPHALOSPORINS

About 3–9% of penicillin-allergic patients are cross-allergic to cephalosporins; specific allergy to cephalosporins in the absence of reactions to penicillin also occurs, albeit rarely. It is generally recommended that cephalosporins should be avoided in patients with a clear history of severe reaction to penicillin. Cross-reactivity between penicillins and carbapenems is even less frequent, while the monobactam aztreonam (p. 237) is only very weakly immunogenic and does not show cross-reactivity with penicillin.

OTHER REACTIONS

Leukopenia has occurred in patients receiving various penicillins, including methicillin and piperacillin. Neutropenia in patients treated with benzylpenicillin for bacterial endocarditis is related both to high dosage (18 g per day) and to low neutrophil counts before treatment. Prolonged bleeding times due to platelet abnormalities have been noted, particularly with carboxypenicillins and, to a lesser extent, with acylureidopenicillins. Various nephrotoxic manifestations have been described with carbenicillin, dicloxacillin and methicillin, and reversible abnormalities of liver function tests with carboxypenicillins and less frequently acylureidopenicillins.

Because penicillins are often administered in large doses as sodium salts, sodium overload and hypokalemia may develop. Large doses of penicillins, especially in patients with impaired renal function, may result in convulsions. Access to the central nervous system of neurotoxic concentrations is related to lipophilicity and protein binding of the compounds.

GROUP 1: BENZYL PENICILLIN AND ITS LONG-ACTING PARENTERAL FORMS

Benzylpenicillin, the first naturally produced penicillin, is poorly absorbed orally and must be given by injection. Because the plasma half-life is short, insoluble salts of penicillin were prepared that act as intramuscular depots for the release of penicillin into the bloodstream. Repository penicillins that are in use include procaine penicillin and benzathine penicillin.

BENZYL PENICILLIN

Penicillin G. Molecular weight (free acid): 334.4.

Archetypal penicillin produced by *P. chrysogenum*; supplied as the highly soluble potassium or sodium salts for intramuscular or intravenous administration. Potency has traditionally been expressed in units (1 unit = 0.6 µg), but use of milligram or gram quantities is now preferred.

ANTIMICROBIAL ACTIVITY

Activity against common pathogenic bacteria is shown in Table 14.2. It has intrinsic activity against almost all Gram-positive pathogens, but is no longer effective against most staphylococci. Most species of streptococci are susceptible, including group B streptococci, an important cause of neonatal infections. Enterococci are more resistant than streptococci. Other susceptible Gram-positive organisms include non-β-lactamase-producing *Bacillus anthracis* and *Listeria*

Table 14.2 Activity of benzylpenicillin and phenoxyethylpenicillin against non-β-lactamase-producing strains of pathogenic bacteria; modal MIC (mg/L)

	Benzylpenicillin	Phenoxyethylpenicillin
<i>Staphylococcus aureus</i> (methicillin-susceptible)	0.03	0.06
<i>Streptococcus pyogenes</i>	0.02	0.02
<i>Str. pneumoniae</i>	0.02	0.02
<i>Enterococcus faecalis</i>	4	2
<i>Neisseria gonorrhoeae</i>	0.02	0.1
<i>N. meningitidis</i>	0.06	0.25
<i>Haemophilus influenzae</i>	0.25	2
<i>Escherichia coli</i>	64	R
<i>Klebsiella pneumoniae</i>	R	R
<i>Pseudomonas aeruginosa</i>	R	R
<i>Bacteroides fragilis</i>	32	ND

R, resistant (MIC >64 mg/L).

monocytogenes. The spirochetes *Borrelia burgdorferi* and *Treponema pallidum* are also susceptible.

The aerobic Gram-negative cocci *Neisseria gonorrhoeae* and *N. meningitidis* were initially highly susceptible to benzylpenicillin, but β-lactamase-producing strains of gonococci are now common. *H. influenzae* and *Moraxella catarrhalis* are usually resistant due to β-lactamase production. The Enterobacteriaceae and most other aerobic Gram-negative bacilli are resistant, as a result of β-lactamase production or the impermeability of the bacterial cell wall. Other resistant organisms include mycobacteria, mycoplasmas, *Nocardia* spp., rickettsiae and chlamydiae.

Anaerobic Gram-positive cocci are susceptible in the absence of β-lactamase production. Most clostridia strains are susceptible, but resistance can be observed. Anaerobic Gram-negative bacilli vary in their sensitivity: the *Bacteroides fragilis* group is resistant as the result of β-lactamase action, but many *Prevotella* and *Fusobacterium* spp. are susceptible.

Benzylpenicillin exhibits concentration-dependent bactericidal activity against growing organisms. Killing of highly susceptible Gram-positive cocci seldom proceeds to eradication, with measurable numbers of survivors ('persisters'), which are fully susceptible on retesting. Some strains of streptococci (including group B) and pneumococci show very large numbers of persisters, resulting in a large difference between the minimum inhibitory concentration (MIC) and the minimum bactericidal concentration (MBC), a phenomenon known as 'tolerance'.

Combination with aminoglycosides results in pronounced bactericidal synergy.

ACQUIRED RESISTANCE

Staph. aureus was originally highly susceptible to benzylpenicillin, but at least 85–90% of clinical isolates are now β -lactamase-producing strains. Most clinical isolates of coagulase-negative staphylococci are also resistant. β -Lactamase-producing strains of *E. faecalis* produce an enzyme identical to staphylococcal penicillinases, but these strains are increasingly uncommon. The emergence of penicillin-resistant staphylococci, enterococci and pneumococci, due to the acquisition of mosaic PBPs with decreased binding affinity for penicillin, has been described worldwide. Most strains of penicillin-resistant Gram-positive clinical isolates also demonstrate reduced susceptibility to other β -lactam agents but, in rare cases, cross-resistance is not seen for all cephalosporins.

Strains of *N. gonorrhoeae* for which the MIC of benzylpenicillin increased from 0.06 mg/L to >2 mg/L appeared in the 1970s, as the result of the production of modified PBPs with reduced affinity for β -lactam antibiotics; fully resistant strains producing TEM-1 β -lactamase also emerged. Currently penicillin resistance occurs in more than 60% of isolates in some parts of the world.

PHARMACOKINETICS

Oral absorption	2–25%
C_{max} 0.6 g intramuscular	12 mg/L
3 g intravenous (3–5 min)	400 mg/L
Plasma half-life	0.5 h
Volume of distribution	0.2–0.7 L/kg
Plasma protein binding	60%

Absorption

Benzylpenicillin is unstable in acid and destroyed in the stomach. As a result, plasma concentrations obtained after oral administration are variable, and are depressed by administration with food. It is absorbed from serous cavities, joints and the subarachnoid space. It is not absorbed following applications to the skin, which should be avoided because of the likelihood of sensitization.

Distribution

The drug is widely distributed in most tissues and body fluids. Highest levels are found in the kidney, with lower levels in the liver, skin and intestines. Low concentrations appear in saliva and in maternal milk. It does not enter uninflamed bone or the CSF. Its entry is limited by its low pK_a (2.6), which results in its almost complete ionization and very low lipid–water partition coefficient at pH 7.4. When the meninges are inflamed, the concentrations obtained in CSF are around 5% of the plasma level. In uremia, accumulated organic acids may enter

the CSF and compete for transport of penicillin, causing the concentration to reach convulsive levels.

It diffuses into wound exudates and experimental transudates when the serum level is high, and enters glandular secretions and the fetal circulation, whence it is excreted in increased concentrations into the amniotic fluid.

Metabolism and excretion

About 40% is metabolized in the liver, mainly to penicilloic acid. After oral dosing, unabsorbed drug is largely degraded by colonic bacteria and little activity remains in the feces. Concentrations 2–4 times those of the plasma are found in bile, but 60–90% is excreted in the urine, largely in the first hour. Probenecid causes a doubling of the peak concentration and prolongation of the plasma half-life. Other drugs, including aspirin, sulfonamides and some non-steroidal anti-inflammatory drugs and diuretics, may prolong the half-life.

TOXICITY AND SIDE EFFECTS

Benzylpenicillin has low toxicity, except for the nervous system (into which it does not normally penetrate), where it is one of the most active convulsants among the β -lactam agents. Excessively high intravenous doses may induce convulsions and intrathecal doses should never exceed 12 mg (20 000 units) in adults or 3 mg (5000 units) in a child as a single daily dose. Inadvertent intravascular administration, especially direct injection into arteries, can cause serious neurotoxic damage, including hyperreflexia, myoclonic twitches, seizures and coma.

Massive intravenous doses of the sodium or potassium salts can lead to severe or fatal electrolyte disturbances. In patients treated with large doses of the potassium salt (60 g or more per day), hyponatremia, hyperkalemia and metabolic acidosis can develop.

Thrombocytopenia and platelet dysfunction resulting in coagulopathy and involving several different mechanisms have been described. Neutropenia associated with fever and allergic rash appears to be related to total dose, usually in excess of 90 g. Although it can be very severe, in most patients recovery occurs within a few days of withdrawal of treatment.

Large doses (24 g [40 megaunits] per day intravenously), or smaller doses given to patients with impaired renal function, may interfere with platelet function.

The most dramatic untoward response is anaphylactic shock due to allergy (p. 202). In addition to the generalized allergic reactions, particular organs may be damaged by a variety of immunological mechanisms. Hemolytic anemia occurs only in patients who have been treated previously with penicillin, and again receive a prolonged course of large doses (commonly 12 g per day). Reversible hemolysis is due to the action of anti-penicillin immunoglobulin G (IgG) on cells that have absorbed the antibiotic. Nephritis, resulting in dysuria, pyuria, proteinuria, azotemia and histological

evidence of nephritis of allergic origin, is only rarely seen, usually in patients receiving large doses (12–36 g [20–60 mega-units] per day).

CLINICAL USE

- Serious infections caused by streptococci (including *Str. pneumoniae*) other than meningitis caused by penicillin-resistant pneumococci
- Serious infections caused by susceptible strains of staphylococci
- Meningococcal septicemia and meningitis
- Gonococcal infections caused by susceptible strains
- Syphilis (including neurosyphilis) and other spirochetal infections
- Anthrax
- Actinomycosis
- Clostridial infections
- Diphtheria (adjunctive therapy to antitoxin and for prevention of carrier state)
- Infections with other susceptible organisms, including *Listeria monocytogenes*, *Pasteurella multocida*, *Erysipelothrix insidiosa* and *Fusobacterium*

Preparations and dosage

- Proprietary names:** Crystapen, Pfizerpen and numerous generic forms.
- Preparation:** Injection.
- Dosage:** Adults, i.m., i.v., 600 mg to 1.2 g per day in 2–4 divided doses; adult meningitis, up to 14.4 g per day may be given in divided doses; bacterial endocarditis, 4.8 g per day or more in divided doses. Children, 1 month to 18 years, 25 mg/kg every 6 h (50 mg/kg every 4–6 h in severe infection); neonates preterm or <7 days, 25 mg/kg every 12 h (double in severe infection), 7–28 days, 25 mg/kg every 8 h (double in severe infection). Meningitis in neonates and children: neonates ≤7 days old, 75 mg/kg every 8 h; neonates >7 days old, 90–120 mg/kg per day in three divided doses; children 1 month to 12 years, 150–300 mg/kg per day in 4–6 divided doses (maximum 2.4 g/dose). Intrathecal, see manufacturer's literature.
- Widely available.

COMPOUNDS LIBERATING BENZYLPCNILLIN

Antimicrobial activity and systemic effects of the long-acting forms are due to the liberation of benzylpenicillin. Intramuscular injection, particularly of benzathine penicillin, may produce local pain or tenderness, and accidental intravascular injection of procaine penicillin may produce acute agitation, hallucinations and collapse.

Long-acting forms have their principal use in the treatment of gonorrhoea and syphilis, and in the follow-on treatment of patients requiring prolonged therapy after initial treatment with benzylpenicillin. They are also used in the prophylaxis of rheumatic fever.

BENZATHINE PENICILLIN

N, N'-dibenzoylethylene diamine dipenicillin salt of benzylpenicillin. It is poorly soluble (1:6000) in water. Available as an intramuscular preparation and in various mixtures with benzyl- and procaine penicillins. It has a local anesthetic effect comparable with that of procaine penicillin.

It is slowly absorbed after intramuscular injection, yielding very low plasma concentrations: a dose of 1.2 mega-units produces mean plasma concentrations of 0.1/0.02/0.002 mg/L 1, 2 and 4 weeks after injection.

Preparations and dosage

- Proprietary name:** Permapen.

- Preparation:** Intramuscular injection.

- Dosage:** Varies according to infection being treated.

- Limited availability; not available in the UK.

CLEMIZOLE PENICILLIN

A long-acting preparation of benzylpenicillin with the antihistamine, clemizole, given by deep intramuscular injection. It is of very limited availability.

PROCAINE PENICILLIN

The procaine salt of benzylpenicillin. Poorly soluble (1:200 in water). Administered intramuscularly as a suspension of crystals which slowly dissolve at the site of the injection.

It must not be given intravenously. Intramuscular administration produces a flat sustained plasma concentration of penicillin, which is much lower than that achieved by an equivalent dose of benzylpenicillin, with plasma levels still detectable 24 h later. An injection of 0.6 g yields a peak plasma concentration of 1–2 mg benzylpenicillin/L after 2–4 h. Free procaine is detectable in the plasma within 30 min.

Very severe and potentially fatal reactions resembling those of anaphylactic shock, but non-allergic in character, may occur, probably due to accidental entry into the vascular system at the site of injection and blockage of pulmonary and cerebral capillaries by crystals of the suspension. Reactions due to liberated procaine may include acute anxiety, hypertension, tachycardia, vomiting, audiovisual hallucinations and acute psychotic disturbance. The most severe reactions lead to convulsions and cardiac arrest. Other reactions are those to liberated benzylpenicillin.

Preparations and dosage

Proprietary names: Bicillin and numerous generic forms.

Preparation: Intramuscular injection.

Dosage: Adults, i.m., 300 mg (plus 60 mg benzylpenicillin) every 12–24 h. Widely available. No longer available in UK.

penicillins were phenethicillin (the immediate homolog of penicillin V) and propicillin, which were both successful in the clinic, but are no longer readily available. Other orally active penicillins of this type include phenbenicillin (phenoxybenzylpenicillin) and azidocillin (D-azidobenzylpenicillin).

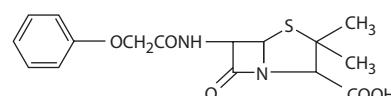

The phenoxybenicillins exhibit lower activity than benzylpenicillin against Gram-positive cocci and are distinctly less active against Gram-negative bacteria. All group 2 penicillins lack stability to β -lactamase.

In general, the absorption efficiency of these compounds increases in parallel with molecular weight. The peak plasma levels obtained from the phenoxybenicillins are well in excess of those required to inhibit the organisms for which benzylpenicillin is normally used.

Phenoxyethylpenicillin is the only member of this group to be considered here. Most of the related compounds are now obsolete.

PHENOXYMETHYLPCNICILLIN

Penicillin V. Molecular weight (free acid): 350.4; (potassium salt): 388.5.

A naturally occurring penicillin produced by *P. chrysogenum* in media containing phenoxyacetic acid as a precursor. It is supplied as the potassium salt for oral administration.

GROUP 2: ORALLY ABSORBED PENICILLINS RESEMBLING BENZYLPCNICILLIN

The first natural penicillin to be identified as a useful oral agent was phenoxyethylpenicillin (penicillin V), produced by the addition of phenoxyacetic acid as a precursor in the fermentation. Penicillin V is more acid stable than benzylpenicillin and is absorbed after oral administration, producing therapeutically useful plasma penicillin concentrations. After the identification of the penicillin nucleus, 6-APA, a number of penicillin V analogs were developed, with claims for superior oral absorption characteristics. The most important of these semisynthetic

ANTIMICROBIAL ACTIVITY

The antibacterial spectrum and level of activity are similar to that of benzylpenicillin (Table 14.2). Enteric Gram-negative bacilli are highly resistant.

PHARMACOKINETICS

Oral absorption	40–70%
C_{max} 250 mg oral	2 mg/L after 1 h
Plasma half-life	c. 0.5 h
Volume of distribution	0.2 L/kg
Plasma protein binding	80%

Absorption

Owing to acid stability, it is not destroyed in the stomach, but absorption is variable, about 30% remaining in the feces. Absorption is better after administration in the fasting state.

Metabolism and excretion

It is fairly extensively metabolized and degraded in the bowel. Some 60% of the dose is excreted in the urine, 25% in the unchanged form and the remainder as metabolites.

TOXICITY AND SIDE EFFECTS

Those common to penicillins (pp. 202–203). As with all penicillins, patients with a history of hypersensitivity to penicillins should be treated cautiously, as serious anaphylactic responses may occur.

CLINICAL USE

It may be prescribed for many indications for which benzylpenicillin is suitable, including streptococcal pharyngitis and skin sepsis, but is not recommended for initial therapy of serious infections. It is useful for continuation therapy after initial control of the disease by parenteral benzylpenicillin when prolonged treatment is required. It has been used prophylactically in recurrent pneumococcal meningitis after head injury and in rheumatic fever. It is not appropriate for infections caused by *H. influenzae* or Gram-negative bacteria, and is not recommended for the treatment of gonorrhea, syphilis or leptospirosis.

Preparations and dosage

Proprietary names: Numerous generic forms.

Preparations: Tablets, oral solution.

Dosage: Adults, oral, 250–500 mg every 6 h. Doses can be doubled.

Children <1 year, 62.5 mg every 6 h; children 1–5 years, 125 mg every 6 h; children 6–12 years, 250 mg every 6 h.

Widely available.

GROUP 3: ANTISTAPHYLOCOCCAL β-LACTAMASE-STABLE PENICILLINS

The members of this group include methicillin, nafcillin and four isoxazolypenicillins: oxacillin, cloxacillin, dicloxacillin and flucloxacillin. All have less intrinsic microbiological

activity than benzylpenicillin, but they are stable to staphylococcal β-lactamase and, as a result, display improved activity against penicillinase-producing strains of *Staph. aureus*. Oxacillin is rather less stable to hydrolysis by staphylococcal β-lactamase than the other compounds, with the order of stability: methicillin >nafcillin >cloxacillin, dicloxacillin and flucloxacillin >oxacillin.

Methicillin has been replaced in clinical practice because of low activity, poor oral absorption and a propensity to cause interstitial nephritis. Cloxacillin and flucloxacillin are used clinically in Europe and elsewhere, whereas nafcillin, oxacillin and dicloxacillin are preferred in North America.

ANTIMICROBIAL ACTIVITY

The compounds are active against staphylococci, streptococci, gonococci and meningococci but have no useful activity against enterococci, *H. influenzae* or enterobacteria (Table 14.3).

ACQUIRED RESISTANCE

The prevalence of strains of *Staph. aureus* resistant to methicillin (MRSA; pp. 35–36) has risen rapidly. Although MRSA and other methicillin-resistant staphylococci produce large amounts of β-lactamase, resistance is due primarily to the

Table 14.3 Activity of group 3 penicillins against susceptible strains of pathogenic bacteria: modal MIC (mg/L)

	Cloxacillin ^a	Methicillin	Nafcillin
<i>Staphylococcus aureus</i> (methicillin-susceptible)	0.25	1	0.1
<i>Staph. epidermidis</i>	0.25	1	0.1
<i>Streptococcus pyogenes</i>	0.06	0.25	0.06
<i>Str. pneumoniae</i>	0.12	0.25	0.1
<i>Enterococcus faecalis</i>	16	16–32	16
<i>Neisseria gonorrhoeae</i>	0.1	0.1–0.5	2
<i>N. meningitidis</i>	0.25	0.25	8
<i>Haemophilus influenzae</i>	8–16	2	4
<i>Escherichia coli</i>	R	R	R
<i>Klebsiella pneumoniae</i>	R	R	R
<i>Pseudomonas aeruginosa</i>	R	R	R
<i>Bacteroides fragilis</i>	R	R	R

^aActivities of dicloxacillin, flucloxacillin and oxacillin are similar.
R, resistant (MIC >64 mg/L).

acquisition of the supplementary PBP 2a with low affinity for methicillin and almost all other β -lactam antibiotics. The bacterial population may be heterogeneous in its response to β -lactam compounds, and only a small minority of cells may appear to be resistant in conventional media. The population can be rendered homogeneously resistant by growth either at 30°C or in a medium containing an excess of electrolytes, such as 5% NaCl; or by lowering the pH. For these reasons, standard susceptibility testing may not detect MRSA and the use of large inocula plus media supplemented with NaCl and/or incubation at 30°C is recommended. Oxacillin is the penicillin of choice for detection of these strains, although the use of the cephamycin cefoxitin (p. 181) may also increase testing sensitivity.

MRSA are resistant to almost all β -lactam agents, including imipenem and meropenem, and many isolates are also resistant to other antistaphylococcal antibiotics, with the exception of vancomycin and the related glycopeptide teicoplanin. Some newer agents, including quinupristin-dalfopristin (p. 334), linezolid (p. 301), daptomycin (p. 361) and tigecycline (p. 354) include MRSA in their spectrum of activity.

PHARMACOKINETICS

Methicillin is the most metabolically stable and least protein bound of the group 3 penicillins. Nafcillin is relatively acid labile and poorly and variably absorbed when dosed orally. Isoxazolylpenicillins are absorbed from the gut to varying degrees, although they are all absorbed considerably better than nafcillin. The mean peak plasma levels of cloxacillin are about twice those resulting from similar doses of oxacillin; those of dicloxacillin and flucloxacillin are about twice those of cloxacillin. Plasma levels are depressed when they are given with food.

Oxacillin is metabolized to a greater extent than dicloxacillin or flucloxacillin. All are highly protein bound. Levels obtained by intravenous bolus injection of isoxazolylpenicillins are higher than those produced by the extensively metabolized nafcillin, but this advantage is offset by their higher protein binding. Overall, dicloxacillin and flucloxacillin are superior to oxacillin and cloxacillin for oral administration. Flucloxacillin is better absorbed and provides more unbound drug than dicloxacillin.

They are widely distributed in the extracellular fluid and serous fluids, but as highly protein-bound agents their access to blister fluid is limited, though their persistence there is prolonged. They do not enter normal CSF, but their entry is somewhat erratically increased by inflammation, nafcillin penetrating better than others.

Little of these drugs appears in the bile, and they are excreted principally unchanged in the urine by both glomerular filtration and tubular secretion to produce very high urinary levels. Plasma half-lives are prolonged by probenecid and in the newborn and, with the exception of oxacillin, in renal

failure. Patients with cystic fibrosis clear the drugs unusually rapidly.

TOXICITY AND SIDE EFFECTS

As with all penicillins, serious anaphylactic responses may occur, but acute anaphylaxis is much less common than with benzylpenicillin. Most side effects are similar to those observed for other penicillins. Pseudomembranous colitis has been reported. Renal damage (generally reversible) has been described, usually in patients receiving large doses.

CLINICAL USE

The only, but important, therapeutic use for these agents is in the treatment of proven staphylococcal infection or (usually in combination therapy) where staphylococcal infection is suspected, and the causative organism is susceptible to the agent. The oral drugs are valuable in the treatment of staphylococcal infections of soft tissues and as continuation therapy in infections of bone and joints. Empirical penicillin usage should be avoided in regions with high MRSA infection rates.

CLOXA CILLIN

Molecular weight (free acid): 435.9.

A semisynthetic isoxazolylpenicillin supplied as the sodium salt for oral or parenteral administration.

ANTIMICROBIAL ACTIVITY

Cloxacillin is active against most Gram-positive cocci, but *E. faecalis* is relatively resistant (Table 14.3). It inhibits β -lactamase-producing strains of staphylococci (MIC 0.1–0.25 mg/L), but is not active against MRSA. Other susceptible bacteria include *N. gonorrhoeae*, *N. meningitidis* and Gram-positive anaerobes (MIC 0.1–0.25 mg/L). *H. influenzae*,

Enterobacteriaceae and *Ps. aeruginosa* are resistant, as are Gram-negative anaerobes. The compound is highly bound to serum protein and activity in vitro is substantially diminished in the presence of serum.

ACQUIRED RESISTANCE

Cloxacillin exhibits complete cross-resistance with other group 3 penicillins. Penicillin-tolerant strains are also tolerant to cloxacillin.

PHARMACOKINETICS

Oral absorption	40–60%
C_{\max} 500 mg oral	8 mg/L (fasting) after 1 h
500 mg intramuscular	15 mg/L after 0.5–1 h
Plasma half-life	0.5 h
Plasma protein binding	93–95%

Absorption and distribution

Cloxacillin is moderately well absorbed by mouth but absorption is depressed by food. Being highly protein bound, it diffuses poorly into normal interstitial fluid, serous cavities and CSF, but enters pus and inflamed bones and joints. It crosses the placenta.

Metabolism and excretion

Some inactivation occurs in the liver and about 10% of the plasma content is in the form of metabolites.

About 10% of an oral dose is excreted in the bile, but the main route of excretion is renal. Around 30% of an oral dose and 40–60% of an intramuscular dose appears in the urine as active antibiotic, with 10–20% in the form of metabolites. Excretion is by both glomerular filtration and tubular secretion and is depressed by probenecid, which elevates and prolongs the plasma concentration. Excretion is impaired in renal failure and there is some accumulation of metabolites.

TOXICITY AND SIDE EFFECTS

In addition to hypersensitivity common to penicillins, nausea and diarrhea may occur on oral dosage, but are usually mild. Other effects are similar to those of benzylpenicillin.

CLINICAL USES

Clinical uses are those of group 3 penicillins (p. 209).

Preparations and dosage

Proprietary names: Orbenin (and other generic formulations).

Preparations: Capsules, injection, oral solution.

Dosage: Adults, oral, 250–500 mg every 6 h; i.m., i.v., 250–500 mg every 4–6 h, the dose may be doubled in severe infections. Children <2 years, all routes, quarter adult dose; children 2–12 years, all routes, half adult dose.

Widely available; not available in the UK.

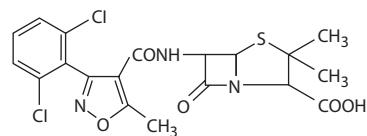

Further information

Bergeron MG, Desaulniers SD, Lessard C, et al. Concentrations of fusidic acid, cloxacillin and cefamandole in sera and atrial appendages of patients undergoing cardiac surgery. *Antimicrob Agents Chemother*. 1985;27:928–932.
Spino M, Chai RP, Isles AF, et al. Cloxacillin absorption and disposition in cystic fibrosis. *J Pediatr*. 1984;105:829–835.

DICLOXA CILLIN

Molecular weight (free acid): 470.4.

A semisynthetic isoxazolylpenicillin which differs from cloxacillin by an additional chlorine atom. It is supplied as the sodium monohydrate for oral administration.

ANTIMICROBIAL ACTIVITY

Its activities are generally similar to those of other isoxazolylpenicillins (Table 14.2). It is very highly bound to serum protein, and its activity in the presence of human serum in vitro is depressed to a greater extent than that of other isoxazolylpenicillins.

PHARMACOKINETICS

Oral absorption	c. 50%
C_{\max} 250 mg oral	9 mg/L after 1 h
500 mg intramuscular	14–16 mg/L after 0.5–1 h
Plasma half-life	0.5 h
Plasma protein binding	95–97%

Absorption

Absorption in the very young is poor and unpredictable.

Metabolism and excretion

Dicloxacillin is partly metabolized in the liver and about 10% of the circulating drug is in the form of metabolites. Some 50–70% of a dose is excreted in the urine, about 20% as metabolites. It is eliminated both in the glomerular filtrate and by tubular secretion, and plasma concentrations are raised by probenecid. Parent drug and increased proportions of metabolites accumulate in renal failure. Elimination is increased through enhanced tubular secretion in patients with cystic fibrosis.

TOXICITY AND CLINICAL USE

Phlebitis is common after intravenous injection. Its toxicity is otherwise similar to that of other penicillins (pp. 202–203). Clinical uses are those of the group 3 penicillins (p. 209).

Preparations and dosage

Proprietary names: Diclocil.

Preparations: Capsules, oral suspension.

Dosage: Adults, oral, 125–250 mg every 6 h. Children, oral, 12.5–25 mg/kg per day in divided doses. Doses can be doubled in severe infections.

Available in continental Europe and the USA.

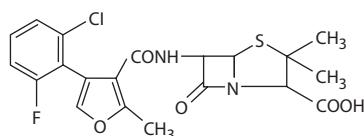

Further information

Lofgren S, Bucht G, Hermansson B, Holm SE, Winblad B, Norrby SR. Single-dose pharmacokinetics of dicloxacillin in healthy subjects of young and old age. *Scand J Infect Dis.* 1986;18:365–369.

Pacifici GM, Viani A, Taddeuchi-Brunelli G, Rizzo G, Carrai M. Plasma protein binding of dicloxacillin: effects of age and disease. *Int J Clin Pharmacol Ther Toxicol.* 1987;25:622–626.

FLUCLOXA CILLIN

Floxacillin. Molecular weight (free acid): 453.9; (sodium salt): 494.9.

A semisynthetic isoxazolypenicillin that differs from dicloxacillin by the substitution of a fluorine atom for a chlorine atom. It is supplied as the sodium salt for oral or parenteral administration and as a suspension of the magnesium salt in a syrup formulation.

ANTIMICROBIAL ACTIVITY

Its antibacterial activity is almost identical to that of cloxacillin (Table 14.3). There is complete cross-resistance with other penicillinase-stable penicillins.

PHARMACOKINETICS

Oral absorption	c. 80%
C_{max} 250 mg (oral)	11 mg/L after 0.5–1 h
Plasma half-life	2 h
Plasma protein binding	95%

Absorption and distribution

It is well absorbed after oral administration and penetrates rapidly into extravascular exudates. Its high protein binding limits its diffusion, notably into the normal CSF.

Metabolism and excretion

Flucloxacillin is partly metabolized in the liver and about 10% of the plasma concentration is made up of metabolites. It is more slowly eliminated than cloxacillin. Some appears in the bile but about 50–80% of an oral dose is recovered from the urine, about 20% as metabolites.

TOXICITY AND SIDE EFFECTS

In patients treated by intravenous infusion, about 5% developed phlebitis by the first and 15% by the second day, after which the proportion rose dramatically. Side effects are otherwise those common to penicillins (pp. 202–203).

CLINICAL USE

Uses are those of group 3 penicillins (p. 209).

Preparations and dosage

Proprietary name: Floxapen.

Preparations: Capsules, oral solution, injection.

Dosage: Adults, oral, i.m., i.v., 500 mg to 1 g every 6 h, the dose may be doubled in severe infections. Endocarditis, 12 g per day in six divided doses. Children <2 years, any route, quarter adult dose; children 2–10 years, any route, half adult dose.

Widely available; not available in the USA.

NAFCILLIN

Molecular weight (free acid): 414.4.

A semisynthetic penicillin supplied as the sodium salt for parenteral use.

ANTIMICROBIAL ACTIVITY

The antibacterial spectrum is similar to that of the isoxazolylpenicillins but it is more active against streptococci and pneumococci (Table 14.3, p. 208). Activity in vitro is depressed in the presence of serum. It is more stable than the isoxazolylpenicillins to staphylococcal β -lactamase. There is complete cross-resistance with other group 3 penicillins.

PHARMACOKINETICS

Oral absorption	c. 35%
C _{max} 1 g intramuscular	8 mg/L after 1 h
500 mg intravenous	30 mg/L after 5 min
Plasma half-life	0.5 h
Plasma protein binding	90%

Absorption and distribution

Nafcillin is poorly absorbed after oral administration, and absorption is further depressed if the drug is given with food. Most dosing is now intravenous. Penetration into tissues is similar to that of the isoxazolylpenicillins. Penetration into normal meninges is low, but is higher in inflamed meninges.

Metabolism and excretion

About 60–70% is inactivated in the liver. Following intramuscular administration, about 30% appears in the urine, producing concentrations up to 1000 mg/L. Administration of probenecid reduces the urinary excretion and raises and prolongs the plasma level. About 8% of the dose is excreted in the bile.

TOXICITY AND SIDE EFFECTS

There is cross-allergenicity with other penicillins. Its side effects are similar to the penicillins. Pseudomembranous colitis has been reported.

CLINICAL USE

Uses are those of group 3 penicillins (p. 209). Nafcillin has been particularly recommended for the treatment of staphylococcal bacteraemia caused by susceptible strains.

Preparations and dosage

Proprietary name: Nallpen.

Preparation: Injection.

Dosage: Adults, i.m., i.v., 0.5–1.5 g every 4–6 h. Children, 25 mg/kg every 12 h; neonates, 10 mg/kg every 12 h.

Available in the USA.

OXACILLIN

Molecular weight (free acid): 401.5.

A semisynthetic penicillin currently supplied primarily for intravenous administration. The first of the isoxazolyl series of β -lactamase-resistant penicillins.

ANTIMICROBIAL ACTIVITY

Its spectrum and activity are those of isoxazolylpenicillins (Table 14.3, p. 208). There is complete cross-resistance and tolerance with other group 3 penicillins. Oxacillin is frequently used to replace methicillin for standardized susceptibility testing to detect resistant staphylococci.

ACQUIRED RESISTANCE

In addition to methicillin-resistant strains producing the low affinity PBP 2a, rare methicillin-susceptible isolates of *Staph. aureus* display reduced susceptibility to oxacillin, due to incompletely defined chromosomal resistance mechanisms.

PHARMACOKINETICS

Oral absorption	30–35%
C_{\max} 500 mg intravenous	43 mg/L after 5 min
Plasma half-life	20–30 min
Plasma protein binding	92–96%

Absorption and distribution

It is the least well absorbed of the isoxazolylpenicillins when dosed orally. It is widely distributed at therapeutic levels into pleural, bile and amniotic fluid. Low concentrations penetrate the CSF.

Metabolism and excretion

Oxacillin is rapidly metabolized by opening of the β -lactam ring. Its main route of elimination is renal, about 25% of the dose being recovered from the urine as active material and another 25% as inactive metabolites. It is more rapidly eliminated in patients with cystic fibrosis.

TOXICITY AND SIDE EFFECTS

There is cross-allergy with other penicillins and reactions are generally typical of the group. Abnormalities of liver function, especially elevation of transaminase levels, may occur, sometimes accompanied by fever, nausea, vomiting and eosinophilia. As with benzylpenicillin, neurotoxicity may develop on high dosage in patients with renal failure. Pseudomembranous colitis has been reported.

CLINICAL USE

Uses are those of group 3 penicillins (p. 209).

Preparations and dosage

Proprietary names: Bristopen and various other generic formulation.

Preparations: Injection.

Dosage: Adults, i.m., i.v., 250 mg to 1 g every 4–6 h. Children (<40 kg), 12.5–25 mg/kg every 4–6 h. Newborn and premature infants, 25 mg/kg per day in divided doses may be given, but used with caution.

Available widely in continental Europe, North America, South America and Japan. Not available in the UK.

OTHER GROUP 3 PENICILLINS

METHICILLIN

2,6-Dimethoxyphenylpenicillin; methicillin (international non-proprietary name). The first β -lactamase-resistant semi-synthetic penicillin. It was initially used widely but has been superseded by other group 3 members and is no longer commercially available.

It is less active than benzylpenicillin or other group 3 penicillins (Table 14.3, p. 208). It is very stable to staphylococcal β -lactamase and is active against β -lactamase-producing strains of *Staph. aureus* that do not produce a functional PBP 2a (p. 30). Resistance is common among staphylococci, with the incidence geographically diverse. Most methicillin-resistant staphylococcal isolates display multiresistance.

It is not acid resistant, and must therefore be administered parenterally. About 10% is metabolized, with 60–80% of the dose excreted in the urine. Toxicity is similar to that of other group 3 penicillins. Nephritis appears to be more common than with other penicillins.

GROUP 4: EXTENDED-SPECTRUM PENICILLINS

The introduction of an amino group in the α-position of the side chain of benzylpenicillin confers a high degree of acid stability together with enhanced activity against Gram-negative bacteria. Ampicillin, the first of the aminopenicillins to be developed, retains the activity of benzylpenicillin against Gram-positive cocci but exhibits increased activity against *H. influenzae* and certain non-β-lactamase-producing Gram-negative bacilli, notably *Escherichia coli*, *Salmonella enterica* serotypes, *Shigella* spp. and *Proteus mirabilis*. The aminopenicillins are readily inactivated by β-lactamases, but in combination with β-lactamase inhibitors (p. 239) they display enhanced activity against many β-lactamase-producing isolates.

The clinical success of ampicillin resulted in the development of a number of modified aminopenicillins with claims for superior properties. Compounds closely related structurally to ampicillin include amoxicillin and ciclacillin.

Amoxicillin differs from ampicillin in possessing a *p*-hydroxy group in the benzene ring of the side chain and has a spectrum of activity essentially identical to that of ampicillin, but is bactericidal to susceptible Gram-negative bacilli at rather lower concentrations. Amoxicillin with its superior absorption characteristics has largely displaced ampicillin for oral therapy, except against the enterococci.

The antibacterial activity of epicillin is virtually identical to that of ampicillin, while that of ciclacillin is substantially less. Neither of these agents is widely used.

Four esters of ampicillin (bacampicillin, lenampicillin, pivampicillin, talampicillin) were developed as prodrugs with oral absorption characteristics superior to those of the parent penicillin. The esters are lipophilic compounds that are devoid of antibacterial activity in their own right, but which are hydrolyzed by tissue esterases during absorption to liberate ampicillin. Two condensation products, hetacillin and metampicillin (formed by combination of ampicillin with acetone and formaldehyde, respectively), hydrolyze spontaneously to release ampicillin, but are no longer used clinically. The antibacterial activity of all these compounds is due solely to the ampicillin liberated.

Two other group 4 penicillins, mecillinam (amdinocillin) and its prodrug pivmecillinam, are structurally different from the aminopenicillins. Like other semisynthetic penicillins they are derived from 6-APA but differ in being 6-α-amidino-penicillanates rather than 6-α-acylaminopenicillanates. This is reflected in the antibacterial spectrum of mecillinam, which is atypical of the penicillins in displaying high activity against Gram-negative bacteria but poor activity against Gram-positive cocci. The mechanism of action of mecillinam differs from that of other penicillins in binding almost exclusively to PBP 2 (p. 13) in Gram-negative bacteria.

PHARMACOKINETICS

The aminopenicillins are acid stable and can be given orally. Ampicillin is the least well absorbed, about one-third of the dose appearing in the urine as active drug, and absorption is further reduced by food. The esters, ciclacillin and amoxicillin, are substantially better absorbed and not significantly affected by food, peak plasma levels generally being at least twice those achieved by equivalent doses of ampicillin. Plasma elimination half-lives are generally around 1 h and plasma protein binding is low (around 20%). Excretion is primarily renal, resulting in high concentrations of active antibiotic in urine; a proportion of an oral dose (10–20%) is metabolized in the liver and small amounts are found in the bile. The aminopenicillins may be administered by parenteral routes, but the esters are given only by mouth. Mecillinam is not absorbed by mouth but its pivaloyloxymethyl ester, pivmecillinam, is relatively well absorbed by the oral route.

TOXICITY AND SIDE EFFECTS

Patients with a history of hypersensitivity to penicillins should be treated cautiously, as serious anaphylactic responses may occur. Ampicillin appears to be less likely than benzylpenicillin to elicit true allergic reactions, but is much more likely to cause rashes that appear not to be of allergic origin, especially in patients with infectious mononucleosis or other lymphoid disorders. The prevalence of rashes in patients treated with amoxicillin is similar. Ampicillin esters naturally have the same potential to give rise to rashes.

Gastrointestinal side effects are relatively common in patients treated with oral ampicillin. Ampicillin esters, amoxicillin, ciclacillin and the ester of mecillinam are more likely to cause upper abdominal discomfort, nausea and vomiting, but are less likely, being better absorbed, to cause diarrhea. Upper abdominal symptoms are substantially ameliorated if the esters are taken with food. Liver function should be monitored in patients receiving prolonged courses, or in those in whom renal or hepatic function is impaired.

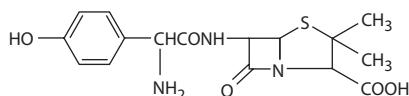

CLINICAL USE

Aminopenicillins are recommended for the wide range of infections that made ampicillin one of the most commonly prescribed agents, notably for urinary and respiratory infections, as well as for gastrointestinal infections caused by susceptible *Salmonella* spp. and *Shigella* spp. However, the increasing frequency of isolation of β-lactamase-producing pathogens has resulted in a reduction in the usefulness of aminopenicillins as monotherapy. This difficulty is overcome by combining ampicillin or amoxicillin with β-lactamase inhibitors (p. 239). Ampicillin and amoxicillin also have a role in the treatment of

severe infections, including endocarditis, meningitis and septicemia, often in combination with other antibacterial agents, such as aminoglycosides. Mecillinam is suitable only for infections involving Gram-negative bacteria and should not be used where Gram-positive organisms may be implicated.

AMOXICILLIN

Amoxycillin. Molecular weight (free acid): 365.4; (trihydrate): 419.5.

Para-hydroxy ampicillin. Supplied as the trihydrate for oral administration and as the sodium salt for parenteral use. A formulation with clavulanic acid (co-amoxiclav) is also available (see p. 240).

ANTIMICROBIAL ACTIVITY

The antibacterial spectrum is identical to that of ampicillin and there are few differences in antibacterial activity (Table 14.4). Like ampicillin, amoxicillin is unstable to most β -lactamases. It has useful activity against *Helicobacter pylori* (<1% resistance), and is included in most combination regimens for the treatment of *H. pylori* infections.

Table 14.4 Activity of group 4 penicillins against non- β -lactamase-producing strains of pathogenic bacteria; modal MIC (mg/L)

	Ampicillin	Amoxicillin	Mecillinam
<i>Staphylococcus aureus</i> (methicillin-susceptible)	1	0.1	128
<i>Streptococcus pyogenes</i>	0.03	0.01	2
<i>Str. pneumoniae</i>	0.02	0.02	2
<i>Enterococcus faecalis</i>	2	2	R
<i>Neisseria gonorrhoeae</i>	0.5	≤ 0.5	0.1
<i>N. meningitidis</i>	0.12–2	≤ 2	ND
<i>Haemophilus influenzae</i>	0.5	0.5	16
<i>Escherichia coli</i>	4	4	0.12
<i>Klebsiella pneumoniae</i>	R	R	0.25
<i>Pseudomonas aeruginosa</i>	R	R	R
<i>Bacteroides fragilis</i>	32	32	R

R, resistant (MIC >64 mg/L); ND, no data.

ACQUIRED RESISTANCE

There is complete cross-resistance with ampicillin. Its action against many β -lactamase-producing strains can be restored by co-administration with β -lactamase inhibitors (p. 239).

PHARMACOKINETICS

Oral absorption	75–90%
C_{max} 500 mg oral	5.5–7.6 mg/L after 1–2 h
500 mg intramuscular	c. 14 mg/L after 1–2 h
Plasma half-life	1 h
Volume of distribution	0.3 L/kg
Plasma protein binding	17–20%

Absorption and distribution

Oral absorption produces over twice the peak concentration achieved by comparable doses of ampicillin, allowing less frequent dosing intervals. Absorption is unaffected by food.

It is well-distributed in multiple body fluids, including pleural, peritoneal and middle ear fluid. It does not penetrate well into the CSF.

Metabolism and excretion

Some 10–25% is converted to the penicilloic acid. Between 50% and 70% of unchanged drug is recovered in the urine in the first 6 h after a dose of 250 mg. Plasma levels are elevated and prolonged by the administration of probenecid.

TOXICITY AND SIDE EFFECTS

Amoxicillin is generally well tolerated, side effects being those common to penicillins, but including non-allergic rashes in patients with glandular fever. As the drug is well absorbed, diarrhea is generally infrequent and rarely sufficiently severe to require withdrawal of treatment.

CLINICAL USE

Isolates should be tested for susceptibility before use, especially for serious infections.

Ear, nose and throat infections other than pharyngitis, which may mask glandular fever
Tracheobronchitis, bronchitis, pneumonia
Genitourinary tract infections, including gonorrhoea
Infections of skin and soft tissues due to streptococci and susceptible staphylococci
Helicobacter pylori infection (in combination with a proton pump inhibitor and at least one other antimicrobial agent such as clarithromycin)
Prophylaxis of endocarditis in patients undergoing dental treatment and other procedures

ANTIMICROBIAL ACTIVITY

Its activity against common pathogenic bacteria is shown in Table 14.4. Ampicillin is slightly less active than benzylpenicillin against most Gram-positive bacteria but is more active against *E. faecalis*. MRSA and strains of *Str. pneumoniae* with reduced susceptibility to benzylpenicillin are resistant. Most group D streptococci, anaerobic Gram-positive cocci and bacilli, including *L. monocytogenes*, *Actinomyces* spp. and *Arachnia* spp., are susceptible. Mycobacteria and nocardia are resistant.

Ampicillin has similar activity to benzylpenicillin against *N. gonorrhoeae*, *N. meningitidis* and *Mor. catarrhalis*. It is 2–8 times more active than benzylpenicillin against *H. influenzae* and many Enterobacteriaceae, but β-lactamase-producing strains are resistant. *Pseudomonas* spp. are resistant, but *Bordetella*, *Brucella*, *Legionella* and *Campylobacter* spp. are often susceptible. Certain Gram-negative anaerobes such as *Prevotella melaninogenica* and *Fusobacterium* spp. are susceptible, but *B. fragilis* is resistant, as are mycoplasmas and rickettsiae.

Activity against molecular class A β-lactamase-producing strains of staphylococci, gonococci, *H. influenzae*, *Mor. catarrhalis*, certain Enterobacteriaceae and *B. fragilis* is enhanced by the presence of β-lactamase inhibitors, specifically clavulanic acid.

Its bactericidal activity resembles that of benzylpenicillin. Bactericidal synergy occurs with aminoglycosides against *E. faecalis* and many enterobacteria, and with mecillinam against a number of ampicillin-resistant enterobacteria.

Preparations and dosage

Proprietary names: Amoxil (and many generic formulations).

Preparations: Capsules, suspension, injection, dispersible tablets, oral sachets.

Dosage: Adults, oral, 250–500 mg every 8 h high-dose therapy, 3 g every 12 h; short-course therapy, simple acute urinary tract infection, two 3 g doses with 10–12 h between doses, gonorrhoea, single 3 g dose; i.m., i.v., 500 mg every 8 h, the dose may be increased to 1 g i.v. every 6 h in severe infections. Children up to 10 years, oral, 125–250 mg every 8 h. In severe otitis media, 750 mg every 12 h for 2 days may be used in children 3–10 years; i.m., i.v., 50–100 mg/kg per day in divided doses (increased to 180 mg/kg per day in severe infections). Widely available.

AMPICILLIN

Molecular weight (free acid): 349.4; (sodium salt): 471.4.

A semisynthetic penicillin administered orally as the trihydrate and parenterally as the soluble sodium salt. Formulations with sulbactam are also available (see p. 242).

ACQUIRED RESISTANCE

β-Lactamase-producing pathogens, including most clinical isolates of *Staph. aureus*, are resistant. Strains of pneumococci, enterococci, gonococci and *H. influenzae* with altered PBPs have reduced susceptibility to ampicillin. Isolates of *N. gonorrhoeae* and *H. influenzae* with a TEM plasmid-mediated β-lactamase (which are more common) are fully resistant. Resistance among *H. influenzae* is often linked with resistance to chloramphenicol, erythromycin or tetracycline, due to plasmid-encoded resistance markers that are co-transferred with the gene for the TEM enzyme. However, at least 70% of current *H. influenzae* isolates remain susceptible to ampicillin worldwide.

The widespread use of ampicillin and other aminopenicillins has led to resistance becoming common in formerly susceptible species of enteric pathogens as a result of the widespread dissemination of plasmid-mediated β-lactamases. Surveillance data from North America and Europe indicate less than 50% susceptibility to ampicillin in *Esch. coli*. At least 90% of current isolates of *Mor. catarrhalis* are β-lactamase-producing strains. Ampicillin-resistant strains of salmonellae, notably *S. enterica* serotypes Typhi and Typhimurium (many

of which are also resistant to chloramphenicol, sulfonamides and tetracyclines) present a serious problem in Africa, Asia and South America. Multiresistant strains of shigellae also predominate in many parts of the world.

PHARMACOKINETICS

Oral absorption	30–40%
C_{max} 500 mg oral	3.2 mg/L after c. 2 h
500 mg intramuscular	5–15 mg/L after 1 h
500 mg intravenous infusion	12–29 mg/L
Plasma half-life	1–1.5 h
Volume of distribution	0.38 L/kg
Plasma protein binding	20%

Absorption and distribution

Ampicillin is highly stable to acid: in 2 h at pH 2 and 37°C, only 5% of activity is lost. Absorption is impaired when it is given with meals.

It is distributed in the extracellular fluid. Adequate concentrations are obtained in serous effusions. Effective CSF levels are obtained only in the presence of inflammation, variable peak concentrations around 3 mg/L being found in the first 3 days of treatment in patients receiving 150 mg/kg per day. It accumulates and persists in the amniotic fluid.

Metabolism and excretion

A small proportion is converted to penicilloic acid. About 34% of an oral dose and 60–80% of parenteral doses are recoverable from the urine, where concentrations around 250–1000 mg/L appear. Excretion is partly in the glomerular filtrate and partly by tubular secretion, which can be blocked by probenecid. Impairment of renal function reduces the rate of excretion, the plasma half-life rising to 8–9 h in anuric patients.

Although excretion is mainly renal, up to 50 times the corresponding serum level may be attained in the bile. There is a degree of enterohepatic recirculation and significant quantities appear in the feces. Bioavailability may be affected in severe liver disease.

TOXICITY AND SIDE EFFECTS

Ampicillin is generally free from severe toxicity and, apart from gastrointestinal intolerance, the only significant side effects seen have been rashes. In common with other semisynthetic penicillins, it appears to be less likely than benzylpenicillin to elicit true allergic reactions. However, it is more likely to cause rashes, which are found in approximately 9% of treated patients and which occur more frequently in patients receiving large doses or in renal failure. Rashes occur in 95%

of patients with infectious mononucleosis or other lymphoid disorders. This unusual susceptibility disappears when the disease resolves. In keeping with a toxic rather than an allergic origin, skin tests to ampicillin and to mixed-allergen moieties of benzylpenicillin are negative. Since the typical maculopapular rash of ampicillin does not have an allergic origin, its development does not indicate penicillin allergy and is not a contraindication to the use of other penicillins.

Gastrointestinal side effects are relatively common (around 10%) in patients treated with oral ampicillin, and occur in 2–3% of patients given the drug parenterally, presumably as a result of drug entering the gut through the bile. The very young and the old are most likely to suffer. Diarrhea can be sufficiently severe to require withdrawal of treatment and pseudomembranous colitis may occur. Interference with the bowel flora, which is presumably implicated in diarrhea, can also affect enterohepatic recirculation of steroids, and the derangement can be sufficient to impair the absorption of oral contraceptives and affect the interpretation of estriol levels.

CLINICAL USE

Isolates should be tested for susceptibility before use, especially for serious infections. For oral therapy, amoxicillin is preferable to ampicillin.

Urinary tract infections
Bacterial meningitis
Respiratory tract infections
Gastrointestinal infections, including typhoid fever and bacillary dysentery
Enterococcal endocarditis and septicemia (in combination with an aminoglycoside)
Listeriosis (in combination with an aminoglycoside)

Preparations and dosage

Proprietary names: Penbritin, Omnipen and many generic preparations.

Preparations: Capsules, syrup, injection.

Dosage: Adults, oral, 250 mg to 1 g every 6 h; i.m., i.v., 500 mg every 4–6 h. Meningitis, i.v., 2 g every 4 h. Children <10 years, any route, half the adult dose. Meningitis, i.v., 150–200 mg/kg per day in divided doses.

Widely available.

AMPICILLIN ESTERS

BACAMPICILLIN

The ethoxycarbonyloxyethyl ester of ampicillin. It is absorbed from the intestine more rapidly and more completely than ampicillin, with average peak plasma levels 2–3 times those produced by equivalent doses of ampicillin. Mean absorption differed considerably among hospital patients and was less than in healthy volunteers.

Preparations and dosage

Proprietary names: Various generic formulations.

Preparations: Tablets, oral suspension.

Dosage: Adults, oral, 400 mg, every 8–12 h; dose doubled in severe infections. Children >5 years, 200 mg every 8 h or 25–50 mg/kg per day in two divided doses.

Widely available; not available in the UK or the USA.

LENAMPICILLIN

The daloxate ester of ampicillin. In volunteers receiving 400 mg orally, peak concentrations were around 6.0 mg/L at about 1 h – about twice those seen with an equimolar dose (250 mg) of ampicillin. Peak plasma concentration is slightly lower and delayed by food.

PIVAMPICILLIN

The pivaloyloxymethyl ester of ampicillin. Its absorption is considerably better than that of the parent ampicillin and is less affected by food. Plasma levels rise more rapidly to 2–3 times those produced by corresponding doses of ampicillin.

TALAMPICILLIN

The phthalidyl thiazolidine carboxylic ester of ampicillin. It is well absorbed when administered orally, doses of 250 or 500 mg producing mean peak plasma levels of 4 or 11 mg/L, respectively, about 2 h after the dose. Administration with food delays and depresses the peak concentration. It is of limited commercial availability.

AMPICILLIN CONDENSATES

Hetacillin, a condensation product of ampicillin and acetone, and metampicillin, a condensation product of ampicillin and formaldehyde, hydrolyze rapidly in the body to liberate ampicillin, leaving little or none of the parent compound detectable in the plasma after oral dosing. For hetacillin, peak levels and excretion are reported to be lower than those for ampicillin. Their toxicity profiles are comparable to that of ampicillin. Both drugs are of very limited availability.

MECILLINAM

Amdinocillin. Molecular weight (free acid): 325.4.

6- β -Amidinopenicillin. Supplied as the hydrochloride dihydrate for parenteral administration and as the hydrochloride salt of the pivaloyloxymethyl ester (pivmecillinam; amdinocillin pivoxil) for oral use.

ANTIMICROBIAL ACTIVITY

The antibacterial spectrum differs greatly from that of the aminopenicillins in that the compound displays high activity against many Gram-negative bacteria but limited activity against Gram-positive organisms (Table 14.4, p. 215). Mecillinam is active against many Enterobacteriaceae due to its selective binding to PBP 2, although the susceptibility of *Proteus* and *Providencia* spp. is variable. *H. influenzae* is less susceptible than enteric bacilli, and *Acinetobacter* spp., *B. fragilis* and *Ps. aeruginosa* are resistant.

It is readily inactivated by many β -lactamases, although it is more stable than ampicillin.

ACQUIRED RESISTANCE

Intrinsic resistance in susceptible species of enterobacteria is uncommon and many ampicillin-resistant strains are susceptible. Bacteria that are resistant to both ampicillin and mecillinam are usually those producing large amounts of β -lactamase, most commonly plasmid-mediated enzymes.

PHARMACOKINETICS

Oral absorption (pivmecillinam)	c. 75%
C_{max} 200 mg intravenous infusion	12 mg/L end infusion
200 mg intramuscular	c. 6 mg/L after 45 min
400 mg oral (pivmecillinam)	2–5 mg/L after c. 1 h
Plasma half-life	50 min
Volume of distribution	0.2–0.4 L/kg
Plasma protein binding	5–10%

Absorption

Oral absorption is very poor, with conventional doses producing plasma levels of <1 mg/L and recovery of only about 5% in the urine.

A 400 mg dose of the pivaloyl ester is equivalent to 273 mg mecillinam. It is relatively well absorbed and rapidly liberates the parent compound.

Metabolism and excretion

The amidino side chain undergoes spontaneous aqueous hydrolysis to the N-formyl derivative, which retains some antibacterial activity. Hydrolysis of the β -lactam ring also occurs.

Approximately 60% is excreted unchanged in the urine in the first 6 h, achieving concentrations exceeding 1 g/L. The concentration in bile can reach 40 or 50 mg/L in patients with normally functioning gallbladders treated with 800 mg intramuscularly.

TOXICITY AND SIDE EFFECTS

It is generally well tolerated, and serious anaphylactic responses are said to be rare. Nausea and vomiting, which may be persistent, occur with diarrhea in some patients treated with pivmecillinam.

CLINICAL USE

Urinary tract infection (pivmecillinam)
Other infections with susceptible Gram-negative bacilli (usually in combination with other agents)

Preparations and dosage

Proprietary names: Selexid.

Preparations: Injection, suspension, tablets.

Dosage: Adults, meccillinam: 5–10 mg/kg every 6–8 h depending on the severity of the infection; pivmecillinam: 200–400 mg every 6–8 h.

Limited availability; pivmecillinam available in the UK.

OTHER GROUP 4 PENICILLINS

CICLACILLIN (CYCLACILLIN)

The structure differs from other aminopenicillins in that the benzene ring is completely saturated and the amino substituent is attached directly to it instead of being linked to an adjacent carbon atom. It is less active than ampicillin against staphylococci, streptococci and *H. influenzae*, but is better absorbed by mouth, peak plasma levels of 10–18 mg/L being reached after a 500 mg oral dose. Its pharmacokinetic properties, side effects and use resemble those of ampicillin. It has limited availability.

EPICILLIN

An analog of ampicillin in which the benzene ring is partially saturated. It closely resembles ampicillin in its antibacterial properties. It is moderately well absorbed, a 500 mg oral dose producing mean peak plasma levels of 2–3 mg/L. Its behavior on intramuscular injection, distribution, excretion, toxicity and uses resemble those of ampicillin. It is of very limited availability.

GROUP 5: PENICILLINS ACTIVE AGAINST *PS. AERUGINOSA*

Certain derivatives of benzylpenicillin or ampicillin exhibit useful activity against *Ps. aeruginosa*. Three derivatives of benzylpenicillin possessing an acidic group in the acyl side chain were developed for clinical use: carbenicillin and ticarcillin are α -carboxypenicillins, and the third, sulbenicillin, possesses a sulfonic acid group in the side chain. Two oral prodrug forms of carbenicillin were formerly used: the phenyl ester, carfecillin, and the indanyl ester, carindacillin. The acyl derivatives of ampicillin active against *Ps. aeruginosa* include the acylureidopenicillins: azlocillin, mezlocillin and piperacillin. Apalcillin and aspoxicillin are also acylaminopenicillins, with properties generally similar to the ureidopenicillins, but lack the ureido group in the side chain. Only piperacillin and ticarcillin are now in widespread use.

ANTIMICROBIAL ACTIVITY

The acylureidopenicillins and the carboxypenicillins display similar antibacterial spectra, but the ureidopenicillins are more active against streptococci and enterococci (Table 14.5). Both groups are as active as ampicillin against susceptible Gram-negative bacteria. However, strains producing elevated amounts of β -lactamase, such as those organisms with derepressed β -lactamase production, are resistant. Interest in these penicillins lies solely in their activity against *Ps. aeruginosa*. Apalcillin, azlocillin and piperacillin display greater activity in vitro than the carboxypenicillins. The superior activity of the ureidopenicillins against *Ps. aeruginosa* may be due to a combination of better penetration characteristics and greater affinity for PBPs. All these compounds exhibit reduced activity against *Bacteroides* spp.

Table 14.5 Activity of group 5 and 6 penicillins against non- β -lactamase-producing strains of pathogenic bacteria; modal MIC (mg/L)

	Azlocillin	Piperacillin	Ticarcillin	Temocillin
<i>Staphylococcus aureus</i> (methicillin-susceptible)	1	0.5	1	R
<i>Streptococcus pyogenes</i>	0.03	0.03	0.25	R
<i>Str. pneumoniae</i>	0.03	0.02	0.5	R
<i>Enterococcus faecalis</i>	2	1	32	R
<i>Neisseria gonorrhoeae</i>	<0.01	<0.01	0.06	0.01–1
<i>N. meningitidis</i>	ND	0.06	0.06	ND
<i>Haemophilus influenzae</i>	0.06	0.03	0.5	0.1–2
<i>Escherichia coli</i>	16	2	4	1–8
<i>Klebsiella pneumoniae</i>	64	16	R	1–16
<i>Pseudomonas aeruginosa</i>	4	4	16–32	R
<i>Bacteroides fragilis</i>	8	8	16	R

R, resistant (MIC >64 mg/L); ND, no data.

ACQUIRED RESISTANCE

Resistance in clinical isolates is due primarily to their hydrolysis by plasmid-encoded β -lactamases or by elevated levels of AmpC cephalosporinases found in many species of Enterobacteriaceae. Activity can often be restored by combinations with β -lactamase inhibitors; fixed combinations of ticarcillin with clavulanic acid (pp. 240–241) and piperacillin with tazobactam (p. 243) have been developed for clinical use.

PHARMACOKINETICS

None of the compounds (other than the prodrugs of carbenicillin; see above) is orally absorbed.

The acylureidopenicillins produce peak plasma levels that are lower than those obtained with the carboxypenicillins. The half-lives and volumes of distribution of the ureidopenicillins are generally similar and increase with larger doses. Elimination from the body is largely by the renal route and most of the drug appears unchanged in the urine, but relatively high concentrations may appear in bile.

CLINICAL USE

A major role of these compounds is the treatment of established pseudomonal infection, but they may also be active against some penicillin-resistant Gram-negative bacilli. They are also used in the treatment and prophylaxis of anaerobic and mixed infections, especially when combined with a β -lactamase inhibitor. A special role has been claimed, particularly for the acylureidopenicillins in providing broad prophylactic cover, notably in bowel surgery (see Ch. 39). An advantage claimed for acylureidopenicillins

over carboxypenicillins is that they are mono- rather than di-sodium salts, thus presenting a substantially lower sodium load.

In neutropenic patients they should be combined with an aminoglycoside. However, it should be noted that penicillins and aminoglycosides should not be mixed in infusion fluids because of the possibility of mutual degradation (p. 149).

Combination therapy with an aminoglycoside is recommended in *Ps. aeruginosa* pneumonia. Soft-tissue and burn wound infections usually respond. Infections requiring treatment with these agents generally arise in patients with underlying disorders, and suppression rather than eradication of infection is often the best result obtainable. Good examples of such 'control' are provided by:

- cystic fibrosis (where accelerated elimination of the drugs requires high dosage)
- urinary tract infection in catheterized patients
- the grave necrotizing otitis externa of diabetes.

With all these agents, treatment failures are often due to the emergence of resistant variants.

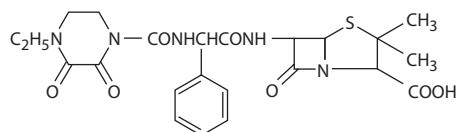

Further information

Tan JS, File Jr TM. Antipseudomonal penicillins. *Med Clin North Am.* 1995;79:679–693.

PIPERACILLIN

Molecular weight (free acid): 517.6; (sodium salt): 539.6.

A semisynthetic acylureidopenicillin supplied as the sodium salt for parenteral administration. A formulation with tazobactam is also available (p. 243).

ANTIMICROBIAL ACTIVITY

The activity against common bacterial pathogens is shown in Table 14.5. It displays good activity against non- β -lactamase-producing strains of *N. gonorrhoeae*, ampicillin-susceptible *H. influenzae* and many Enterobacteriaceae. It is the most active of the antipseudomonal penicillins against *Ps. aeruginosa* and retains its activity in the absence of a β -lactamase inhibitor. Synergy with aminoglycosides has been demonstrated against many strains of Enterobacteriaceae and *Ps. aeruginosa*.

ACQUIRED RESISTANCE

There is complete cross-resistance with other ureidopenicillins, but ticarcillin-resistant strains of *Ps. aeruginosa* may be susceptible. Piperacillin-resistant strains of *B. fragilis* and other *Bacteroides* spp. are common. Because piperacillin is hydrolyzed by most β -lactamases, many β -lactamase-producing isolates are resistant unless it is protected by β -lactamase inhibitors.

PHARMACOKINETICS

Oral absorption	Negligible
C_{max} 2 g (2–3 min intravenous injection)	305 mg/L after 5 min
Plasma half-life	0.9 h
Volume of distribution	16–24 L/1.73 m ²
Plasma protein binding	16%

In patients with meningitis, mean CSF penetration of 30% has been found. The urine is the principal route of excretion, 50–70% of the dose appearing over 12 h, most in the first 4 h. Most is excreted via the tubules, 75–90% in active form. The half-life is prolonged in renal failure but much less than is the case with carboxypenicillins. There is substantial biliary excretion, levels in the common duct bile after a 1 g intravenous dose commonly reaching 500 mg/L or more. During hemodialysis the plasma half-life remains elevated and only 10–15% of the dose is removed.

TOXICITY AND SIDE EFFECTS

Piperacillin is generally well tolerated, with mild to moderate pain on injection, thrombophlebitis and diarrhea in some patients. It otherwise exhibits side effects common to the group, including hypersensitivity, leukopenia and abnormalities of platelet aggregation without coagulation defect, except on prolonged treatment.

CLINICAL USES

Intra-abdominal infection
Urinary tract infections
Gynecological and gonococcal infections
Septicemia
Lower respiratory infections
Skin and skin structure infections
Bone and joint infections

Preparations and dosage

Proprietary names: Pipril; Pipracil; Tazocin, Zosyn (with tazobactam).

Preparation: Injection.

Dosage: Piperacillin, adults, i.m., i.v., 100–150 mg/kg per day in divided doses, increased to 200–300 mg/kg per day in severe infections; in life-threatening infections a dose of not less than 16 g per day is recommended. Children 2 months to 12 years, 100–300 mg/kg per day in 3–4 divided doses; neonates and infants <2 months, 150–300 mg/kg per day in 2–3 divided doses. Piperacillin with tazobactam, adults and children >12 years, i.v., 2.25–4.5 g every 6–8 h.

Widely available.

Further information

Tartaglione TA, Nye I, Vishniavsky N, Poynor W, Polk RE. Multiple dose pharmacokinetics of piperacillin and azlocillin in 12 healthy volunteers. *Clin Pharmacol*. 1986;5:941–946.

TICARCILLIN

Molecular weight (free acid): 384.4; (disodium salt): 428.4.

A semisynthetic carboxypenicillin supplied as the disodium salt for parenteral use. A formulation with clavulanic acid is also available (p. 240).

ANTIMICROBIAL ACTIVITY

The activity against common bacterial pathogens is shown in Table 14.5. Because it is hydrolyzed less rapidly than ampicillin, non- β -lactamase-producing strains of *N. gonorrhoeae*, ampicillin-susceptible *H. influenzae* and some Enterobacteriaceae are susceptible. Most aerobic and anaerobic Gram-positive bacteria are susceptible, with the exception of *E. faecalis* and β -lactamase-producing *Staph. aureus*. Anaerobic Gram-negative bacteria including *B. fragilis* are usually susceptible. Bactericidal synergy with aminoglycosides is demonstrable against *Ps. aeruginosa* and enterobacteria.

ACQUIRED RESISTANCE

Ticarcillin is generally cross-resistant with carbenicillin. It is somewhat stable to hydrolysis by AmpC-mediated

β -lactamases of Gram-negative bacilli, but can be hydrolyzed by most other chromosomally and plasmid-mediated enzymes unless protected by a β -lactamase inhibitor.

PHARMACOKINETICS

Oral absorption	Negligible
C_{\max} 1 g intramuscular	35 mg/L after 1 h
Plasma half-life	1.3 h
Volume of distribution	0.21 L/kg
Plasma protein binding	50–60%

Absorption and distribution

It is not orally absorbed. On parenteral co-administration with gentamicin, the plasma concentration of ticarcillin is unaffected, but the concentration of gentamicin is lowered. It enters the serous fluids, providing concentrations up to 60% of those of the plasma. It does not cross the normal meninges but levels of up to 50% of those of the plasma can be found in meningitis.

Metabolism and excretion

Up to 15% is excreted as penicilloic acid, a higher percentage than for carbenicillin (up to 5%). Some is excreted in the bile, producing levels 2–3 times those in the plasma, but the main route of excretion is through the kidneys (80%), principally as unchanged drug, appearing in the urine in the first 6 h. It is more rapidly eliminated in children with cystic fibrosis.

TOXICITY AND SIDE EFFECTS

As with all penicillins, hypersensitivity reactions may occur, but are less frequent and severe than those associated with benzylpenicillin. Rashes and eosinophilia occur; reversible abnormalities of liver function can develop. Since large doses of the drug have to be used, convulsions can occur, as with other penicillins, and being a disodium salt, electrolyte disturbances can result from the sodium load and from loss of potassium.

CLINICAL USE

Serious infection, including septicemia, respiratory tract infections, genitourinary tract infections and skin and soft-tissue infections caused by susceptible bacteria

Preparations and dosage

Proprietary names: Ticar, Timentin (with clavulanic acid).

Preparation: Injection.

Dosage: Ticarcillin, adults, i.v., 15–20 g per day in divided doses. Children, 200–300 mg/kg per day in divided doses. Ticarcillin with clavulanic acid, adults, i.v., 3.2 g every 6–8 h, increased to every 4 h in more severe infections. Children, 80 mg/kg every 6–8 h; neonates, 80 mg/kg every 6–8 h. Widely available.

Because of the increasing prevalence of bacteria possessing class A β -lactamases, it is now more commonly used in combination with clavulanic acid.

Further information

Anonymous. Ticarcillin (disodium). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:T106–T109.

OTHER GROUP 5 PENICILLINS

APALCILLIN

A semisynthetic acylaminopenicillin supplied as the sodium salt for parenteral administration. The antibacterial spectrum and toxicity profile are similar to those of the acylureidopenicillins. It is relatively labile to many β -lactamases, including the common TEM plasmid-mediated enzyme. It has very limited commercial availability.

ASPOXICILLIN

An acylaminopenicillin, synthesized from amoxicillin. It is more active than carbenicillin against *Ps. aeruginosa* and is less active than piperacillin against *Staph. aureus*, *H. influenzae*, the Enterobacteriaceae and *Ps. aeruginosa*. It is not absorbed when dosed orally; the plasma half-life is 87 min after intravenous infusion.

Aspoxicillin has been used in the treatment of respiratory, skin and soft tissue and urinary infections in adults and children, and, in combination with aminoglycosides, against gynecological infections and infections in patients with hematological disorders.

Further information

Geyer J, Hoffler D, Koeppe P. Pharmacokinetics of aspoxicillin in subjects with normal and impaired renal function. *Arzneimittelforschung*. 1988;11:1635–1639.

AZLOCILLIN

A semisynthetic acylureidopenicillin supplied as the sodium salt for parenteral administration. It is active against a wide range of other Gram-negative bacteria, but is distinguished mainly by its activity against *Ps. aeruginosa* (Table 14.5). *B. fragilis* and other anaerobes are moderately susceptible. Like other ureidopenicillins, azlocillin is active against Gram-positive cocci, *H. influenzae* and *N. gonorrhoeae*. Because it can be hydrolyzed by most β -lactamases, β -lactamase-producing isolates are resistant.

It attains peak concentrations of 250 mg/L after a 3 g intravenous infusion, with a plasma half-life of approximately 1 h. Protein binding is 20–30%. It distributes into multiple tissues and human body fluids at therapeutically useful concentrations. Up to 60% of the dose is recoverable from the urine, mostly unchanged, although some hydrolysis of the β -lactam ring takes place in the body.

Toxicity and side effects are similar to those associated with carboxypenicillins. Its clinical use is for serious infections with susceptible organisms, including lower respiratory tract, intra-abdominal, urinary tract and gynecological infections. Commercial availability is quite limited.

Further information

Anonymous. Azlocillin sodium. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:A265–A267.

CARBENICILLIN

α -Carboxybenzylpenicillin; the first antipseudomonal penicillin to be developed. A semisynthetic carboxypenicillin supplied as the disodium salt for parenteral administration. The two esterified prodrug formulations, carindacillin (carbenicillin indanyl sodium) and carfecillin (carbenicillin carboxyphenyl ester) are no longer available.

It is the least active of the group 5 agents, even against *Ps. aeruginosa* (MIC 64 mg/L) with notably reduced activity against Gram-positive cocci. It is labile to many plasmid-mediated β -lactamases, but is comparatively stable to class C chromosomal β -lactamases (pp. 228–230). Synergy is demonstrable with aminoglycosides against *Ps. aeruginosa* and other Gram-negative bacteria.

It is not orally absorbed, except in esterified form. A 1 g intramuscular injection achieves a plasma peak concentration of 20–30 mg/L after 0.5–1.5 h. The half-life is around 1 h. Plasma protein binding is 50–60%.

The drug is distributed in the extracellular fluid, providing concentrations up to 60% of those of the plasma. In patients with cystic fibrosis sputum concentrations may not reach inhibitory levels for *Ps. aeruginosa*. It does not cross the normal meninges but levels of up to 50% of those of the plasma can be found in patients with meningitis. Around 80% of the

dose appears as unchanged drug in the urine, producing very high levels (2–4 g/L). It is more rapidly disposed of in patients with cystic fibrosis.

Hypersensitivity reactions may occur, but these are less frequent and severe than those associated with benzylpenicillin. High blood levels sometimes cause a coagulation defect that has occasionally progressed to life-threatening bleeding in patients with impaired excretion while receiving 500 mg/kg per day or more. Reversible abnormalities of liver function apparently occur more commonly than with other anti-pseudomonal penicillins. Since large doses of the drug have to be used, convulsions can occur (as with other penicillins; p. 203) and, being administered as the disodium salt, electrolyte disturbances can result. It was formerly used for treatment of serious infections, especially those involving *Ps. aeruginosa*. It has extremely limited availability.

Further information

Symposium. Symposium on carbenicillin: a clinical profile. *J Infect Dis*. 1970;122(suppl):S1–S116.

MEZLOCILLIN

A semisynthetic acylureidopenicillin supplied as the sodium salt for parenteral administration.

Ampicillin-susceptible strains of *H. influenzae* and *Neisseria* spp. are very susceptible, but β -lactamase-producing organisms are usually resistant. It is less active than azlocillin and piperacillin against *Ps. aeruginosa* and has variable activity against *B. fragilis*, independent of β -lactamase production. It exhibits typical β -lactam synergy with aminoglycosides against *Ps. aeruginosa* and enterobacteria.

It attains peak concentrations of 250 mg/L after a 2 g intravenous infusion, with a plasma half-life of 55 min. Protein binding is 20–30%. It distributes into multiple tissues and human body fluids at therapeutically useful concentrations. Up to 60% of the dose is recoverable unchanged from the urine, with up to 2.5% excreted in the bile.

Toxicity and side effects are similar to those associated with carboxypenicillins. Its clinical use is for serious infections with susceptible organisms, including lower respiratory tract, intra-abdominal, urinary tract and gynecological infections. Commercial availability is quite limited.

Further information

Anonymous. Mezlocillin. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:M158–M161.

SULBENICILLIN

α -Sulfonylbenzylpenicillin, a semisynthetic penicillin supplied as the disodium salt. Its antimicrobial spectrum and phar-

macokinetic behavior closely resemble those of carbenicillin. Following intravenous administration of 4 g, the mean plasma concentration at 1 h was approximately 160 mg/L, with a plasma elimination half-life of around 70 min. It is largely excreted in the urine, about 80% of the dose appearing in the first 24 h, less than 5% as the penicilloic acid. It has been noted that the penicilloic acid causes much stronger platelet aggregation than its parent. It is of very limited availability.

Further information

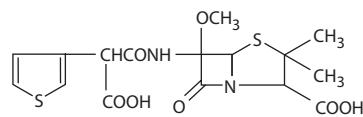

Hansen I, Jacobsen E, Weiss J. Pharmacokinetics of sulbenicillin, a new broad-spectrum semisynthetic penicillin. *Clin Pharmacol Ther*. 1975;17:339–347.

GROUP 6: β -LACTAMASE-RESISTANT PENICILLINS

The introduction of substituents into the 6- α -position of the penicillin nucleus generally results in loss of antibacterial activity, but the 6- α -methoxy derivative of ticarcillin, temocillin, possesses useful antibacterial and pharmacokinetic properties and has attained clinical status. Like the cephamycins (p. 170), which also contain an α -methoxy group on the β -lactam nucleus, it is highly resistant to most bacterial β -lactamases. As a result, it has attracted renewed attention for its potential utility to treat infections caused by class A and class C β -lactamase-producing Enterobacteriaceae (see pp. 228–230). It is not absorbed by the oral route, but it has a long serum half-life after parenteral administration. The α -methylphenyl ester produced substantial serum concentrations after oral dosing to human volunteers, but has not progressed to clinical trial.

TEMOCILLIN

Molecular weight (free acid): 414.4; (disodium salt): 458.4.

A semisynthetic 6- α -methoxypenicillin supplied as the disodium salt for parenteral administration.

ANTIMICROBIAL ACTIVITY

Activity against common pathogenic bacteria is shown in Table 14.5 (p. 220). The introduction of the 6- α -methoxy group has resulted in loss of activity against Gram-positive cocci and anaerobic Gram-negative bacilli, but it is active against enterobacteria (MIC 1–8 mg/L), *H. influenzae* and *Mor. catarrhalis*, with somewhat elevated MICs against carbapenemase-producing isolates of *K. pneumoniae* (MIC

16–64 mg/L) and *Esch. coli* (modal MICs 8–16 mg/L). In most cases, β -lactamase-positive and negative strains are equally susceptible. In contrast to the structurally related ticarcillin, it is inactive against *Ps. aeruginosa*, but *Burkholderia cepacia*, *Ps. acidovorans* and *Aeromonas* spp. are susceptible (MIC 4 mg/L). Most *Acinetobacter* spp. are resistant, and *Ser. marcescens* exhibits variable susceptibility.

It is bactericidal at concentrations 2–4 times the MIC; filaments formed at lower concentrations slowly lyse at higher drug levels. Temocillin consists of diastereoisomers. The naturally predominant *R* epimer is more rapidly bactericidal than the *S* epimer. It is highly resistant to most bacterial β -lactamases, including those that confer resistance to extended-spectrum cephalosporins. It is hydrolyzed by β -lactamases produced by *Flavobacterium* spp. and by those of *Bacteroides* spp.

PHARMACOKINETICS

Oral absorption	Negligible
C_{\max} 1 g intramuscular injection	70 mg/L
1 g rapid intravenous infusion	172 mg/L after 5 min
Plasma half-life	4.3–5.4 h
Plasma protein binding	85%

Absorption and distribution

It is not absorbed when given orally and must be administered parenterally. Relatively high protein binding, together with its distribution in a volume less than the extracellular fluid, accounts for its relatively low renal clearance and subsequent high urinary concentrations that may be effective against some Enterobacteriaceae resistant to other β -lactam antibiotics. In artificial blister fluid and peritoneal fluid, concentrations reach 50% of the peak plasma level; in lymph, concentrations reach 25–60% of the simultaneous plasma level, with a similar half-life. The *R* epimer differs from the *S* epimer in lower protein binding, a 25% greater volume of distribution and a 60% shorter half-life.

Metabolism and excretion

Elimination is principally in the glomerular filtrate, with 80% of the dose appearing in the urine in the first 24 h. A small amount is disposed of in the bile and by degradation. Elimination declines in parallel with renal function, the half-life reaching 30 h in patients with creatinine clearance below 5%.

TOXICITY AND SIDE EFFECTS

As with all penicillins, hypersensitivity reactions, including serious anaphylactic responses, may occur. It is generally well tolerated and administration of 4 g intravenously every 12 h produced no significant effect on template bleeding time, prothrombin time or ADP-induced platelet aggregation.

CLINICAL USE

Severe infection with susceptible bacteria, including urinary and respiratory tract infections, peritonitis and septicemia.

Preparations and dosage

Proprietary name: Negaban.

Preparation: Injection.

Dosage: Adults, i.m., i.v., 1–2 g every 12 h.

Available in UK and Belgium.

15 Other β -lactam antibiotics

Karen Bush

In the penicillins and cephalosporins, the β -lactam ring is fused to a five- and six-membered ring, respectively, but monocyclic β -lactam compounds also exist. There are six chemical skeletons other than penicillins or cephalosporins which support β -lactam-containing agents that have current therapeutic use. Although many of these novel β -lactam structures are based on natural products, classes of agents such as the penems and the oxacephems are purely synthetic molecules that have relied on previous knowledge of β -lactam properties to design agents with broad-spectrum antibacterial activity. Characteristics of each of the various classes are listed below:

- **Penams (penicillins)** N -acylated derivatives of 6- β -aminopenicillanic acid. In these compounds the β -lactam ring is fused with a saturated five-membered thiazolidine ring containing sulfur.
- **Penicillanic acid sulfones** Penams that lack a 6-amino substituent and in which the sulfur is oxidized synthetically to a sulfone to yield β -lactamase inhibitors such as sulbactam or tazobactam.
- **Penems** These differ from penams by the presence of a double bond between C-2 and C-3.
- **Carbapenams and carbapenems** Compounds in which CH_2 replaces sulfur in the five-membered ring. Many natural and synthetic members of the group have been described, of which the most useful therapeutically are derivatives of the natural product thienamycin.
- **Cephems (cephalosporins)** N -acylated derivatives of 7- β -aminocephalosporanic acid. In these compounds, the β -lactam ring is fused with a six-membered dihydrothiazine ring containing sulfur and a double bond. Closely related are: cephemycins, which are substituted at the 7-position with an α -methoxy group; oxacephems, notably latamoxef, in which the sulfur of cephalosporins is replaced by oxygen; and carbacephems, including loracarbef, in which the sulfur is replaced by carbon.
- **Clavams** Compounds that differ from penams in the substitution of oxygen for sulfur. The only notable member of the clavam family at present is clavulanic acid, a compound that owes its therapeutic place to its ability to inhibit many class A (functional group 2) bacterial β -lactamases.

• **Monobactams** β -lactam compounds with no fused secondary ring. The monocyclic β -lactam antibiotics are represented therapeutically by aztreonam and carumonam, but the group also contains the nocardicins which have not been developed as antibacterial drugs.

The penicillins are considered in Chapter 14, and the cephalosporins and their close relatives, the cephemycins, oxacephems and carbacephems, in Chapter 13. This chapter deals with the remaining agents: carbapenems, penems and monobactams, which are notable for their antibacterial activity; and clavulanic acid and the penicillanic acid sulfones, which are primarily of interest as inhibitors of β -lactamases. The antibacterial activity of these inhibitors is associated with the synergistic activity seen with the accompanying penicillin in a β -lactamase inhibitor combination.

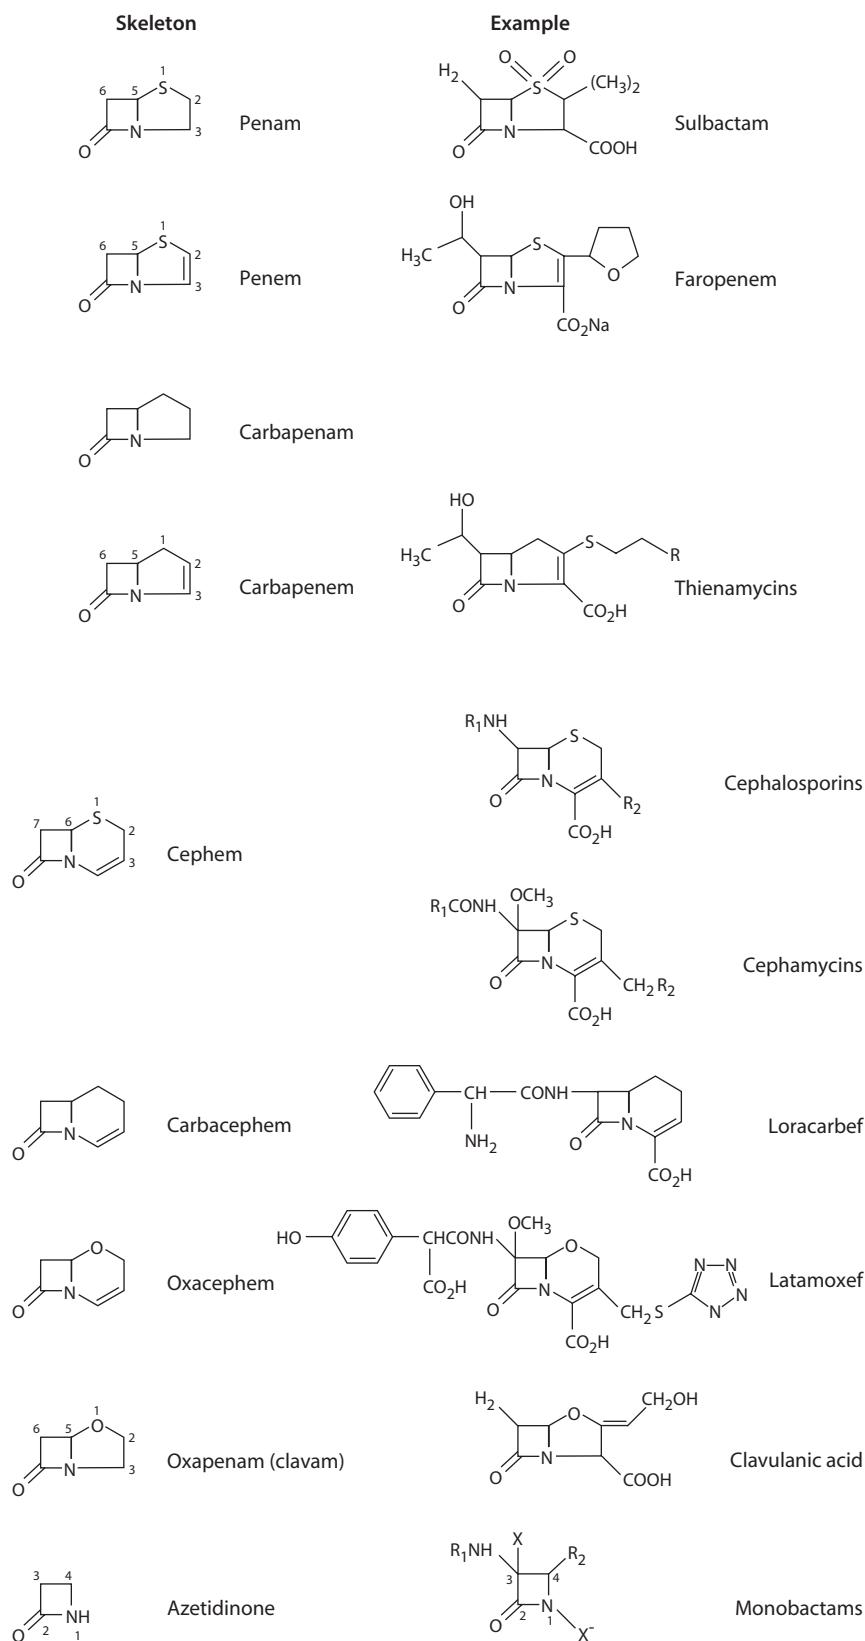

In-vitro activity of agents in each of these classes is highly dependent upon the chemical class to which it belongs. For example, carbapenems, penems and β -lactamase inhibitor combinations tend to have broad-spectrum activity covering Gram-positive and Gram-negative anaerobic and aerobic organisms, whereas the monobactams lack useful activity against Gram-positive bacteria and anaerobes.

Resistance to β -lactam agents is most frequently associated with production of enzymes that hydrolyze the β -lactam ring and since these novel compounds are all characterized by resistance to at least some β -lactamases, the classification of these enzymes is also dealt with in this chapter.

β -LACTAMASES

Even before penicillin was widely used clinically, bacteria such as *Escherichia coli* and *Staphylococcus aureus* were reported to have the capability of degrading this agent. The bacterial enzyme shown to hydrolyze the β -lactam ring was initially called ‘penicillinase’, and penicillinase-producing *Staph. aureus* became of great importance in outbreaks of hospital infection in the 1950s. Since that time, similar enzymes have become increasingly important as a cause of resistance in many pathogenic Gram-positive and Gram-negative bacteria, and even in legionellae, mycobacteria and nocardia. Because of their collective ability to destroy a wide range of β -lactam agents, the enzymes have been renamed β -lactamases. In the case of the penicillins the products are stable penicilloates, but in the case of cephalosporins the ‘cephalosporoates’ may rapidly undergo further degradation, liberating a variety of fragments depending on the C-3 substituent. Every β -lactam, including monobactams, β -lactamase inhibitors and carbapenems, can be inactivated by an appropriate β -lactamase.

β -Lactam antibiotics can be attacked at other chemical sites by microbial acylases and esterases, but these enzymes, which have important uses in semisynthetic processes, are of no significance as a cause of clinical resistance. The presence of esterases in mammalian tissues is exploited in the cleavage of oral prodrug esters of penicillins and cephalosporins with liberation of the active parent compound. Some penems and carbapenems can also be hydrolyzed by mammalian dehydro-peptidases (see below).

GENERAL PROPERTIES

With the advent in the early 1960s of the broad-spectrum penicillins ampicillin and carbenicillin, resistance of Gram-negative bacilli to these agents was most often associated with β -lactamase production. Most aerobic and anaerobic Gram-negative bacilli produce chromosomally mediated β -lactamases characteristic of each species, which accounted for the intrinsic resistance to benzylpenicillin and ampicillin in organisms such as *Bacteroides fragilis*, *Klebsiella pneumoniae* and other enterobacteria. The discovery in 1965 that β -lactamases could be encoded by plasmids and readily transferred by conjugation among Gram-negative bacilli led to widespread dissemination of plasmid-mediated β -lactamase-producing Gram-negative bacilli that are currently a major and increasing clinical problem. In addition, β -lactamase-producing strains of *Haemophilus influenzae*, *Moraxella catarrhalis* and *Neisseria gonorrhoeae*, which were unknown before the mid-1970s, are now common causes of infection. The proliferation of β -lactamases and the identification of new β -lactamase entities have often followed the development and use of new β -lactam-containing agents that have served as the selecting agents for the next generation of enzymes.

Bacterial β -lactamases may be chromosomally encoded, with inducible or constitutive production; only rare reports of inducible plasmid-encoded enzymes have been documented. The β -lactamase genes may be translocated from or into the chromosome or into another plasmid by transposons (see Ch. 3), resulting in transfer within and between species or genera. For instance, the TEM β -lactamases are found in virtually every genus of Enterobacteriaceae. Plasmid-encoded cephalosporinases derived from common class C chromosomal cephalosporinases are being identified more frequently. Most seriously, plasmid-encoded carbapenemases capable of hydrolyzing almost all classes of β -lactam agent may also be refractory to inhibition by commercially available β -lactamase inhibitors.

Those β -lactamases found in Gram-positive organisms are often extracellular enzymes, but Gram-negative β -lactamases are almost invariably confined to the periplasmic space. Because the outer membrane of Gram-negative bacteria generally restricts transport of large molecules, little β -lactamase activity is detected extracellularly, unless cell lysis occurs. Quantitative measurement of β -lactamase activity in intact cells can be difficult, depending upon the permeability properties of the specific outer membrane of an organism, so that the enzymes are usually studied in extracts after disruption of the cell.

CLASSIFICATION

β -Lactamases are usually characterized on the basis of one of two properties: molecular characteristics, which routinely include a full nucleotide or amino acid sequence; or functional characteristics, including substrate and inhibition profiles (Table 15.1). Numerous classification schemes have been proposed. The two most cited schemes are that of Ambler, who proposed a classification based upon molecular structure, and that of Bush, Jacoby and Medeiros, who combined the functional properties with the known molecular sequences of β -lactamases from both Gram-positive and Gram-negative bacteria. The number of enzymes that have been classified using the latter scheme numbered at least 850 in 2009.

Hydrolytic activity is customarily defined by comparison with benzylpenicillin or cephaloridine, with rates of hydrolysis normalized to 100 for the reference compound. Inhibitory properties deemed to be significant include inhibition by clavulanic acid (an inactivator of many β -lactamases that contain an active site serine) and inhibition by the chelating agent ethylenediaminetetraacetic acid (EDTA), which is used to identify the zinc-containing metallo- β -lactamases. Characteristics of representative β -lactamases from each class are shown in Table 15.2.

Molecular classification of β -lactamases requires sequence determinations of either the gene encoding the enzyme or the amino acid sequence of the protein. Class A, C and D β -lactamases are all enzymes that require an active site serine to acylate the β -lactam substrate during the hydrolysis

Table 15.1 Classification of bacterial β-lactamases

Functional group	Molecular class	Preferred substrates	Inhibited by		Representative enzymes
			CA	EDTA	
1	C	Ceph	–	–	AmpC, plasmid-encoded cephalosporinases (FOX-1, ACT-1 in Gram-negative bacteria), CMY-1
2a	A	Pen	+	–	Penicillinases from Gram-positive bacteria
2b	A	Pen, ceph	+	–	TEM-1, TEM-2, SHV-1
2be	A	Pen, ceph, extended-spectrum ceph, monobactam	+	–	TEM-3, TEM-26, TEM-168, SHV-2, SHV-120
2br	A	Pen	–	–	TEM-30 to TEM-39 (IRT 1 to IRT-26), SHV-10
2c	A	Pen, carbenicillin	+	–	PSE-1, PSE-3, PSE-4
2d	D	Pen, cloxacillin	+/-	–	OXA-1, OXA-10 = PSE-2
2de	D	Pen, oxacillin, extended spectrum ceph	–	–	OXA-11, OXA-15
2df	D	Pen, carbapenems	+/-	–	OXA-23, OXA-48
2e	A	Ceph	+	–	Inducible cephalosporinases from <i>Pr. vulgaris</i> , SFO-1
2f	A	Ceph, pen, carbapenems	+	–	IMI-1, KPC-2, SME-1
3	B	Carbapenems. Often, all ceph, pen. No monobactam	–	+	L1 from <i>Sten. maltophilia</i> , VIM-1, IMP-1, CfiA/CcrA from <i>B. fragilis</i>

CA, clavulanic acid; Ceph, cephalosporin; EDTA, ethylenediaminetetraacetic acid; Pen, penicillin.

^aInhibited by EDTA.K_{cat} – catalytic constant (molecules of substrate hydrolyzed per molecule of enzyme per second); Amp, ampicillin; Lor, cephaloridine; Ctx, cefotaxime; Caz, ceftazidime; Imp, imipenem.Data from Bush K, Jacoby GA, Medeiros AA 1995 *Antimicrobial Agents and Chemotherapy* 39: 1211–1233; Yigit H, Queenan AM, Rasheed JK, et al. 2003 *Antimicrobial Agents and Chemotherapy* 47: 3881–3889.

reaction. Class C β -lactamases tend to have higher molecular weights than the other classes. Class B β -lactamases contain at least one functional Zn^{2+} atom at the active site that participates in the hydrolytic process. A number of characteristic amino acid sequences have been identified to differentiate the various molecular classes.

Functional (Bush et al) groups are identified according to inhibitory properties based primarily upon clavulanic acid and EDTA. For many enzymes, the inhibitory activities of clavulanic acid and tazobactam are similar. Additional subgroups are identified according to substrate hydrolysis profiles.

Functional group 1 cephalosporinases include the chromosomal β -lactamases from Enterobacteriaceae that are not inhibited well by clavulanic acid. A second cephalosporinase class was segregated into group 2e due to high affinity for clavulanic acid, a good inhibitor of these enzymes. Sequencing data have shown that functional group 1 enzymes belong to molecular class C, whereas the functional group 2e enzymes are members of molecular class A, like most group 2 β -lactamases.

Other group 2 enzymes are generally inhibited by clavulanate, with the exception of the rare TEM-1 β -lactamase derivatives, the inhibitor-resistant TEM (IRT) enzymes, which have reduced affinity for the inhibitor, and many of the class D oxacillin-hydrolyzing enzymes. Group 2a enzymes are penicillinas; group 2b enzymes have a broader spectrum of activity, hydrolyzing penicillins and early cephalosporins almost equally well. Group 2be enzymes, the extended-spectrum β -lactamases (ESBLs), may be derived from group 2b enzymes, but exhibit enhanced hydrolytic properties that enable them to hydrolyze extended-spectrum cephalosporins and monobactams. Group 2c enzymes hydrolyze carbenicillin, and group 2d enzymes hydrolyze isoxazolyl penicillins such as cloxacillin or oxacillin. The 2d enzymes, the only β -lactamases that belong to molecular class D, may be further subdivided according to the ability to hydrolyze extended-spectrum cephalosporins (group 2de) or carbapenems (group 2df). Group 2f enzymes are carbapenem-hydrolyzing enzymes that are class A serine β -lactamases rather than metalloenzymes. The group 3 metallo- β -lactamases are readily distinguished from other β -lactamases because they can hydrolyze carbapenems and are not inhibited by clavulanic acid, but are inhibited by metal-ion chelators such as EDTA.

STAPHYLOCOCCUS AUREUS β -LACTAMASE

Today at least 90% of *Staph. aureus* causing infections in community and hospital practice are β -lactamase-producing strains. The enzyme produced occurs in four serologically distinct forms that are closely related on a molecular level. Production may be plasmid encoded or chromosomal. The chromosomal enzymes can be induced by penicillins such as methicillin or by the β -lactamase inhibitor sulbactam.

The enzymes are predominantly active against penicillins, but can be differentiated on the basis of hydrolysis of cephalosporins including cephaloridine, nitrocefén and cefazolin.

CHROMOSOMAL CEPHALOSPORINASES OF GRAM-NEGATIVE BACTERIA

Most Gram-negative bacteria elaborate chromosomally mediated enzymes, most of which fall into group 1. These hydrolyze cephalosporins up to 1000 times more rapidly than penicillins, some of which (e.g. cloxacillin) may inhibit them. Traditional β -lactamase-inhibitors work poorly against these enzymes, but monobactams such as aztreonam bind tightly and can act like potent inactivators.

In some species, including *Acinetobacter*, *Citrobacter*, *Enterobacter*, *Morganella*, *Pseudomonas* and *Serratia*, group 1 cephalosporinases are inducible and often species specific. Plasmid-encoded forms of these enzymes, such as those designated FOX-1, LAT-1, MIR-1 and MOX-1, have appeared, particularly in *K. pneumoniae* strains that have an additional β -lactamase. Sequence data indicate high homology with the AmpC cephalosporinases from *Pseudomonas aeruginosa*, *Serratia marcescens*, *Enterobacter cloacae* or *Citrobacter freundii*.

Induction is a clinically relevant phenomenon when the inducing molecule is a substrate that can be hydrolyzed by the enzyme, such as ampicillin or amoxicillin. Many good inducers, such as cefoxitin and imipenem, are not good substrates for these enzymes, and pose problems primarily when they are co-administered with a second β -lactam agent. Because induction is a transient event, the producing organisms revert to their original low basal production of β -lactamase on removal of the inducer. A more serious problem occurs if there is selection for a permanently altered organism with derepressed production of the chromosomal β -lactamase. Enterobacteriaceae that hyperproduce group 1 cephalosporinases are sometimes responsible for clinical failures of cephalosporins. Interestingly, β -lactam compounds that are good inducers rarely select for derepressed hyperproducing mutants.

PLASMID-ENCODED β -LACTAMASES

Plasmid-encoded enzymes account for perhaps the most important β -lactamase-related resistance mechanisms. The most common β -lactamase in Gram-negative organisms is the TEM-1 β -lactamase, responsible for transferable ampicillin resistance among Enterobacteriaceae worldwide. In *K. pneumoniae*, the broad-spectrum SHV-1 β -lactamase predominates, and appears as a chromosomal β -lactamase in most *K. pneumoniae* species. Other important families of plasmid-encoded β -lactamases include the OXA enzymes that hydrolyze oxacillin and the recently identified CTX-M family of extended spectrum β -lactamases (ESBLs).

In the mid-1980s, plasmid-encoded β -lactamases that conferred resistance to oxyimino β -lactam agents, notably cefotaxime, and/or ceftazidime and aztreonam, began

to appear in central Europe. The major families of ESBLs (functional group 2be) include numerous variants of TEM-1 and SHV-1 that are numbered through at least TEM-168 and SHV-120. It should be noted that the sequential numbers of each family include approximately 24 inhibitor-resistant TEM enzyme sequences, as well as sequences that have been withdrawn.

Organisms elaborating ESBLs may remain susceptible to cefoxitin and imipenem, or piperacillin–tazobactam, unless they produce multiple β -lactamases. The enzymes are readily inhibited by clavulanic acid or tazobactam. They differ from their parent TEM and SHV enzymes by selected point mutations; two or more amino acid substitutions often lead to high-level resistance (minimum inhibitory concentrations [MICs] of cephalosporins >32 mg/L). Such organisms have spread rapidly within localized metropolitan areas to cause hospital outbreaks and colonization in nursing homes. Infections caused by organisms producing TEM variants resistant to β -lactamase inhibitors do not respond to clavulanic acid or sulbactam– β -lactam combinations, but are often susceptible to early cephalosporins. Plasmid-encoded carbapenemases have become associated with one of the most serious multidrug resistance mechanisms in the Enterobacteriaceae, spreading throughout the world. Genes encoding enzymes such as the KPC β -lactamases can be transferred among species, together with resistance determinants for other antibiotic classes, resulting in pathogens that are susceptible to few antibiotics (e.g. only polymyxin B and tigecycline).

METALLO- β -LACTAMASES

Another formidable β -lactamase group includes the metallo- β -lactamases, which rapidly hydrolyze most β -lactam agents, especially the carbapenems, but not the monobactams, and are resistant to β -lactamase inhibitors. These enzymes were originally described as chromosomal enzymes in a few species, such as *Stenotrophomonas maltophilia*, *B. fragilis* and *Bacillus cereus*, but were then identified in Japan on plasmids found in *B. fragilis*, *S. marcescens*, *K. pneumoniae* and *Ps. aeruginosa*. Such strains have now been identified in most parts of the world, with the IMP and VIM families the predominant members. Because of the low catalytic efficiencies of these enzymes, they are almost always produced in combination with at least one other β -lactamase of a different class, thus expanding the hydrolytic repertoire for the organism.

CARBAPENEMS AND PENEMS

Many novel molecules containing a β -lactam ring have been investigated, but few have survived the early stages of development. Prominent among those that have are the carbapenems, in which carbon replaces sulfur in the fused ring structure, and penems, which have a more conventional core structure (see above).

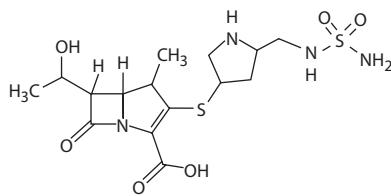

Only one penem, faropenem, has entered limited clinical use, but dozens of carbapenems have been isolated from fermentation products of various streptomycetes. Their nomenclature has been complicated by the use of multiple generic names to describe the same class of compounds, including thienamycins, olivanic acids, carpetimycins, asparenomycins and pluracidomycins. They demonstrate potent activity against a broad range of Gram-positive and Gram-negative bacteria and are resistant to hydrolysis by most β -lactamases. Some are also β -lactamase inhibitors. The most active of the natural compounds, thienamycin, is produced by *Streptomyces cattleya*, although concentration-related instability precludes its clinical use.

A search for more stable derivatives that retain potent antibacterial activity led to the development of *N*-formimidoyl-thienamycin, imipenem. This compound is stable to all bacterial β -lactamases other than the carbapenemases. It is rapidly degraded by the mammalian renal dipeptidase, dehydropeptidase I, which hydrolyzes carbapenems and penems, but not penicillins, cephalosporins or monobactams. Cilastatin is a dehydropeptidase inhibitor that is co-administered with imipenem for therapeutic use. Coincidentally, cilastatin also acts as a nephroprotectant when administered with imipenem.

Addition of a 1- β -methyl substituent on the carbapenem ring confers stability to hydrolysis by dehydropeptidase. As a result, semisynthetic carbapenems such as meropenem, ertapenem, biapenem and doripenem have been developed. These compounds retain broad-spectrum antimicrobial activity and β -lactamase stability, and do not need to be administered with a dehydropeptidase inhibitor.

DORIPENEM

Molecular weight (monohydrate): 438.52.

A 1- β -carbapenem, formulated as the monohydrate for parenteral administration. It is relatively stable to renal dehydro-peptidase and can be administered as a single agent.

ANTIMICROBIAL ACTIVITY

Activity against aerobic and anaerobic Gram-negative pathogens is similar to that of other carbapenems (Table 15.3). MIC values against Gram-positive cocci are generally higher than for imipenem and those for Gram-negative bacilli are lower.

PHARMACOKINETICS

C_{max} 500 mg intravenous infusion (1 h)	c. 23 mg/L after 1 h
500 mg intravenous infusion (4 h)	c. 8 mg/L
Plasma half-life	1 h
Volume of distribution	16.8 L (steady state)
Plasma protein binding	8.1%

Absorption and distribution

Doripenem is not absorbed after oral administration. It penetrates well into most tissues and fluid, achieving concentrations matching or exceeding those required to inhibit most susceptible bacteria at the site of infection for the approved indications.

Metabolism and excretion

Metabolism of doripenem to the microbiologically inactive ring-opened metabolite occurs primarily by renal dehydro-peptidase. Based on area under the concentration–time curve (AUC) values in plasma following a single 500 mg dose in healthy volunteers, 18% appears as metabolite and the rest as unchanged drug.

Excretion is primarily by the renal route. Within 24 h after dosing, 78.7% and 18.5% of the dose was recovered in urine as unchanged drug and the ring-opened metabolite, respectively. After administration of radiolabeled doripenem, 0.7% of the total radioactivity was recovered in feces after 1 week.

TOXICITY AND SIDE EFFECTS

Seizure and central nervous system (CNS) side effects are observed rarely (<1%), though headache is reported by 2.3% of patients. Other common drug-related adverse reactions are diarrhea (2.0%), nausea (1.9%), anemia (1.4%) and phlebitis (1.4%). Hypersensitivity reactions related to intravenous

Table 15.3 Activity of the carbapenems doripenem, ertapenem, imipenem and meropenem, the monobactam, aztreonam and the penem, faropenem against common bacterial pathogens: MIC (mg/L)^a

Organism	Doripenem	Ertapenem	Imipenem	Meropenem	Aztreonam	Faropenem
<i>Staphylococcus aureus</i> (MSSA)	≤0.06	0.12	0.03	0.12	R	0.06
<i>Staph. aureus</i> (MRSA)	>2.0	2.0	0.5	2.0	R	2.0

<i>Chlamydia</i> spp.	No data	No data	No data	No data	≤0.25	No data

^aMIC against 50% of strains. R, resistant (MIC >32 mg/L). MSSA, methicillin-sensitive *Staph. aureus*; MRSA, methicillin-resistant *Staph. aureus*.

administration of the study drug and *Clostridium difficile* colitis occurred at a rate of less than 1%. However, patients with a history of hypersensitivity reactions to other β -lactam agents should be treated cautiously.

CLINICAL USE

Complicated intra-abdominal infections
Complicated urinary tract infections, including pyelonephritis
Nosocomial pneumonia, including ventilator-associated pneumonia (Europe)

Ertapenem is stable to most serine β -lactamases, but is hydrolyzed by serine carbapenemases and metallo- β -lactamases.

PHARMACOKINETICS

C_{max} 1 g intramuscular	c. 67 mg/L after 2 h
1 g intravenous infusion (30 min)	c. 155 mg/L end infusion
Plasma half-life	c. 4 h
Volume of distribution	c. 0.12 L/kg (steady state)
Plasma protein binding	85–95%

Absorption after intramuscular injection is essentially complete with 90% bioavailability. The modestly extended plasma half-life allows once-daily dosing.

Excretion is predominantly by the renal route, about 80% being recovered in the urine within 24 h. About 40% is eliminated unchanged, the rest as a biologically inactive ring-opened metabolite. Dosage should be reduced in severe renal impairment.

Preparations and dosage

Proprietary names: Doribax, Finibax.
Preparation: Intravenous infusion.
Dosage: Adults, 500 mg by infusion over 1 h or 4 h every 8 h daily for 5–14 days depending on infection. Not recommended for use in children.
Available in the USA, Europe, Japan and Canada.

ERTAPENEM

Molecular weight (monosodium salt): 497.5.

A 1- β -carbapenem, formulated as the sodium salt for parenteral administration. It is stable to renal dehydropeptidase and can be administered as a single agent.

ANTIMICROBIAL ACTIVITY

Activity against aerobic and anaerobic pathogens is comparable to that of imipenem (Table 15.3): MIC values for Gram-negative bacilli (with the exception of *Ps. aeruginosa*) are generally lower and those for Gram-positive cocci higher.

TOXICITY AND SIDE EFFECTS

Ertapenem appears to be generally well tolerated. The most common drug-related adverse experiences are diarrhea (5.5%), infused vein complication (3.7%), nausea (3.1%), headache (2.2%), vaginitis (2.1%), phlebitis/thrombophlebitis (1.3%) and vomiting (1.1%). Seizures have occasionally been reported (0.5%) in patients with a history of disorders of the CNS.

CLINICAL USE

Complicated intra-abdominal infections
Complicated skin and skin structure infections, including diabetic foot infections without osteomyelitis
Community acquired pneumonia
Complicated urinary tract infections including pyelonephritis
Acute pelvic infections including postpartum endometritis, septic abortion and postsurgical gynecologic infections
Prophylaxis of surgical site infection following elective colorectal surgery

Preparations and dosage

Proprietary name: Invanz.
Preparation: Lyophilized powder for reconstitution for i.m. injection (with 1% lidocaine) or i.v. infusion over 30 min.
Dosage: Adults, 1 g i.m. or i.v. infusion per day for 3–14 days depending on infection type. Children >3 months, 15 mg/kg i.m. or i.v. infusion every 12 h for 3–14 days depending on infection type.
Available in the UK and the USA.

IMIPENEM

N-formimidoylthienamycin. Molecular weight (monohydrate): 317.37.

A semisynthetic carbapenem available as the monohydrate; formulated in a 1:1 ratio with the dehydropeptidase inhibitor, cilastatin sodium (molecular weight [monosodium salt] 380.43) for intramuscular and intravenous administration.

It is stable in the solid state for 6 months at 37°C. In aqueous solution at room temperature it decays at 10%/h.

ANTIMICROBIAL ACTIVITY

Imipenem shows potent activity against a wide range of Gram-positive and Gram-negative aerobes and anaerobes, including many resistant to other agents. Its activity against common pathogenic organisms is shown in Table 15.3. Concentrations (mg/L) inhibiting 50% of strains of other organisms are: *Listeria monocytogenes*, 0.03; *Legionella pneumophila*, 0.03; *Enterococcus faecium*, 4; *Yersinia* spp., 0.06. *Mycobacterium fortuitum* is inhibited by 6.25 mg/L. Imipenem is active against many *Pseudomonas* species, but not *Sten. maltophilia*. It is active against most anaerobes, with the exception of *Cl. perfringens*, which is only moderately susceptible. It is bactericidal at 2–4 times the MIC for most species, but some strains of *Staph. aureus* exhibit ‘tolerance’ (see p. 204). Bactericidal synergy with aminoglycosides, glycopeptides, fosfomycin and rifampicin (rifampin) has been observed against many strains of *Staph. aureus* and enterococci.

Antibacterial activity is unaffected by the presence of cilastatin, which is itself devoid of antimicrobial activity.

Imipenem is stable to hydrolysis by most serine β -lactamases, with the exception of the group 2f carbapenem-hydrolyzing

enzymes (see above). Strains of *B. fragilis*, *Aeromonas* spp. and *Sten. maltophilia* can produce metallo- β -lactamases that hydrolyze the drug rapidly. These strains, in addition to occasional strains of enterobacteria, *Acinetobacter baumannii* and *Ps. aeruginosa*, show variable resistance to imipenem depending upon the level of carbapenem-hydrolyzing enzymes and the presence or absence of imipenem-specific porins. Efflux pumps also exist that may extrude imipenem from Gram-negative bacteria.

ACQUIRED RESISTANCE

Some strains of *Citrobacter*, *Enterobacter*, *Proteus vulgaris*, *Providencia*, *Ps. aeruginosa* and *Serratia* spp. may be resistant to imipenem and other β -lactam agents, often because of the selection of stably derepressed mutants expressing high levels of group 1 β -lactamases coupled with decreased intracellular drug levels due to porin mutations or increased efflux.

Induction of class 1 β -lactamases by imipenem in strains of *Aeromonas*, *Pseudomonas* and *Serratia* spp. is responsible for antagonism of β -lactamase-labile β -lactam agents in vitro. Imipenem resistance in *Ps. aeruginosa* can occur following selection of mutants that hyperproduce the group 1 cephalosporinase and which are also deficient in an outer membrane protein (OprD or D2) which specifically transports imipenem, but not cephalosporins or monobactams.

PHARMACOKINETICS

C_{\max} 500 mg intravenous (20-min infusion)	21–58 mg/L end infusion
Plasma half-life	1 h
Volume of distribution	c. 0.2 L/kg
Plasma protein binding	20%

Absorption and distribution

Imipenem is not absorbed by the oral route. No accumulation of imipenem is reported following multiple dosing with cilastatin. Imipenem and cilastatin are both widely distributed in multiple fluids and tissues. Although cerebrospinal fluid (CSF) concentrations of 1–2.6 mg/L have been reported, imipenem is not approved for use in meningitis.

Metabolism

In the absence of cilastatin, imipenem is slowly hydrolyzed, with a half-life of 0.7 h in serum in vitro. Most destruction occurs in the kidney and only 5–40% of the drug is recovered in the urine, where 80–90% is in the open-ring form. When imipenem is administered with cilastatin in a 1:1 ratio, urinary recovery of imipenem rises to c. 70%, with only 20% as the open-ring metabolite.

Excretion

In volunteers receiving 2 g of the mixture intravenously over 30 min, every 6 h for 40 doses, half-lives were 0.9 h after the first dose and 0.8 h after the last. Renal excretion was 55–60%. Probenecid has little effect on the plasma half-life, but markedly increases urinary recovery. Renal excretion of cilastatin closely follows that of imipenem, 75% being excreted unchanged in the urine over 6 h, with about 12% as the *N*-acetyl metabolite.

In patients with chronic renal failure, about 75% of the mixture was eliminated by 3 h hemofiltration. The half-lives of the two components differed markedly: around 3.4 h for imipenem and 16 h for cilastatin.

TOXICITY AND SIDE EFFECTS

CNS effects such as confusional states and seizures have been reported, especially when recommended doses were exceeded, and in patients with renal failure or creatinine clearances of ≤ 20 mL/min/1.73 m².

Other reactions include phlebitis/thrombophlebitis (3.1%), nausea (2.0%), diarrhea (1.8%) and vomiting (1.5%). Increased hepatic enzymes may be seen in adults and children. Superinfection with *Aspergillus*, *Candida* and resistant *Pseudomonas* spp. have been described and pseudomembranous colitis has been reported.

Patients with a history of hypersensitivity reactions to penicillins, cephalosporins or other β -lactam antibiotics should be treated cautiously with carbapenems.

CLINICAL USE

- Lower respiratory tract infections
- Urinary tract infections (complicated and uncomplicated)
- Intra-abdominal infections
- Gynecological infections
- Bacterial septicemia
- Bone and joint infections
- Skin and skin structure infections
- Endocarditis
- PolyMICROBIAL infections

Preparations and dosage

Proprietary name: Primaxin.

Preparations: Injection

Dosage: Adults, deep i.m. injection, 500–750 mg every 12 h, depending on the severity of the infection; gonococcal urethritis or cervicitis, 500 mg as a single dose. (Not available in the USA.)

Adults, i.v., 1–2 g per day in 3–4 divided doses (maximum dose, 4 g per day); the dose is determined by the severity of the infection and the condition of the patient. Children 3 months (<40 kg body weight), 15 mg/kg every 6 h, with a maximum dose of 60 mg/kg per day (2 g per day), or 4 g per day if infections are caused by *Ps. aeruginosa*.

Widely available.

MEROPENEM

Molecular weight (trihydrate): 437.52.

A semisynthetic carbapenem formulated as the trihydrate for intravenous infusion. It is soluble in 5% monobasic potassium phosphate solution, sparingly soluble in water, and very slightly soluble in hydrated ethanol. The β -methyl group at C-1 confers increased stability to hydrolysis by most mammalian dehydropeptidase I enzymes (excluding rodents), thereby eliminating the need for a dehydropeptidase inhibitor in the dosing regimen.

ANTIMICROBIAL ACTIVITY

The unique side chain at C-2 is associated with increased activity against Gram-negative bacteria, including *H. influenzae*. It is slightly less active than imipenem against Gram-positive organisms (Table 15.3). It is active against anaerobes and more active against some strains that are less susceptible to imipenem. Its excellent activity against Gram-negative organisms is due to high affinity for multiple penicillin-binding proteins (PBPs; see p. 29). Activity is little affected by inoculum size or the presence of serum. It is bactericidal at concentrations close to the MIC.

Stability to β -lactamases is similar to that of other carbapenems: it is highly resistant to most serine β -lactamases, including extended-spectrum enzymes, but can be hydrolyzed by metallo- β -lactamases and by serine carbapenemases.

PHARMACOKINETICS

C_{max}	500 mg intravenous (30-min infusion)	23 mg/L end infusion
1 g	intravenous (30-min infusion)	49 mg/L end infusion
Plasma half-life		1 h
Volume of distribution		c. 0.3 L/kg
Plasma protein binding		2%

Absorption and distribution

Meropenem is not absorbed after oral administration. It penetrates well into most body fluids and tissues, including CSF, achieving concentrations matching or exceeding those required to inhibit most susceptible bacteria. In pediatric patients (1 month to 15 years) with inflamed meninges it achieves CSF levels of 0.9–6.5 mg/L after a single intravenous infusion (40 mg/kg) over 30 min. After a single intravenous dose, the highest mean concentrations of meropenem were found in tissues and fluids at 1 h (0.5–1.5 h) after the start of infusion.

Metabolism and excretion

The mean recovery of unchanged meropenem is approximately 70%. The remainder consists of the microbiologically inactive open-ring form. Renal excretion is greater than 70% of unchanged drug over 12 h. Co-administration with probenecid prolongs the half-life 38%, but peak concentrations are not greatly affected. In patients with renal impairment the dose should be adjusted. Parent drug and metabolite are removed by hemodialysis.

TOXICITY AND SIDE EFFECTS

Seizures and other CNS adverse experiences have been reported in 0.7% of all adult patients, most commonly those with pre-existing CNS disorders. Pseudomembranous colitis has been reported. Other reactions include diarrhea (4.8%), nausea and vomiting (3.6%), inflammation at the site of injection (2.4%) and headache (2.3%). Moniliasis occurs in 1.9–3.1% of pediatric patients.

Patients with a history of hypersensitivity reactions to other β -lactam agents should be treated cautiously.

CLINICAL USE

Intra-abdominal infections
Bacterial meningitis (pediatric patients >3 months)
Complicated skin and skin structure infections

Preparations and dosage

Proprietary names: Merrem, Meronem.

Preparation: Injection.

Dosage: Adults, i.v., 0.5–2 g every 8 h. Children >3 months, 20 mg/kg every 8 h for intra-abdominal infections, or 40 mg/kg every 8 h for meningitis, or 10 mg/kg every 8 h for skin infections.

Widely available.

OTHER CARBAPENEMS AND PENEMS

BIAPENEM

A semisynthetic carbapenem with a 2-substituted triazolium moiety. It has broad-spectrum activity against most aerobic and anaerobic Gram-positive and Gram-negative organisms. It is equivalent to, or slightly more active than, imipenem against Gram-negative aerobic bacteria and slightly less active than imipenem against Gram-positive organisms. It is stable to hydrolysis by dehydropeptidase. It is not hydrolyzed by most serine β -lactamases, but like all carbapenems and penems is readily hydrolyzed by carbapenemases. It penetrates into bronchial epithelial lining fluid with peak concentrations of 2.4–4.4 mg/L. The plasma half-life is 1.5–1.9 h. The potential for neurotoxicity is less than that of imipenem.

Further information

FAROPENEM

An orally active penem with a broad spectrum of antibacterial activity, including activity against selected anaerobic pathogens (Table 15.3). Although it is active against most

enterobacteria, it has reduced activity against *Ser. marcescens*, *Enterobacter* spp. and some *Providencia* spp. It generally retains activity against many Gram-positive organisms, but has no useful activity against *Ps. aeruginosa*. It has reduced activity against *E. faecium*, methicillin-resistant *Staph. aureus* (MRSA) and some strains of coagulase-negative staphylococci. It is stable to hydrolysis by extended spectrum β -lactamases, but is hydrolyzed by carbapenemases. Esterified prodrugs with increased bioavailability have been studied in clinical trials but have not received regulatory approval.

Woodcock JM, Andrews JM, Brenwald NP, Ashby JP, Wise R. The in vitro activity of faropenem, a novel oral penem. *J Antimicrob Chemother*. 1997;39:35–43.

PANIPENEM

A 3-acetimidoylpyrrolidinyl-substituted carbapenem with no methyl group at the C-1 position. It has broad-spectrum antibacterial activity against Gram-positive and Gram-negative organisms very similar to that of other carbapenems. Activity against *Ps. aeruginosa* is similar to that of imipenem. It is co-administered in a ratio of 1:1 with betamipron (*N*-benzoyl- β -alanine), a renal anion transport inhibitor that decreases nephrotoxicity. Panipenem is slightly more stable to hydrolysis by dehydropeptidase than imipenem, but not as stable as meropenem or biapenem. It is hydrolyzed by carbapenemases.

Mean maximum blood concentrations following intravenous infusion of 0.5 g and 0.75 g of each component were 37 and 61 mg/L for panipenem and 24 and 39 mg/L for betamipron. Following intravenous infusion in children (10 mg or 20 mg of each component per kg), the half-life of panipenem was about 1.2 h; that of betamipron about 0.9 h. Drug levels in the CSF were at least eight-fold lower than serum concentrations.

Side effects are similar to those reported for other carbapenems (incidence <10%) and are generally mild. Patients with a history of previous hypersensitivity reactions to penicillins, cephalosporins or other β -lactam antibiotics should be treated cautiously.

Clinical use in serious infections is similar to that of other carbapenems.

MONOBACTAMS

Study of the structural basis of activity of early β -lactam compounds led to the expectation that compounds in which the β -lactam ring was not strained by fusion to another ring would be inactive as antimicrobial agents. However, some natural monocyclic β -lactam antibiotics, including certain monobactams and nocardicins, are active in vitro against Gram-negative bacteria, including *Ps. aeruginosa*.

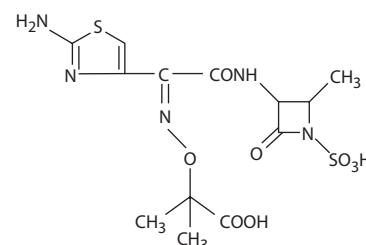

In contrast to penicillins and cephalosporins, which are commonly produced by fungi and actinomycetes, naturally occurring monobactams are produced by bacteria. Because of their simplicity of structure, they can be obtained easily by total synthesis. In some monobactams the β -lactam ring carries an α -methoxy group, similar to the β -lactamase-stable cephemycins, but the first monobactam used therapeutically, and the only one to achieve modest commercial acceptability, aztreonam, lacks this substituent.

Monobactams exhibit no useful activity against Gram-positive organisms or strict anaerobes because of poor binding to PBPs (p. 29). Activity against Gram-negative bacteria, including *Ps. aeruginosa*, is due to tight binding to PBP 3 (*Esch. coli* numbering). As a result, the organisms convert to filaments, which slowly lyse.

Monobactams are hydrolyzed poorly by many serine β -lactamases and all metallo- β -lactamases, but can be hydrolyzed by ESBLs and serine carbapenemases. Group 1 cephalosporinases have high affinities for non-methoxylated monobactams, whereas group 2 β -lactamases generally bind aztreonam poorly. They are generally not inducers of the group 1 chromosomal cephalosporinases of Gram-negative bacteria.

AZTREONAM

Molecular weight: 435.43.

A synthetic analog of a monobactam antibiotic from the bacterium *Chromobacterium violaceum*. Now obtained by chemical synthesis and available for intramuscular or intravenous administration.

ANTIMICROBIAL ACTIVITY

Its activity against common Gram-negative organisms is shown in Table 15.3 (p. 232). Concentrations (mg/L) inhibiting 50% of other organisms are: *Aeromonas* spp., 0.1;

Acinetobacter spp., 16; *Mor. catarrhalis*, 0.1; *Burkholderia cepacia*, 2; and *Yersinia* spp., 0.1. Synergy has been shown with gentamicin, tobramycin and amikacin against 52–89% of strains of *P. aeruginosa* and gentamicin-resistant Gram-negative bacteria.

PHARMACOKINETICS

C_{max}	1 g intravenous	90 mg/L end infusion
	1 g intramuscular	46 mg/L after 1 h
Plasma half-life		1.7 h
Volume of distribution		0.18 L/kg
Plasma protein binding		56%

Absorption and distribution

Oral bioavailability is less than 1%. Peak concentrations above the median MIC for most Gram-negative pathogens are achieved in most tissues and body fluids after 1 g intramuscular or intravenous doses.

Metabolism and excretion

It is not extensively metabolized, the most prominent product, resulting from opening the β -lactam ring, being scarcely detectable in the serum and accounting for about 6% of the dose in the urine and 3% in the feces.

It is predominantly eliminated in the urine, where 58–72% appears within 8 h. Less than 12% is eliminated unchanged in the feces, suggesting low biliary excretion.

TOXICITY AND SIDE EFFECTS

Local reactions occasionally occur at the injection site. Systemic reactions include diarrhea, nausea and/or vomiting and rash (1–1.3%). Neutropenia was seen in 11.3% of the pediatric patients younger than 2 years. Pseudomembranous colitis has been reported.

There are no reactions in patients with immunoglobulin E (IgE) antibodies to benzylpenicillin or penicillin moieties. It is rarely cross-reactive with other β -lactam antibiotics and is weakly immunogenic.

CLINICAL USE

- Urinary tract infections, including pyelonephritis and cystitis
- Lower respiratory tract infections, including pneumonia and bronchitis caused by Gram-negative bacilli
- Septicemia
- Skin and skin structure infections, including postoperative wounds, ulcers and burns
- Intra-abdominal infections, including peritonitis
- Gynecological infections, including endometritis and pelvic cellulitis

Preparations and dosage

Proprietary name: Azactam.

Preparations: Injection, infusion.

Dosage: Adults, i.m., i.v., i.v. infusion, 1–8 g per day in 2–4 divided doses. Route, frequency and dose are determined by the severity of the infection and the condition of the patient. Children, 30 mg/kg every 6–8 h (up to 50 mg/kg every 6–8 h in severe infection and cystic fibrosis).

Widely available, including the USA and the UK.

OTHER MONOBACTAMS

CARUMONAM

A synthetic monobactam with activity against common pathogenic organisms similar to that of aztreonam. It is resistant to hydrolysis by the common plasmid and chromosomal β -lactamases, but it can be hydrolyzed by ESBLs.

It is administered intravenously, achieving a concentration of c. 78 mg/L after a 20-min infusion of 1 g. The plasma half-life is 1.7 h and the plasma protein binding 18–28%.

Carumonam is almost entirely eliminated in the glomerular filtrate, probenecid having no effect on excretion; 96% of labeled compound is found in the urine, with 3% in the feces. Between 68% and 91% of the dose appears in the urine within 24 h.

Side effects and clinical use are similar to those of aztreonam.

Preparations and dosage

Preparation: Injection.

Dosage: Adult, i.m., i.v., 1–2 g per day in two divided doses.

Available in Japan. Not available in Europe or the USA.

β-LACTAMASE INHIBITORS

Because β-lactamase production is the predominant cause of clinically important resistance to β-lactam antibiotics in most bacteria, an attractive therapeutic approach is to co-administer a β-lactamase inhibitor together with the labile antibiotic. Implicit in this approach, however, are some demanding requirements:

- The inhibitor must be active against a wide range of β-lactamases.
- The absorption, distribution and excretion characteristics of the inhibitor must match closely those of the β-lactam agent with which it is to be paired.
- Its use must not add materially to the toxicity.

The ability of certain β-lactam agents to inhibit selected β-lactamases has been known for a long time. A directed search for potent β-lactamase inhibitors resulted in the discovery of clavulanic acid as a natural product, and the subsequent synthesis of the sulfones, sulbactam and tazobactam. The β-lactamase inhibitors in therapeutic use have poor, or no, antimicrobial activity and act synergistically in combination with β-lactamase-labile penicillins or cephalosporins. None is effective against metallo-β-lactamases. In some organisms these inhibitors may act as inducers of β-lactamase activity.

Carbapenems and monobactams act like competitive inhibitors, or, more specifically, competitive substrates of some serine β-lactamases, with monobactams inhibiting group 1 cephalosporinases at nanomolar concentrations. Their action is reversible, leaving the enzyme intact, because they simply act as poor substrates that are bound tightly to the β-lactamase and are hydrolyzed slowly. The effective inhibitors that have been developed commercially are irreversible inactivators, or 'suicide' inhibitors. The enzyme and inhibitor interact competitively initially and then progressively form a complex in which the enzyme is inactivated over time, usually after a fixed amount of inhibitor has been hydrolyzed like a normal substrate. Clavulanic acid, sulbactam and tazobactam are all of this form, although the precise nature, rate and degree of inactivation differ considerably among the various combinations of agents and enzymes.

Inhibitory effects are dependent upon the amount of enzyme in the organism, so that increased β-lactamase production results in lower efficacy for inhibitor-β-lactam combinations. Resistance may arise through hyperproduction of a sensitive β-lactamase or the occurrence of relatively rare 'inhibitor-resistant' TEM or SHV variants with one or two amino acid changes in the parent enzymes.

Payne DJ, Cramp R, Winstanley DJ, Knowles DJC. Comparative activities of clavulanic acid, sulbactam, and tazobactam against clinically important β-lactamases. *Antimicrob Agents Chemother*. 1994;38:767–772.

CLAVULANIC ACID

Molecular weight (potassium salt): 237.25.

An oxapenam (clavam) produced by *Streptomyces clavuligerus*. It is available as the potassium salt for oral and intravenous use in fixed-ratio combination with amoxicillin and for intravenous use in combination with ticarcillin. It is freely soluble in water.

ANTIMICROBIAL ACTIVITY

It exhibits broad-spectrum but low intrinsic activity, most MICs being in the range 16–128 mg/L. Enterobacteriaceae and *Staph. aureus* are among the more sensitive and *Ps. aeruginosa* the most resistant organisms. MICs of 8 mg/L against *H. influenzae* and 0.1–4 mg/L for penicillinase-producing *N. gonorrhoeae* are notable.

β-LACTAMASE INHIBITORY ACTIVITY

Clavulanic acid is a potent, progressive inhibitor of most group 2 β-lactamases, with the exception of some TEM and many OXA variants. It is very active against the *K. pneumoniae* K1 (group 2be) enzyme, the group 2e chromosomal enzymes produced by *Pr. vulgaris* and *B. fragilis*, both enzymes produced by *Mor. catarrhalis* and the group 2a penicillinases from *Staph. aureus*. It does not effectively inhibit the group 1 chromosomal cephalosporinases from Enterobacteriaceae or the group 3 metallo-β-lactamases.

In the presence of low concentrations of clavulanic acid (0.5–1 mg/L) the MICs of amoxicillin and ticarcillin for many β-lactamase-producing *Staph. aureus*, *Mor. catarrhalis*, *N. gonorrhoeae*, *H. influenzae*, enterobacteria and *B. fragilis* strains are reduced 8- to 64-fold. In *B. fragilis* strains resistant to penicillin, the addition of clavulanic acid renders most of the strains susceptible to amoxicillin or ticarcillin. Susceptibility of methicillin-resistant strains of *Staph. aureus* is unaffected by the presence of clavulanic acid.

Resistance that develops during therapy is generally due to overproduction of the sensitive β-lactamase, e.g. TEM-1 or SHV-1, which is no longer effectively inhibited by a limited quantity of clavulanic acid or to the production of occasional 'inhibitor-resistant' β-lactamases.

AMOXICILLIN-CLAVULANIC ACID

Co-amoxiclav. A mixture of potassium clavulanate and amoxicillin trihydrate (oral formulations) or amoxicillin sodium (parenteral formulations). The ratio of amoxicillin to clavulanic acid in the commercially available oral preparations is variable.

ANTIMICROBIAL ACTIVITY

Activity is that of amoxicillin (p. 215), the role of the inhibitor being to restore the activity against β -lactamase-producing strains that would otherwise hydrolyze the drug.

PHARMACOKINETICS

	Amoxicillin	Clavulanic acid
Oral absorption	c. 90%	c. 90%
C_{\max} 500 mg amoxicillin + 125 mg clavulanic acid oral	7.2 mg/L after 1 h	2.4 mg/L after 1 h
2000 g amoxicillin + 125 mg clavulanic acid (extended-release formulation)	17 mg/L after 1.5 h	2.05 mg/L after 1 h
400 mg amoxicillin + 57 mg clavulanic acid oral	6.9 mg/L	1.1 mg/L
Plasma half-life	1.3 h	1.0 h
Plasma protein binding	18%	25%

Absorption and distribution

There is little effect on the pharmacokinetics of each agent from the presence of the other, although clavulanic acid is marginally better absorbed in the presence of amoxicillin. There is wide individual variation in bioavailability (30–99%).

Effective levels are found in most body tissues and fluids. Total penetration into the CSF was 8% and 6% of the corresponding plasma values for clavulanate and amoxicillin, respectively. Clavulanate penetrates poorly into sputum after oral dosing.

Metabolism and excretion

Clavulanic acid appears to be metabolized extensively, with metabolites eliminated via the urine, bile, feces and lungs. Variation in bioavailability may be related to differences in first-pass effects through those organs.

Approximately 50–70% of the administered amoxicillin and 25–40% of clavulanic acid are recovered intact from the urine. Most renal excretion occurs in the first 6 h and is unaffected by probenecid, although probenecid prolongs the renal excretion of amoxicillin. In renal failure, the volume of distribution and systemic availability are unaffected after oral or intravenous administration, but clearance is progressively depressed with renal function.

TOXICITY AND SIDE EFFECTS

Cholestatic jaundice is more common with co-amoxiclav than with amoxicillin alone and the combination is contraindicated in patients with a history of hepatic dysfunction associated with the drug.

Other common side effects are diarrhea (9%), nausea (3%), skin rashes and urticaria (3%), vomiting (1%) and vaginitis (1%). The overall incidence of side effects, and in particular diarrhea, increases with the higher recommended dose. Pseudomembranous colitis has been reported.

For side effects attributable to amoxicillin, see page 215.

CLINICAL USE

Lower respiratory tract infections
Otitis media
Sinusitis
Skin and skin structure infections
Urinary tract infections

It is usually recommended for use against amoxicillin-resistant organisms if the susceptibility status is known.

Preparations and dosage

Proprietary name: Augmentin.

Preparations: Tablets, suspension, injection.

Dosage: Adults, oral, 250/125 mg every 8 h, or 500/125 mg every 12 h; 500/125 mg every 8 h, or 875/125 or 2000/125 mg every 12 h for more serious infections. Children, the dose varies according to age and severity of infection.

Adults, i.v., 1.2 g every 6–8 h depending on the severity of the infection. Infants <3 months, 30 mg/kg every 12 h; children 3 months to 12 years, 20–45 mg/kg every 8–12 h depending on the severity of the infection. (Not available in the USA.)

Widely available.

TICARCILLIN-CLAVULANIC ACID

A mixture of potassium clavulanate and ticarcillin disodium in a 1:15 or 1:30 ratio for parenteral administration.

ANTIMICROBIAL ACTIVITY

Activity is that of ticarcillin (p. 222), the role of the inhibitor being to restore the activity against β-lactamase-producing strains that would otherwise hydrolyze the drug.

PHARMACOKINETICS

	Ticarcillin	Clavulanic acid
C_{max} 3 g ticarcillin + 100 mg clavulanate intravenous infusion (30 min)	330 mg/L end infusion	8 mg/L end infusion
Plasma half-life	1.1 h	1.1 h
Plasma protein binding	45%	25%

The pharmacokinetics of the two agents are mutually unaffected by co-administration. Ticarcillin can be detected in tissues and interstitial fluid following parenteral administration. Penetration into bile, peritoneal fluid and pleural fluid has been demonstrated. Concentrations in blister fluid were significantly lower than those in serum.

Around 60–70% of ticarcillin and 35–45% of clavulanic acid are excreted unchanged in urine during the first 6 h after administration of a single dose of the mixture.

TOXICITY AND SIDE EFFECTS

Adverse reactions associated with ticarcillin occur (see p. 222). As with co-amoxiclav, there is a risk of cholestatic jaundice (see above). Pseudomembranous colitis has been reported.

CLINICAL USE

- Septicemia, including bacteremia
- Lower respiratory infections
- Bone and joint infections
- Skin and skin structure infections
- Urinary tract infections (complicated and uncomplicated)
- Gynecological infections, endometritis
- Intra-abdominal infections, peritonitis

Its main use is in infections in which *Ps. aeruginosa* is suspected or proven.

Preparations and dosage

Proprietary name: Timentin.

Preparation: Infusion.

Dosage: Adults, i.v. infusion, 3.0/0.2 g every 4–6 h. Children <60 kg, 200–300 mg/kg per day in 4–6 divided doses; 60 kg, 3.0/0.2 g every 4–6 h depending on the severity of the infection.

Widely available.

Resistance to ticarcillin-potassium clavulanate among clinical isolates of the family Enterobacteriaceae: the role of PSE-1 β-lactamase and high levels of TEM-1 and SHV-1 and problems with false susceptibility in disk diffusion tests. *Antimicrob Agents Chemother.* 1988;32:1365–1369.

SULBACTAM

Molecular weight (sodium salt): 255.22.

A penicillanic acid sulfone available as the sodium salt. Formulations combining ampicillin or cefoperazone with sulbactam in a 2:1 ratio are available for parenteral use. A methylene-linked double ester of penicillin and sulbactam, sultamicillin, is used for oral administration.

ANTIMICROBIAL ACTIVITY

Sulbactam has very weak antimicrobial activity against most bacteria. Its only notable activity is against *N. gonorrhoeae*, *N. meningitidis* and *Acinetobacter baumannii*.

β-LACTAMASE-INHIBITORY ACTIVITY

It inhibits a wide range of group 2 β-lactamases, including those from *Staph. aureus*, *K. pneumoniae* and *B. fragilis*. It is a good-to-moderate inhibitor of the TEM enzymes of groups 2b and 2be but has little effect on group 1, group 2br or group 3 β-lactamases. It does not induce the activity of cephalosporinases from Gram-negative bacteria but is a weak inducer of penicillinases from *Staph. aureus*.

A concentration of 4–8 mg/L restores the activity of ampicillin for many β -lactamase-producing strains of *Staph. aureus*, *H. influenzae*, *Mor. catarrhalis*, enterobacteria and *B. fragilis*, but there is a large inoculum effect.

AMPICILLIN-SULBACTAM

ANTIMICROBIAL ACTIVITY

Activity is that of ampicillin (p. 216), the role of the inhibitor being to restore the activity against β -lactamase-producing strains that would otherwise hydrolyze the drug.

PHARMACOKINETICS

	Ampicillin	Sulbactam
Oral absorption (sultamicillin)	>80%	>80%
C_{max} ampicillin 2 g + sulbactam 1 g intravenous 750 mg oral (sultamicillin)	109–150 mg/L end infusion	48–88 mg/L end infusion
Plasma half-life	1 h	1 h
Plasma protein binding	28%	38%

Absorption and distribution

The sodium salt of sulbactam is poorly absorbed orally, but the linked prodrug sultamicillin is well absorbed; it undergoes first-pass hydrolysis to liberate equimolecular proportions of the components.

Ampicillin-sulbactam is completely bioavailable after intramuscular injection, doses of 1.0 and 0.5 g producing mean peak plasma levels of 8–37 and 6–24 mg/L, respectively. After intravenous administration both drugs penetrate peritoneal fluid, blister fluid (cantharides-induced), tissue fluid and intestinal mucosa to provide concentrations ≥ 7 mg/L. Penetration of both ampicillin and sulbactam into CSF in the presence of inflamed meninges has been demonstrated after intravenous infusion.

Metabolism and excretion

Sulbactam is not metabolized. Ampicillin metabolism is described on page 217. In normal volunteers 75–85% of both ampicillin and sulbactam are excreted unchanged in the urine during the first 8 h after administration.

TOXICITY AND SIDE EFFECTS

Local adverse reactions include pain at the injection site (intramuscular 16%, intravenous 3%) and thrombophlebitis (3%). Systemic adverse reactions include diarrhea (3%). Pseudomembranous colitis has been reported. For side effects attributable to ampicillin, see page 217.

CLINICAL USE

Skin and skin structure infections
Intra-abdominal infections
Gynecological infections

Preparations and dosage

Preparation: Injection.

Dosage: Adult, i.m., i.v., 1/0.5–2/1 g every 6 h; Children, 300 mg/kg per day in four divided doses.

Available in the USA, but not available in the UK.

Sulbactam-cefoperazone and sultamicillin are available in Japan.

TAZOBACTAM

Molecular weight (sodium salt): 322.3.

A synthetic penicillanic acid sulfone available as the sodium salt. It is formulated with piperacillin in a piperacillin:tazobactam ratio of 8:1.

ANTIMICROBIAL ACTIVITY

Tazobactam exhibits little useful antimicrobial activity, although weak activity against *Acinetobacter* spp. and *Borrelia burgdorferi* has been reported.

β-LACTAMASE INHIBITORY ACTIVITY

Tazobactam inhibits a wide range of β-lactamases, including the group 2 penicillinases from *Staph. aureus*, the TEM-1 and SHV-1 β-lactamases, many extended-spectrum enzymes, and the common group 2e cephalosporinases of *B. fragilis*. Against the group 1 cephalosporinases, activity is strongly influenced by the amount of enzyme produced. The inhibitor-resistant group 2br β-lactamases are poorly inhibited and group 3 metallo-β-lactamases are not inhibited at clinically useful levels. It is a poor inducer of β-lactamases of Gram-positive and Gram-negative organisms.

At a concentration of 4 mg/L it markedly reduces the MIC and enhances the bactericidal activity of piperacillin against many β-lactamase-producing organisms, but only moderately against those elaborating group 1 cephalosporinases. It enhances activity against β-lactamase-producing *Staph. aureus*, *H. influenzae*, *Mor. catarrhalis*, most of the *B. fragilis* group, *Acinetobacter* spp., many enterobacteria, especially *Pr. mirabilis* and *Morganella morganii*, and occasional *Enterobacter* spp. and *C. freundii*.

PIPERACILLIN-TAZOBACTAM

ANTIMICROBIAL ACTIVITY

Activity is that of piperacillin (p. 221), the role of the inhibitor being to restore the activity against β-lactamase-producing strains that would otherwise hydrolyze the drug. Although the activity of piperacillin against *Ps. aeruginosa* is not enhanced, it remains the most active inhibitor combination in vitro against *Ps. aeruginosa*.

PHARMACOKINETICS

	Piperacillin	Tazobactam
C_{max} , 3 g piperacillin + 375 mg tazobactam intravenous infusion	242 mg/L end infusion	24 mg/L end infusion
Plasma half-life	1 h	1.1 h
Plasma protein binding	30%	30%

Absorption and distribution

The components are not absorbed orally. The combination has good tissue distribution, with mean tissue concentrations 50–100% of those in plasma. Co-administration of tazobactam does not affect the pharmacokinetics of piperacillin. Co-administration of piperacillin and tazobactam with vancomycin resulted in no significant change in pharmacokinetic interactions.

Metabolism and excretion

A small amount of piperacillin is metabolized to a microbiologically active desethyl metabolite, and some undergoes cleavage of the β-lactam ring. Tazobactam is metabolized to a ring-opened compound that further degrades to a derivative devoid of pharmacological activity.

Renal clearance of both drugs occurs by glomerular filtration and tubular secretion. Urinary excretion of piperacillin is 68%, whereas tazobactam and its metabolite are eliminated primarily by renal excretion (80%). Biliary secretion of piperacillin, tazobactam and desethyl piperacillin are also observed.

TOXICITY AND SIDE EFFECTS

Most adverse events are mild to moderate, and transient. Most common drug-related events are rash and pruritus (1.3%) and gastrointestinal effects (0.9%). Pseudomembranous colitis has been reported.

For side effect attributable to piperacillin, see page 221.

CLINICAL USE

Uncomplicated and complicated skin and skin structure infection
Postpartum endometritis or pelvic inflammatory disease
Community-acquired pneumonia (moderate severity)
Nosocomial pneumonia (moderate to severe)
Appendicitis and peritonitis

Preparations and dosage

Proprietary names: Tazocin, Zosyn.

Preparation: Injection.

Dosage: Adults and children over 12 years, by i.v. injection, 3.0/0.375 g every 6 h; may be dosed 4.0/0.5 g every 6 h plus amikacin or gentamicin for patients with nosocomial pneumonia caused by *Ps. aeruginosa*. Children >9 months, 100/12.5 mg/kg every 8 h. Children 2–9 months, 80 g/kg every 8 h.

Widely available.

CHAPTER

16 Chloramphenicol and thiamphenicol

Mark H. Wilcox

Chloramphenicol was the first broad-spectrum antibiotic to be discovered. It was isolated independently from streptomycetes from soil in Venezuela and a compost heap in Illinois. The commercial product is manufactured synthetically. There are four isomers, all of which have been synthesized, but none has greater activity than the natural compound. The major drawback is a rare, idiosyncratic, often fatal aplastic anemia, and numerous attempts have been made to manufacture related agents which retain the spectrum of activity and pharmacokinetics of the parent compound, but not the toxicity. The only derivative to come into commercial use in which this is believed to have been achieved is thiamphenicol, in which the nitro group of chloramphenicol is replaced by a sulfomethyl group. However, compounds in which the nitro group is replaced are all less active than the parent compound.

Substitution of the 3'-OH group or fluorine for chlorine has produced analogs of chloramphenicol and thiamphenicol that are active against strains of bacteria that owe their resistance to chloramphenicol acetylation, but not against organisms with reduced permeability. Fluorinated derivatives are not marketed for human use, but florfenicol is available in veterinary practice and aquaculture in some countries.

CHLORAMPHENICOL

Molecular weight: 323.1.

A fermentation product of *Streptomyces venezuelae*. Commercially manufactured synthetically. Formulated as the free compound (which is extremely bitter) or as the palmitate ester for oral administration; as the free compound for topical use; and as the sodium succinate for injection. Aqueous solutions are extremely stable, but some hydrolysis occurs on autoclaving.

ANTIMICROBIAL ACTIVITY

It is active against a very wide range of organisms. The susceptibility of common pathogenic bacteria is shown in Table 16.1. Minimum inhibitory concentrations (MICs) (mg/L) for other organisms are: *Staphylococcus epidermidis*, 1–8; *Corynebacterium diphtheriae*, 0.5–2; *Bacillus anthracis*, 1–4; *Clostridium perfringens*, 2–8; *Mycobacterium tuberculosis*, 8–32; *Legionella pneumophila*, 0.5–1; *Bordetella pertussis*, 0.25–4; *Brucella abortus*, 1–4; *Campylobacter fetus*, 2–4; *Pasteurella* spp., 0.25–4; *Serratia marcescens*, 2–8; *Burkholderia pseudomallei*, 4–8. Most Gram-negative bacilli are susceptible, but *Pseudomonas aeruginosa* is resistant. *Leptospira* spp., *Treponema pallidum*, chlamydiae, mycoplasmas and rickettsiae are all susceptible, but *Nocardia* spp. are resistant. It is widely active against anaerobes, including *Actinomyces israelii* (MIC 1–4 mg/L), *Peptostreptococcus* spp. (MIC 0.1–8 mg/L), and *Fusobacterium* spp. (MIC 0.5–2 mg/L), but *Bacteroides fragilis* is only moderately susceptible (MIC about 8 mg/L).

It is strictly bacteriostatic against almost all bacterial species, but exerts a bactericidal effect at 2–4 times the MIC against some strains of Gram-positive cocci, *Haemophilus influenzae* and *Neisseria* spp. The minimum bactericidal concentrations (MBCs) for penicillin-resistant pneumococci are often significantly higher than those for penicillin-susceptible strains, although this cannot be detected by conventional disk susceptibility testing or MIC determination. Its bacteriostatic effect may inhibit the action of penicillins and other β-lactam antibiotics against *Klebsiella pneumoniae* and other enterobacteria in vitro, but the clinical

Table 16.1 Activity of chloramphenicol and thiamphenicol: MIC (mg/L)

	Chloramphenicol	Thiamphenicol
<i>Staphylococcus aureus</i>	2–8	4–32
<i>Streptococcus pyogenes</i>	2–4	1–2
<i>Str. pneumoniae</i>	1–4	2–4
<i>Enterococcus faecalis</i>	4–16	8–32
<i>Neisseria gonorrhoeae</i>	0.5–2	0.5–2
<i>N. meningitidis</i>	0.5–2	0.5–2
<i>Haemophilus influenzae</i>	0.25–0.5	0.1–2
<i>Escherichia coli</i>	2–8	4–64
<i>Klebsiella pneumoniae</i>	0.5–32	4–32
<i>Salmonella enterica</i>	0.5–8	0.5–8
<i>Shigella</i> spp.	1–8	2–8
<i>Pseudomonas aeruginosa</i>	32–R	16–R
<i>Bacteroides</i> spp.	1–8	0.5–32

R, resistant (MIC >64 mg/L).

significance of this is doubtful. The presence of ampicillin does not affect the bactericidal effect of chloramphenicol on *H. influenzae*.

ACQUIRED RESISTANCE

The prevalence of resistant strains in many Gram-positive and Gram-negative organisms reflects usage of the antibiotic. Over-the-counter sales are believed to have compounded the problem in some countries. For example, it has long been the drug of choice for the treatment of typhoid and paratyphoid fevers, but widespread use led to a high prevalence of resistant *Salmonella enterica* serotype Typhi. Outbreaks of infection caused by chloramphenicol-resistant *S. Typhi* have been seen since the early 1970s. Use of co-trimoxazole and fluoroquinolones in typhoid has resulted in a decline in chloramphenicol resistance in some endemic areas. Many hospital outbreaks caused by multiresistant strains of enterobacteria, notably *Enterobacter*, *Klebsiella* and *Serratia* spp., have been described.

Plasmid-borne resistance was first noted in shigellae in Japan and subsequently spread widely in Central America, where it was responsible for a huge outbreak. Strains of *S. Typhi* resistant to many antibiotics including chloramphenicol are particularly common in the Indian subcontinent. Resistance in shigellae is also relatively common in some parts of the world.

Resistant strains of *H. influenzae* (some also resistant to ampicillin), *Staph. aureus* and *Streptococcus pyogenes* are also encountered. Most *N. meningitidis* strains remain susceptible,

but high-level resistance (MIC >64 mg/L) due to the production of chloramphenicol acetyltransferase (p. 27) has been described; the nucleotide sequence of the resistance gene was indistinguishable from that found on a transposon in *C. perfringens*. Resistant strains of *Enterococcus faecalis* are relatively common, and resistance to chloramphenicol is found in some multiresistant pneumococci.

Resistance in *Staph. aureus* is caused by an inducible acetyltransferase; additionally, the *cfr* (chloramphenicol-florfenicol resistance) gene encodes a 23S rRNA methyltransferase that also confers resistance to linezolid. In *Escherichia coli*, the capacity to acetylate chloramphenicol (at least three enzymes are involved) is carried by R factors. Replacement of the 3-OH group, which is the target of acetylation, accounts for the activity of fluorinated analogs against strains resistant to chloramphenicol and thiamphenicol. The resistance of *B. fragilis* and some strains of *H. influenzae* is also due to elaboration of a plasmid-encoded acetylating enzyme; in others it is due to reduced permeability resulting from loss of an outer membrane protein. Some resistant bacteria reduce the nitro group or hydrolyze the amide linkage. Resistance of *Ps. aeruginosa* is partly enzymic and partly due to impermeability.

PHARMACOKINETICS

Oral absorption	80–90%
C_{\max} 500 mg oral	10–13 mg/L after 1–2 h
Plasma half-life	1.5–3.5 h
Volume of distribution	0.25–2 L/kg
Plasma protein binding	c. 25–60%

Absorption

The plasma concentration achieved is proportional to the dose administered. Suspensions for oral administration to children contain chloramphenicol palmitate, a tasteless and bacteriologically inert compound, which is hydrolyzed in the gut to liberate chloramphenicol. Following a dose of 25 mg/kg, peak plasma levels around 6–12 mg/L are obtained, but there is much individual variation.

Pancreatic lipase is deficient in neonates and, because of poor hydrolysis, the palmitate should be avoided. In very young infants, deficient ability to form glucuronides, and low glomerular and tubular excretion greatly prolong the plasma half-life.

For parenteral use, chloramphenicol sodium succinate, which is freely soluble and undergoes hydrolysis in the tissues with the liberation of chloramphenicol, can be injected intravenously or in small volumes intramuscularly. The plasma concentrations after administration by these routes are unpredictable, and approximate to only 30–70% of those obtained after the same dose by the oral route. Protein binding is reduced in cirrhotic patients and neonates, with correspondingly elevated concentrations of free drug.

Distribution

Free diffusion occurs into serous effusions. Penetration occurs into all parts of the eye, the therapeutic levels in the aqueous humor being obtained even after local application of 0.5% ophthalmic solution. Concentrations obtained in cerebrospinal fluid (CSF) in the absence of meningitis are 30–50% of those of the blood and greater in brain. It crosses the placenta into the fetal circulation and appears in breast milk.

Metabolism

It is largely inactivated in the liver by conjugation with glucuronic acid or by reduction to inactive arylamines; clearance of the drug in patients with impaired liver function is depressed in relation to the plasma bilirubin level. It has been suggested that genetically determined variance of hepatic glucuronyl transferase might determine the disposition and toxicity of the drug.

Excretion

It is excreted in the glomerular filtrate, and in the newborn elimination may be impaired by the concomitant administration of benzylpenicillin, which is handled early in life by the same route. Inactive derivatives are eliminated partly in the glomerular filtrate and partly by active tubular secretion. Over 24 h, 75–90% of the dose appears in the urine, 5–10% in biologically active forms and the rest as metabolites, chiefly as a glucuronide conjugate. Excretion diminishes linearly with renal function and at a creatinine clearance of <20 ml/min, maximum urinary concentrations are 10–20 mg/L rather than the 150–200 mg/L found in normal subjects. Because of metabolism, blood levels of active drug are only marginally elevated in renal failure, but microbiologically inactive metabolites accumulate. The plasma half-life of the products in the anuric patient is around 100 h, and little is removed by peritoneal or hemodialysis. Dosage modification is normally unnecessary in renal failure as the metabolites are less toxic than the parent compound. About 3% of the administered dose is excreted in the bile, but only 1% appears in the feces, and this mostly in inactive forms.

INTERACTIONS

Induction of liver microsomal enzymes, for example by phenobarbital (phenobarbitone) or rifampicin (rifampin), diminishes blood levels of chloramphenicol; conversely, chloramphenicol, which inhibits hepatic microsomal oxidases, potentiates the activity of dicoumarol (dicumarol), phenytoin, tolbutamide and those barbiturates that are eliminated by metabolism. It also depresses the action of cyclophosphamide, which depends for its cytotoxicity on transformation into active metabolites. It is uncertain whether this interaction

may lead to a clinically significant level of inhibition of the activity of cyclophosphamide. The half-life of chloramphenicol is considerably prolonged if paracetamol (acetaminophen) is given concurrently, and co-administration of these drugs should be avoided.

TOXICITY AND SIDE EFFECTS

Glossitis, associated with overgrowth of *Candida albicans*, is fairly common if the course of treatment exceeds 1 week. Stomatitis, nausea, vomiting and diarrhea may occur, but are uncommon. Hypersensitivity reactions are very uncommon. Jarisch–Herxheimer-like reactions have been described in patients treated for brucellosis, enteric fever and syphilis.

Bone marrow effects

Chloramphenicol exerts a dose-related but reversible depressant effect on the marrow of all those treated, resulting in vacuolization of erythroid and myeloid cells, reticulocytopenia and ferrokinetic changes indicative of decreased erythropoiesis. Evidence of bone-marrow depression is regularly seen if the plasma concentration exceeds 25 mg/L, and leukopenia and thrombocytopenia may be severe. There is no evidence that this common marrow depression is the precursor of potentially fatal aplasia, which differs in that it is fortunately rare, late in onset, usually irreversible and may follow the smallest dose. Aplasia can follow systemic, oral and even ophthalmic administration and may be potentiated by cimetidine. Liver disease, uremia and pre-existing bone marrow dysfunction may increase the risk. It is unusual for manifestations to appear during treatment, and the interval between cessation of treatment and onset of dyscrasia can be months. A few patients survive with protracted aplasia, and myeloblastic leukemia then often supervenes.

It is thought that the toxic agent is not chloramphenicol itself but an as yet unidentified metabolite. Chloramphenicol is partially metabolized to produce oxidized, reduced and conjugated products. The toxic metabolite may be a short-lived product of reduction of the nitro group, which damages DNA by helix destabilization and strand breakage. Predisposition to aplasia may be explained by genetically determined differences in metabolism of the agent. Risk of fatal aplastic anemia has been estimated to increase 13-fold on average treatment with 4 g of chloramphenicol. Corresponding increases are 10-fold in patients treated with mepacrine (quinacrine) and 4-fold in patients treated with oxyphenbutazone.

Children

Infants given large doses may develop exceedingly high plasma levels of the drug because of their immature conjugation and excretion mechanisms. A life-threatening

disorder called the 'gray baby' syndrome, characterized by vomiting, refusal to suck and abdominal distension followed by circulatory collapse, may appear when the plasma concentration exceeds 20 mg/L. If concentrations reach 200 mg/L, the disorder can develop in older children or even adults.

Optic neuritis has been described in children with cystic fibrosis receiving prolonged treatment for pulmonary infection. Most improve when the drug is discontinued, but central visual acuity can be permanently impaired. There is some experimental evidence that ear drops containing 5% chloramphenicol sodium succinate can damage hearing. One study identified an increased risk of acute leukemia following childhood administration of chloramphenicol, particularly for durations exceeding 10 days.

CLINICAL USE

- Typhoid fever and other severe infections due to salmonellae
- Rickettsial infections
- Meningitis
- Invasive infection caused by *H. influenzae*
- Destructive lung lesions involving anaerobes
- Eye infections (topical)

Reference is made to its use in cholera, plague, tularemia and bartonellosis, melioidosis, Whipple's disease and relapsing fever. In enteric fever in adults, fluoroquinolones are associated with a lower clinical relapse rate. Treatment for other serious infections should be restricted to organisms that are resistant or much less susceptible to other antibiotics. A study in low resource countries found ampicillin plus gentamicin superior to injectable chloramphenicol for the treatment of very severe community-acquired pneumonia in children.

It has been used with varying success to treat infections caused by glycopeptide-resistant enterococci. Meningitis caused by penicillin-resistant pneumococci responds poorly, apparently due to failure to achieve bactericidal concentrations in CSF. It should never be given systemically for minor infections. Topical use in the treatment of eye infections is controversial given the unsubstantiated risk of bone marrow aplasia. A placebo-controlled study in children with infective conjunctivitis in the community found no clinical benefit in the use of chloramphenicol eye drops.

The daily dose should not normally exceed 2 g, and the duration of the course should be limited (e.g. 10 days). Although patients may show toxic manifestations after receiving very little drug, the danger is almost certainly increased by excessive or repeated dosage or by the treatment of patients with impaired hepatic or renal function, including those at the extremes of life. The wide pharmacokinetic variability of the antibiotic in neonates makes monitoring of serum concentrations advisable. Determination of full blood counts should be carried out twice weekly.

Preparations and dosage

Proprietary names: Chloromycetin, Kemicetine.

Preparations: Capsules, suspension, injection.

Dosage: Adults, oral, i.v., 50 mg/kg per day in four divided doses; the dose may be doubled for severe infections and reduced as soon as clinically indicated. Children, 50–100 mg/kg per day in divided doses; infants <2 weeks, 25 mg/kg per day in four divided doses; infants 2 weeks to 1 year, 50 mg/kg per day in four divided doses.

Widely available.

THIAMPHENICOL

Molecular weight: 356.2.

A chloramphenicol analog in which a sulfomethyl group is substituted for the *p*-nitro group. Also available as the glycinate hydrochloride (1.26 g approximately equivalent to 1 g thiampenicol). Aqueous solutions are very stable.

ANTIMICROBIAL ACTIVITY

It is generally less active than chloramphenicol (Table 16.1), but is equally active against *Str. pyogenes*, *Str. pneumoniae*, *H. influenzae* and *N. meningitidis*, including some strains

resistant to chloramphenicol. It is more actively bactericidal against *Haemophilus* and *Neisseria* spp.

ACQUIRED RESISTANCE

There is complete cross-resistance with chloramphenicol in those bacteria which elaborate acetyltransferase, although the affinity of the enzyme for thiamphenicol is lower. Organisms that owe their resistance to other mechanisms may be susceptible.

PHARMACOKINETICS

An oral dose of 500 mg produces a peak plasma level of 3–6 mg/L after about 2 h. The plasma half-life is 2.6–3.5 h. It is said to reach the bronchial lumen in concentrations sufficient to exert a bactericidal effect on *H. influenzae*. Unlike chloramphenicol it is not a substrate for hepatic glucuronyl transferase; it is not eliminated by conjugation, and its half-life is not affected by phenobarbital induction.

About 50% of the dose can be recovered in an active form in the urine within 8 h and 70% over 24 h. The drug is correspondingly retained in the presence of renal failure, and in anuric patients the plasma half-life has been reported to be 9 h, a value not significantly affected by peritoneal dialysis. Biliary excretion is believed to account for removal of the antibiotic in anuric patients. The plasma concentration is elevated and half-life prolonged in patients with hepatitis or cirrhosis.

TOXICITY AND SIDE EFFECTS

There are no reports of irreversible bone-marrow toxicity. This has been related to the absence of the nitro group, and hence its reduction products, and differences in the biochemical effects of thiamphenicol and chloramphenicol on mammalian cells. It exerts a greater dose-dependent reversible depression of hemopoiesis and immunogenesis than chloramphenicol, and has been used for its immunosuppressive effect. Therapeutic doses (1–1.5 g) are likely to depress erythropoiesis in the elderly or others with impaired renal function.

CLINICAL USE

Similar to that of chloramphenicol.

Preparations and dosage

Preparations: Oral, injection.

Dosage: Adults, i.m., oral, 1.5–3 g per day in divided doses depending on severity of infection. Children, 30–100 mg/kg per day in divided doses.

Limited availability in continental Europe and Japan. Not available in the UK or the USA.

17 Diaminopyrimidines

Göte Swedberg and Lars Sundström

This group of agents comprises mainly 5-substituted 2,4-diaminopyrimidines, such as trimethoprim, cycloguanil and pyrimethamine, which have antibacterial or antiprotozoal activity. The diaminopyrimidine moiety can also be part of a pteridine or quinazoline ring system, as in the antineoplastic agents methotrexate and trimetrexate.

They are potent inhibitors of the enzyme dihydrofolate reductase (see Ch. 2) and are generally termed antifolates.

Trimethoprim and pyrimethamine emerged from an antimetabolite program initiated in the 1940s by G.H. Hitchings and colleagues. Several trimethoprim analogs were subsequently synthesized, and derivatives with increased spectrum and activity against resistant strains remain under investigation. Activity against eukaryotic parasites is of special interest because of the relative lack of good alternatives. The determination of three-dimensional structures of the target enzyme is aiding further development of the field.

Clinical development of trimethoprim concentrated on a synergistic combination with sulfamethoxazole (co-trimoxazole), which exploits the sequential blockade of two steps in the biosynthesis of reduced folates. This double blockade results in greatly enhanced antibacterial activity, extends the antibacterial spectrum, slows down resistance development (at least under laboratory conditions) and increases the bactericidal potency. Co-trimoxazole became very successful, but the practice of applying a potent agent such as trimethoprim exclusively in combination with a sulfonamide was disputed on several grounds:

- Although the pharmacokinetic properties of trimethoprim and sulfamethoxazole match fairly well in the plasma, conditions far from those optimal for synergy prevail in different body compartments.

- Synergy is relevant only at sites in which concentrations fall below levels effective alone, whereas the combination is administered at doses that produce plasma levels of both components above the inhibitory concentration.
- Resistance to sulfonamides was already widespread at the time of launch of the combination, so that trimethoprim alone is the active component against such strains.
- The sulfonamide component, which is in five-fold excess over trimethoprim, is responsible for many of the undesirable side effects.
- The high concentrations of trimethoprim reached in urine are sufficient to treat uncomplicated cystitis and other infections of the urinary tract.

These considerations led to the clinical use of trimethoprim alone, especially in urinary tract infections. In other conditions it is often still used as a fixed combination with sulfonamides, usually sulfamethoxazole, although some licensing agencies recommend combined use solely for infections, such as the treatment and prophylaxis of *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia, in which there are good grounds for preferring it over trimethoprim alone.

PYRIMETHAMINE

2,4-Diamino-5-(p-chlorophenyl)-6-ethylpyrimidine.
Molecular weight: 248.717.

A synthetic diaminopyrimidine. Extremely insoluble. Available as a single agent (Daraprim) or in fixed combination with sulfadoxine (Fansidar), dapsone (Maloprim) or triple combination with mefloquine and sulfadoxine (Fansimef).

ANTIMICROBIAL ACTIVITY

Most notable activity is against *Plasmodium* spp., *Toxoplasma gondii* and *Pn. jirovecii*. It is about 1000 times more active against plasmodial dihydrofolate reductase than against the human enzyme. It has no useful antibacterial activity. Slow growing bradyzoite forms of *Tox. gondii* in tissue cysts are less sensitive than the intracellular tachyzoites. It is strongly recommended that it is used together with a sulfonamide for the treatment of malaria and toxoplasmosis, since the mixture lowers the ED₅₀ and clinically curative dose approximately 10-fold.

ACQUIRED RESISTANCE

Plasmodium falciparum generally acquires resistance gradually by step-wise mutations in dihydrofolate reductase. The first mutation was a change from Ser to Asn in residue 108, with subsequent mutations at positions 51 (Asn to Ile), 59 (Cys to Arg) and 164 (Leu to Ile). Parasites with all four mutations have the highest level of resistance; they are still rare in Africa but much more prevalent in Asia. A further increase in resistance may be caused by an increased copy number of the gene coding for GTP cyclohydrolase, the first and rate-limiting enzyme in the folate biosynthetic pathway. Copy number mutations have so far been seen only in Asia. Resistance to pyrimethamine-sulfadoxine (Fansidar) is also affected by mutations in the gene coding for the dihydropteroate synthase target of sulfonamides, although the relation between such mutations and the level of resistance is less clear. The key mutation is a change at residue 437 (Ala to Gly), which in Africa is usually found in combination with a mutation at residue 540 (Lys to Glu), less commonly at residue 581 (Ala to Gly). Other mutations are found in Asia. Changes in membrane proteins like PfMRP1 have an effect on folate transport and may also influence antifolate action.

PHARMACOKINETICS

Oral absorption	Well absorbed
C _{max} (25 mg orally)	0.13–0.4 mg/L after 2–6 h
Plasma half-life	111 (54–148) h
Volume of distribution	0.68 L/kg
Plasma protein binding	87%

Absorption

Pyrimethamine is well absorbed orally. The plasma half-life is unaffected by partner drugs like dapsone and sulfadoxine. Absorption is markedly poorer in patients with HIV.

Distribution

Levels in cerebrospinal fluid (CSF) are around 10–25% of the simultaneous plasma level. A substantial part of the dose appears in maternal milk, the ratio of milk:serum area under the concentration–time curve (AUC) being 0.46–0.66, so that an infant might ingest almost half the maternal dose over 9 days. There is placental transfer of pyrimethamine, resulting in 50–100% of the maternal plasma concentrations in the neonate.

Metabolism and excretion

Plasma clearance is 0.3–0.4 mL/min/kg and elimination is mainly by hepatic metabolism. Few studies have been done on pyrimethamine metabolism, but some cytochrome P₄₅₀ enzymes have been shown to be involved in the relatively slow metabolism.

TOXICITY AND SIDE EFFECTS

When administered with a sulfonamide or dapsone, all major side effects of these agents (including Stevens–Johnson syndrome) may occur, particularly hypersensitivity reactions. The principal toxic effect of pyrimethamine is on the bone marrow, producing megaloblastic anemia, leukocytopenia, thrombocytopenia or pancytopenia. This is particularly seen on prolonged administration and with the high doses used in toxoplasmosis. A relatively high incidence of side effects of pyrimethamine and other drugs was seen during treatment of ocular toxoplasmosis, with stomach problems as the main complaint. Very large doses in children have produced vomiting, convulsions, respiratory failure and death. Aggravation of subclinical folate deficiency may be alleviated by folic acid. Pyrimethamine is teratogenic in animals and produces significant abnormalities. It should be used in pregnant women only after thoroughly weighing the risk–benefit for mother and child. However, the use of Fansidar in intermittent preventive treatment programs in Africa suggests that it is generally safe.

CLINICAL USE

Malaria (usually in combination with sulfadoxine, sulfalene [sulfametopyrazine] or dapsone)

Toxoplasmosis (usually in combination with sulfadiazine)

Pneumocystis pneumonia (usually in combination with dapsone)

Preparations and dosage

Proprietary names: Daraprim, Fansidar (with sulfadoxine), Maloprim (with dapsone).

Preparation: Tablets.

Dosage: Depends on indication. For acute malaria treatment 2–3 tablets (25 mg, plus sulfonamide) is the usual dose. Children 9–14 years, two tablets; 4–8 years, one tablet; under 4 years half a tablet. For prophylaxis (no longer recommended), adult dose one tablet per week, children 5–10 years half a tablet per week. For toxoplasmosis the starting dose is 50–75 mg of pyrimethamine daily, with 1–4 g of a sulfonamide.

Widely available as combination, limited availability of pyrimethamine alone.

TRIMETHOPRIM

2,4-Diamino-5-(3,4,5-trimethoxybenzyl)-pyrimidine.
Molecular weight: 290.323.

The most frequently used synthetic diaminopyrimidine. It is poorly soluble in water and has a very bitter taste. It is available in oral formulations or, as trimethoprim lactate, as an injectable preparation.

ANTIMICROBIAL ACTIVITY

It has broad-spectrum activity (Table 17.1). It is active against Gram-positive bacilli and cocci, including *Staphylococcus aureus*, irrespective of β-lactamase production or methicillin resistance. *Enterococcus faecalis* is unusual in being able to utilize preformed folic acid, thymine and thymidine. Folinic acid antagonizes the activity of trimethoprim and sulfamethoxazole in vitro and the efficacy in enterococcal infections is controversial.

Haemophilus spp., including β-lactamase-producing strains and *Haemophilus ducreyi* (minimum inhibitory concentration [MIC] 0.03–0.6 mg/L) are susceptible. Most enterobacteria are susceptible, as are *Bordetella*, *Legionella*, *Pasteurella* and *Vibrio* spp. Pseudomonads, with the exception of *Burkholderia cepacia* (MIC 1–2 mg/L) are resistant. Nocardiae, *Neisseria* spp. and *Brucella* spp. are relatively resistant, owing to their species-specific dihydrofolate reductase sensitivities, although they are susceptible to trimethoprim–sulfonamide combinations.

Most anaerobes are resistant, as are *Chlamydia*, *Coxiella*, *Leptospira*, *Mycoplasma*, *Rickettsia* and *Treponema* spp. *Mycobacterium tuberculosis* is resistant, but *M. marinum* (MIC 16 mg/L) and *M. smegmatis* (MIC 4 mg/L) are susceptible, as are *Listeria* spp.

Table 17.1 Representative minimum inhibitory concentrations of trimethoprim and co-trimoxazole for common pathogenic bacteria^a (mg/L)

Organism	Trimethoprim	Co-trimoxazole ^b
<i>Staphylococcus aureus</i>	0.2–2	0.03–0.06
<i>Streptococcus pneumoniae</i>	0.5–2	0.06–2
<i>Str. pyogenes</i>	0.5–1	0.03–2
<i>Enterococcus faecalis</i>	0.15–0.5	0.015–0.4
<i>Haemophilus influenzae</i>	0.02–1	0.02–16
<i>Neisseria gonorrhoeae</i>	8–R	0.15–4
<i>N. meningitidis</i>	4–32	0.01–2
<i>Escherichia coli</i>	0.05–R	0.25–64
<i>Klebsiella pneumoniae</i>	0.5–8	0.5–4
<i>Pseudomonas aeruginosa</i>	R	R
<i>Bacteroides fragilis</i>	8–16	>4

^aData from various studies; a broad range indicates that resistant strains were included.

^bTested as a 1 + 19 fixed combination of trimethoprim with sulfamethoxazole. R, resistant (MIC >64 mg/L).

Among non-bacterial organisms, *Naegleria* spp., *Plasmodium* spp., *Pn. jirovecii*, and *Tox. gondii* exhibit some sensitivity to trimethoprim, which can often be potentiated by a sulfonamide.

ACQUIRED RESISTANCE

Resistance can be due to a variety of mechanisms. Chromosomal mutations in the structural gene for dihydrofolate reductase or in its promoter can result in modification or over-production of the target enzyme. In addition, alterations in the metabolic pathway, or changes that affect the permeability of the cell or efflux pumps generally, confer moderate degrees of resistance. More than one mechanism can occur in the same cell, leading to higher resistance levels.

Plasmid-encoded resistance is widespread, especially in enteric Gram-negative bacilli including *Escherichia coli*, *Salmonella enterica* serotypes and *Acinetobacter* spp. It usually results in the synthesis of an additional, trimethoprim-resistant dihydrofolate reductase and confers high levels of resistance. Many distinct enzymes are known in Gram-negative bacteria and their prevalence varies with geographic region. Most frequently found are the enzyme types Ib, VIII, V and Ia.

Only a few of these enzymes have so far been described in Gram-positive bacteria, mainly in staphylococci but also in enterococci and *Listeria*. The most prevalent type in staphylococci is the S1 enzyme, which probably originated in *Staph. epidermidis*. Other resistance genes have been detected in *Staph. haemolyticus* and *E. faecalis*. Most cases of trimethoprim resistance in Gram-positive bacteria are due to alterations of chromosomally encoded enzymes. In *Streptococcus pneumoniae* a basic resistance-determining mutation has been identified at amino acid 100 (Ile to Leu). Other mutations may lead to higher levels of resistance. Corresponding mutations have been seen in the related commensal flora of streptococci.

Campylobacter jejuni owes its high level resistance to acquired *dfr1* and *dfr9* genes. In contrast, trimethoprim resistance in *H. influenzae* seems to be frequently caused by mutations in the *dfr* promoter region or the trimethoprim-binding domains of the structural gene. In *Pseudomonas aeruginosa* intrinsic resistance may be mediated by a multidrug efflux system.

Since thymidine can supply the metabolic requirement imposed by trimethoprim blockade, thymine-requiring bacteria are resistant. Such organisms are rarely implicated in infection, either because tissues generally fail to provide the necessary thymidine or because they escape detection owing to their slow growth on conventional media, which are low in thymine and thymidine. Infection with trimethoprim-resistant, thymine-requiring mutants has occasionally been observed in patients treated for prolonged periods with co-trimoxazole. Under certain pathological conditions these mutants seem to rescue enough thymidine from body fluid.

PHARMACOKINETICS

Oral absorption	95–100%
C_{\max} (100 mg orally)	c. 1 mg/L after 1.5–3.5 h
Plasma half-life	8–11 h
Volume of distribution	69–133 L
Plasma protein binding	42–46%

Absorption and distribution

It is rapidly absorbed from the gut after oral administration. Plasma levels increase in a dose-proportional fashion. It is widely distributed in tissues and body fluids, including CSF, in which concentrations around half the simultaneous plasma level are achieved. It passes the placental barrier and is excreted in breast milk.

Metabolism and excretion

About 10–20% is metabolized, primarily in the liver. The remainder is excreted unchanged in the urine. Main metabolites are 1- and 3-oxide, and 3'- and 4'-hydroxy derivatives.

Elimination is mainly through glomerular filtration and tubular secretion. High concentrations are found in urine, reaching 30–160 mg/L within 4 h of a single 100 mg oral dose, and declining to 18–91 mg/L during the following 8–24 h. About 70% is excreted in the first 24 h, but detectable levels are present in the urine for 4–5 days, during which time about 90% of the dose can be recovered. The renal clearance of trimethoprim in normal subjects is 19–148 mL/min, the wide variation largely being accounted for by the influence of pH. Trimethoprim is a weak base, and urinary excretion rises sharply with falling pH as the drug ionizes and non-ionic back diffusion in the tubules decreases. In patients with severely impaired renal function the half-life increases and a dose adjustment is needed.

TOXICITY AND SIDE EFFECTS

Rash, pruritus, nausea, vomiting and glossitis are the most common adverse effects. Hypersensitivity reactions (exfoliative dermatitis, erythema multiforme, Stevens–Johnson syndrome, Lyell's syndrome, anaphylaxis, aseptic meningitis) are rare, as are hematological side effects.

The induction of folate deficiency and consequent interference with hematopoiesis is rarely observed, even after high doses or prolonged administration. Trimethoprim should, however, be given with caution to pregnant women and to patients with possible folate deficiency. Reduced folates can be administered without interfering with the antibacterial activity.

Mutagenicity tests have been uniformly negative. Teratogenic effects have been observed in rats and rabbits only at doses far exceeding those used in humans.

Common clinical doses may inhibit the hepatic metabolism of phenytoin, increasing the half-life by 51% and lowering the metabolic clearance rate by 30%. Trimethoprim has some effect on the metabolism of antiretroviral drugs but these effects do not prevent the use of trimethoprim-sulfa drug combinations for prophylaxis during antiretroviral treatment.

CLINICAL USE

Urinary tract infections
Enteric fever
Prophylaxis and treatment of *Pn. jirovecii* infection

Topical preparations have been used in the treatment of burns and, combined with polymyxin, as eye drops to treat infective conjunctivitis.

Preparations and dosage

Proprietary names: Ipral, Monotrim, Solotrim, Trimpex.

Preparations: Tablets, suspension, injection.

Dosage: Oral: Adults, acute infections, 100 mg every 12 h, 200 mg every 12 or 24 h. Children 6–12 years, 100 mg every 12 h; 6 months to 5 years, 50 mg every 12 h; 6 weeks to 5 months, 25 mg every 12 h (approx. 8 mg/kg day).

Long-term and prophylaxis: Adults, 100 mg at night. Children 6–12 years, 50 mg at night; 6 months to 5 years, 25 mg at night.

Intravenous injection: Adults, 150–250 mg every 12 h. Children <12 years, 6–9 mg/kg per day in 2–3 divided doses.

Widely available.

OTHER DIAMINOPYRIMIDINES AND RELATED STRUCTURES

BRODIMOPRIM

A trimethoprim analog in which bromine replaces methoxy at position 4 of the phenyl substituent. It is used as a single agent for the oral treatment of bacterial infections of the respiratory tract, but has been withdrawn from most markets. Its antibacterial and toxicological properties are similar to those of trimethoprim, but its pharmacokinetic behavior is distinctly different. It has a long elimination half-life of 32–35 h, allowing once-daily dosing.

CYCLOGUANIL

A 2,4-diaminotriazine inhibitor of plasmodial dihydrofolate reductase. It is the major human metabolite of proguanil (see p. 415).

ICLAPRIM

A novel cyclopropyl dimethoxypyrimidine that shows increased hydrophobic interactions with the active site of dihydrofolate reductase including trimethoprim-resistant dihydrofolate reductase enzymes of *Staph. aureus*. It is active against *Staph. aureus* (including methicillin-resistant strains), β-hemolytic streptococci, penicillin-susceptible pneumococci and enterococci, as well as *Listeria*, *Legionella* and *Chlamydia* spp. Activity against *H. influenzae*, *Moraxella catarrhalis* and some Enterobacteriaceae is moderate. The action against Gram-positive pathogens, including methicillin-resistant *Staph. aureus* (MRSA), is rapidly bactericidal and unaffected by human plasma.

Oral bioavailability is approximately 40%. The plasma half-life is around 3 h. A standard dose maintains an inhibitory concentration against a range of pathogens for up to 7 h. It is metabolized by cytochromes and glucuronidation, with elimination of metabolites via the urine (about two-thirds) and feces (about one-third). The drug has a large volume of distribution and can accumulate intracellularly, suggesting that it could be used to treat infections caused by susceptible intracellular pathogens. It accumulates in epithelial lining fluid and alveolar macrophages but not bronchial mucosa. Protein binding is about 92–94%, but this does not impair the effective bactericidal effect.

At the time of writing it is not licensed for use.

- Sader H, Fritsche T, Jones R. Potency and bactericidal activity of iclaprim against recent clinical Gram-positive isolates. *Antimicrob Agents Chemother*. 2009;53:2171–2175.

TETOXOPRIM

A close analog of trimethoprim with a modified 3'-methoxy group. It was formerly used in some countries in combination with sulfadiazine, but has few, if any, advantages over co-trimoxazole.

TRIMETREXATE

A synthetic 2,4-diaminoquinazoline, structurally related to the anticancer drug methotrexate. Formulated as the glucuronate. It is a non-specific inhibitor of dihydrofolate reductase. It is more lipophilic than methotrexate and uses different routes for cellular uptake. It exhibits non-specific activity against dihydrofolate reductases, but is a much more potent inhibitor of the *Pn. jirovecii* and mammalian enzymes than trimethoprim.

After intravenous infusion of 30 mg/m² to adult patients with AIDS, concentrations of trimetrexate were around 2 µmol/L at 4 h. It is usually administered by intravenous infusion, but oral bioavailability is about 44% and concentrations comparable to those achieved by an intravenous infusion of 30 mg/m² were achieved 2 h after an oral dose of 60 mg/m². Elimination half-lives varied from 8.3 to 10 h for the early or late phase of a treatment course and terminal elimination half-lives were as long as 15–16 h. Protein binding is >95%. Excretion is largely by the renal route, with 10–20% of the dose being found in urine after 24–48 h; a substantial proportion of the dose is excreted as metabolites.

It is extremely toxic. The high affinity for the mammalian enzyme has to be circumvented by the concurrent administration of leucovorin (folic acid), which *Pn. jirovecii* cannot take up. Important hematological side effects include neutropenia, thrombocytopenia, bone marrow suppression and anaemia. Other adverse reactions are ulceration of the oral and gastric mucosa, and impairment of hepatic and renal function. Administration of leucovorin should be continued for 72 h after the last dose of trimetrexate in order to minimize these complications.

Trimetrexate glucuronate has been administered (together with leucovorin) in moderate to severe *Pn. jirovecii* pneumonia in patients who are intolerant of or refractory to co-trimoxazole, or those in whom co-trimoxazole is contraindicated. It is no longer available in the UK or the USA.

DIAMINOPYRIMIDINE-SULFONAMIDE COMBINATIONS

Several fixed-ratio combinations have been marketed over the years, but few have survived. By far the most widely used is co-trimoxazole, a 1:5 mixture of trimethoprim and sulfamethoxazole. Also used is co-trimazine, a 1:5 mixture of trimethoprim and sulfadiazine. Among other combinations the 4:5 mixture of trimethoprim and sulfamethoxypyridazine has higher activity than co-trimoxazole against *Pn. jirovecii* and may be better tolerated.

In addition to these preparations, the antiprotozoal agent pyrimethamine is used together with dapsone or sulfonamides (see Ch. 62). Proguanil, the metabolic precursor of cycloguanil, is used in combination with atovaquone (p. 417).

These combinations exhibit the activity of, and synergy between, the two components. They may also mutually cross-suppress the emergence of resistance. As well as lowering the concentration required to inhibit growth, the mixture is often bactericidal when the individual components are bacteriostatic. Occasionally synergy may be so marked that organisms conventionally regarded as resistant to one or the other agent are rendered susceptible to the combination. The pharmacokinetic behavior of the different mixtures is that of the components, there being no significant interactions between them.

Synergy is most impressive against organisms that are only moderately susceptible to one of the components alone. In most cases maximum potentiation occurs when the drugs are present in the ratio of their MICs, but for some organisms, notably neisseriae and *Pn. jirovecii*, proportionally more trimethoprim is required as they are more susceptible to sulfonamide than trimethoprim. In some cases synergy is an in-vitro phenomenon with no clear clinical advantage, but with neisseriae, nocardiae, malaria parasites and *Pn. jirovecii* it clearly translates into clinical benefit.

Rifampicin (rifampin) and polymyxin also act synergistically with both sulfonamides and trimethoprim against Gram-negative bacilli. Formulations of trimethoprim with polymyxin B are widely available for topical use in eye drops and ointment. The triple mixture of sulfamethoxazole, trimethoprim and colistin may be more active than any pair of these agents against some organisms, including multiresistant *Serratia*.

CO-TRIMOXAZOLE

A fixed-ratio (1:5) combination of trimethoprim and sulfamethoxazole.

ANTIMICROBIAL ACTIVITY

The antimicrobial spectrum covers pathogens susceptible to the individual agents and is expanded by synergistic interaction. Some organisms that are refractory to many other antibiotics remain susceptible to co-trimoxazole. These include *Acinetobacter* spp., *Burk. cepacia*, *Stenotrophomonas maltophilia* and some fast-growing mycobacteria such as *M. marinum* and *M. kansasii*.

ACQUIRED RESISTANCE

There are large regional and local differences in rates of resistance. A study of MRSA isolates in 20 European hospitals found 71% to be susceptible to co-trimoxazole; higher rates have been reported in areas in which co-trimoxazole prophylaxis in HIV-positive patients is common. Large regional variations have been found for co-trimoxazole resistance in pneumococci, ranging from 8.6% in the Czech Republic in 1997 to 79.6% in Hong Kong. A large survey in Finland covering 1988–2004 found variance in resistance rates of 14.1–21.4% for *Str. pneumoniae*, 9.7–18.7% for *H. influenzae*, and 3.2–14.5% for *Mor. catarrhalis*, linked to regional variation in the use of co-trimoxazole. A similar study in the USA showed a resistance rate of 23.4%. Resistance is lowest in penicillin-susceptible pneumococci and highest in penicillin-resistant pneumococci. It has been suggested that the use of sulfadoxine–pyrimethamine in malaria and co-trimoxazole for pneumocystis prophylaxis may select for co-trimoxazole-resistant pneumococci. Accordingly, in parts of Africa, resistance rates close to 100% have been reported in pneumococci. The mechanism of resistance in Gram-positive cocci and in *Neisseria* spp. is generally mutational alteration of the chromosomally encoded target proteins.

Among Gram-negative organisms, a large study of blood-stream isolates from the USA, Canada and Latin America in 1998 reported susceptibility to co-trimoxazole in 47.5–77.9% of *Esch. coli* isolates, 81–87.7% of *Klebsiella* spp. and 69.8–83.1% of *Enterobacter* spp. The lower figure is for Latin America and the higher for the USA. A study from 2004 to 2006 found 18.1% resistance in patients with complicated urinary tract infection and 30.6% in patients with acute pyelonephritis. The resistance mechanism among Gram-negative bacilli is generally mediated by plasmid-encoded variants of the respective target genes.

Emergence of resistance in the course of treatment is not usually a problem.

PHARMACOKINETICS

	Trimethoprim	Sulfamethoxazole
Oral absorption	>95%	85%
C_{\max} 160 mg trimethoprim + 800 mg sulfamethoxazole) orally	1–2 mg/L after 1 h	30–40 mg/L after 2 h
Plasma half-life	c. 7 h	c. 9 h
Volume of distribution	100–120 L	12–18 L
Plasma protein binding	c. 44%	c. 70%

Absorption

Trimethoprim is usually absorbed more rapidly than sulfamethoxazole when given as a single oral dose of the combination. After twice-daily administration of one tablet the steady state is reached in adults after 2–3 days; the steady state peak serum concentrations are approximately 50% greater than the peak levels after a single dose. Elderly patients behave as normal adults.

Distribution

Because of unequal distribution there is a wide range of concentration ratios of the two drugs in body tissues and fluids. The concentration of trimethoprim is equal to or greater than the simultaneous plasma level in saliva, intracellular fluid, breast milk, prostatic tissue, sputum, lung tissue, vaginal secretions, bile and urine. Concentrations of sulfamethoxazole in all these tissues and fluids, except urine, are lower than in plasma. Concentrations of trimethoprim in prostatic fluid are twice as high as in the plasma in elderly men. Trimethoprim and sulfamethoxazole both cross the human placenta and penetrate the CSF, where concentrations around half of the simultaneous plasma levels are usually reached.

Metabolism and excretion

Metabolism and excretion of the components of co-trimoxazole are described on pages 253 and 341. The excretion of trimethoprim increases in acid urine, while that of sulfonamide is unchanged; in alkaline urine the excretion of trimethoprim is depressed and that of sulfamethoxazole enhanced. As a result, the ratio of the urinary concentrations of active sulfonamide to trimethoprim is around 1 in acid urine and around 5 in alkaline urine. When the creatinine clearance falls below 30 mL/min the elimination half-lives of both drugs can increase up to 45–60 h and the quantity of the drug cleared by the kidney decreases.

TOXICITY AND SIDE EFFECTS

Side effects are those described for the two components (see pp. 253–254 and 339); most adverse reactions are usually attributed to the sulfonamide. Serious toxicity is uncommon, but the increased risks of co-trimoxazole compared with trimethoprim alone, particularly in the elderly, have been sufficient to limit the licensed indications for the combination. Co-trimoxazole is less well tolerated in HIV-positive patients than in other patient groups. The production of a toxic hydroxylamine metabolite of sulfamethoxazole by the cytochrome P₄₅₀ pathway is suspected to be the underlying reason for this.

Administration of co-trimoxazole (or trimethoprim alone) results in marked depression of fecal enterobacteria with little or no effect on fecal anaerobes. Corresponding clearance of enterobacteria from the perineal area is believed to be an important feature of the value of the drug in the control of recurrent urinary tract infection (see Ch. 54). While intrinsically resistant species, including *Ps. aeruginosa*, have naturally persisted, major overgrowth has not been a troublesome feature.

In the rat, doses greater than 200 mg/kg per day are teratogenic, but complete protection is afforded by folinic acid or dietary folate supplements. No abnormalities were produced in the rabbit or infants born to treated mothers, but use of the drug in pregnancy is not recommended. Although one extensive case control study in humans found an increased risk for congenital abnormalities during co-trimoxazole treatment, most reports state the risks as small.

Hyperkalemia is a well-described complication of therapy with high-dose trimethoprim (20 mg/kg per day) in patients with AIDS and may also develop in about 20% of patients under standard therapy with co-trimoxazole, and in up to 85% of patients with renal insufficiency. The reason is probably blocking of sodium channels, thus disturbing the sodium–potassium balance. The effect is

reversible by supplementing sodium intake and restricting potassium.

CLINICAL USE

Treatment and prophylaxis of *Pn. jirovecii* pneumonia

Toxoplasmosis

Urinary tract infections

Acute otitis media

Acne

Acute exacerbations of chronic bronchitis

Nocardiosis, listeriosis, brucellosis, melioidosis

Shigellosis and other enteric infections caused by pathogens susceptible to co-trimoxazole

Stenotrophomonas maltophilia infections

Chancroid, donovanosis (granuloma inguinale)

Whipple's disease, Wegener's granulomatosis

The only first-line indication in the UK is the treatment and prophylaxis of *Pn. jirovecii* pneumonitis. It can also be used in other conditions in which there is microbiological evidence of sensitivity to the combination and good reason (including resistance to other front-line drugs) to prefer the combination to trimethoprim alone. Leucovorin is sometimes used to reduce the incidence of neutropenia; this may, however, interfere with the efficacy of co-trimoxazole against *Pn. jirovecii*. Co-trimoxazole has activity against some protozoa and is used for treatment of human *Isospora belli* and *Cyclospora cayetanensis* infections.

Preparations and dosage

Proprietary names: Bactrim, Septrin, Cotrim and others.

Preparations: Tablets (400 mg sulfamethoxazole plus 80 mg trimethoprim, or double-strength tablet: 800 mg sulfamethoxazole plus 160 mg trimethoprim), injections, pediatric suspension.

Dosage: Adults, oral, 960 mg every 12 h, increased to 1.44 g every 12 h in severe infections. Children >12 years, as for adults; 6 weeks to 5 months, 120 mg every 12 h; 6 months to 5 years, 240 mg every 12 h; 6–12 years, 480 mg every 12 h.

High dose therapy for *Pn. jirovecii* infections: 120 mg/kg per day, in 2–4 divided doses, for 14 days.

Pn. jirovecii prophylaxis: Many recommended regimens; consult local formularies.

Widely available.

OTHER DIAMINOPYRIMIDINE-SULFONAMIDE COMBINATIONS

CO-TRIMAZINE

A fixed-ratio (1:5) combination of trimethoprim and sulfadiazine. Its antimicrobial activity is that of its components and synergistic interaction between them. Following a dose of 1 g, mean peak serum concentrations of sulfadiazine are around 25 mg/L, with a plasma elimination half-life of 9.3 h. Untoward effects resemble those of co-trimoxazole and its clinical uses are similar. It is no longer much used except in veterinary medicine.

CHAPTER

18 Fosfomycin and fosmidomycin

David Greenwood

Fosfomycin (originally called phosphonomycin) was discovered in Spain in 1969 and jointly developed in Spain and the USA. Fosmidomycin was synthesized in Japan a decade later. They are phosphonic acid derivatives, with unique structures that set them apart from other antimicrobial agents and, probably, from each other.

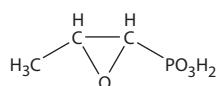

Uptake of these compounds in many Gram-negative bacteria, notably *Escherichia coli*, is induced by glucose 6-phosphate and this substance greatly potentiates the activity in vitro. Glucose 6-phosphate is present in places where glycolysis takes place, but the tissue content generally is low and located intracellularly. It is not present in the serum or cerebrospinal fluid (CSF) and is probably suboptimal at sites of infection, since the efficacy of the agents in experimental infection is increased by co-administration of glucose 6-phosphate. Nonetheless, the correlation between their in-vivo and in-vitro activity is better when tested in the presence of the inducer.

Synergy with aminoglycosides and with other cell-wall active agents, notably β -lactam antibiotics, has been demonstrated against some organisms.

Resistant mutants, typically exhibiting loss of the hexose phosphate transport system induced by glucose 6-phosphate, arise in vitro with relatively high frequency (10^{-4} – 10^{-5}). Resistance that emerges in vivo is generally associated with deletion of the α -glycerophosphate transport mechanism. Plasmid-encoded resistance to fosfomycin also occurs in some species and such strains may remain susceptible to fosmidomycin.

FOSFOMYCIN

cis-1,2-Epoxypropylphosphonic acid. Molecular weight: 138.

A fermentation product of *Streptomyces fradiae*, *Streptomyces viridochromogenes* and *Streptomyces wedmorensis*. Commercially produced synthetically. It is stable for several years in powder form and for 48 h in aqueous solution. Fosfomycin tromethamine (*syn*: trometamol; tris(hydroxymethyl)aminomethane) and

the much less soluble calcium salt are used in oral preparations; the very soluble sodium and disodium salts are used for parenteral administration.

ANTIMICROBIAL ACTIVITY

Fosfomycin is moderately active against a wide range of pathogens, but its activity in vitro is reduced at an alkaline pH and in the presence of glucose, phosphates or sodium chloride. Consequently, different results may be obtained depending on the medium used: inhibitory concentrations observed in simple nutrient broth or agar are usually lower than those in Mueller-Hinton medium. Addition of glucose 6-phosphate (25 mg/L) to the medium enhances the activity of the drug against most enterobacteria. Its activity against common pathogens (in the presence of glucose-6-phosphate) is shown in Table 18.1. It is, in general, more active against Gram-negative bacilli than Gram-positive cocci, although most strains of *Staphylococcus aureus* (including methicillin-resistant strains) are susceptible and *Pseudomonas aeruginosa* is usually resistant. Synergy with a variety of β -lactam antibiotics, aminoglycosides and other agents has been exhibited against some enterococci, methicillin-resistant *Staph. aureus* and enterobacteria. The tromethamine salt exhibits half the activity of other derivatives in tests in vitro since the tromethamine component has a molecular weight similar to that of fosfomycin itself.

It has been suggested that fosfomycin has immunomodulatory activity that may be of value in respiratory syncytial virus infection by suppressing cytokines involved in the pathogenesis of the disease.

ACQUIRED RESISTANCE

Bacterial populations contain variants that are resistant to the drug, but these are not highly prevalent even in those countries in which it has been widely used. There is no cross-resistance

Table 18.1 Activity of fosfomycin and fosmidomycin, in the presence of glucose 6-phosphate against common pathogenic bacteria: MIC (mg/L)

	Fosfomycin	Fosmidomycin
<i>Staphylococcus aureus</i>	2–32	R
<i>Streptococcus pyogenes</i>	8–64	R
<i>Str. pneumoniae</i>	8–64	R
<i>Enterococcus faecalis</i>	64	R
<i>Haemophilus influenzae</i>	4	0.5–R
<i>Neisseria</i> spp.	32–64	R
<i>Escherichia coli</i>	1–4	1
<i>Klebsiella pneumoniae</i>	2–64	0.5
<i>Enterobacter</i> spp.	2–R	0.1
<i>Pseudomonas aeruginosa</i>	4–R	2–R
<i>Bacteroides fragilis</i>	R	R

R, resistant (MIC >64 mg/L).

with other antibiotics, and it is active against many strains resistant to other agents. A type of enzyme-mediated resistance in which the epoxide ring is opened in the presence of glutathione is transferred by plasmids and may be associated with multidrug resistance.

PHARMACOKINETICS

Oral absorption	
calcium salt	c. 30–40%
tromethamine salt	c. 60%
C_{max} , calcium salt 1 g oral	7 mg/L after 4 h
tromethamine salt 50 mg/kg oral	32 mg/L after 2 h
sodium salt 1 g intramuscular	28 mg/L after 1 h
sodium salt 20 mg/kg intravenous	130 mg/L end infusion
Plasma half-life	2–5 h
Volume of distribution	20–22 L
Plasma protein binding	<3%

Absorption

Absorption of the tromethamine salt is dose dependent, the fraction recovered from the urine falling from about one-half after 2 g to one-fifth after 5 g. The effect of food is variable, but generally depresses absorption. The sodium salt causes gastric irritation and is used only for parenteral administration. There is some accumulation after repeated doses given every 6 h. Constant intravenous infusion of 500 mg/h produced a steady-state blood level of about 60 mg/L.

Distribution

Fosfomycin diffuses freely into interstitial fluid and tissues. Diffusion into CSF is modest, but improves with meningeal inflammation. In patients with acute meningitis, CSF levels were 10.9 mg/L when the serum level was 65.2 mg/L. In patients with pleural effusions given 30 mg/kg as an intravenous bolus, average peak concentrations in pleural fluid around 43 mg/L were found at 3.7 h; clearance was slower than from plasma. Relatively high concentrations have been found in fetal blood (17.6 mg/L) and amniotic fluid (45 mg/L). Concentrations in breast milk are about 10% of the mother's plasma levels.

Metabolism and excretion

Fosfomycin is not metabolized in human beings. The drug is excreted into urine by glomerular filtration. About 80% of an intravenous dose is recoverable in urine in the first 24 h, achieving a peak concentration in excess of 1000 mg/L. Less than 20% of an oral dose of the calcium salt finds its way into urine, but a single 50 mg/kg dose of the tromethamine salt provides a urinary concentration that remains above 1000 mg/L for 12 h. Renal impairment increases the half-life proportional to the fall in creatinine clearance, reaching around 50 h as the creatinine clearance level falls below 10 mL/min. Most of the drug is removed by hemodialysis. Fosfomycin is excreted into bile, but is returned to the circulation by enterohepatic recycling.

TOXICITY AND SIDE EFFECTS

Adverse reactions have been observed in about 10–17% of patients, mostly slight gastrointestinal disorders. There may be a transient rise in transaminase levels.

Sodium salt

Respiratory, gastrointestinal, generalized and genitourinary infections

Tromethamine salt

Single-dose treatment of cystitis

Prophylaxis in transurethral surgery

Preparations and dosage

Fosfomycin trometamol

Proprietary names: Monuril, Monurol.

Preparations: Granules in 3 g sachets.

Dosage: Urinary tract infection: Adults, oral, 3 g as a single dose. Surgical prophylaxis: 3 g preoperatively; 3 g after 24 h. Widely available. Not available in the UK.

Fosfomycin sodium

Limited availability; not available in the UK or the USA.

Stein GE. Comparison of single-dose fosfomycin and a 7-day course of nitrofurantoin in female patients with uncomplicated urinary tract infection. *Clin Ther*. 1999;21:1864–1872.

FOSMIDOMYCIN

Sodium hydrogen-3 (*N*-hydroxyformamido) propyl phosphate. Molecular weight (sodium salt): 191.

ANTIMICROBIAL ACTIVITY

Fosmidomycin is active against a broad range of enterobacteria, but not against Gram-positive organisms or anaerobes (Table 18.1). Activity is affected by medium composition and enhanced by glucose 6-phosphate. It is slowly bactericidal at concentrations close to the minimum inhibitory concentration and shows synergy with aminoglycosides and β -lactam antibiotics. Bacteria resistant to fosfomycin are usually, but not always, cross-resistant to fosmidomycin.

Interest in fosmidomycin has been revived by demonstration of activity against malaria parasites.

PHARMACOKINETICS

Oral absorption	c. 25%
C_{max} 500 mg oral 7.5 mg/kg intramuscular 30 mg/kg intravenous	2.3 mg/L after 2.4 h 11 mg/L after 1 h 160 mg/L end infusion
Plasma half-life	1.6–1.8 h
Plasma protein binding	<5%

It is not metabolized and there is no evidence of accumulation after multiple dosing. Elimination is almost entirely renal: mean urinary recoveries in the first 24 h after oral, intramuscular and intravenous administration are around 25%, 65% and 85%, respectively.

TOXICITY, SIDE EFFECTS AND CLINICAL USE

Fosmidomycin appears to be well tolerated. Uses are similar to those of fosfomycin against Gram-negative organisms. Fosmidomycin is being investigated as a potential antimalarial agent in combination with clindamycin, with which it appears to interact synergically, or artemisinin.

CHAPTER

19 Fusidanes

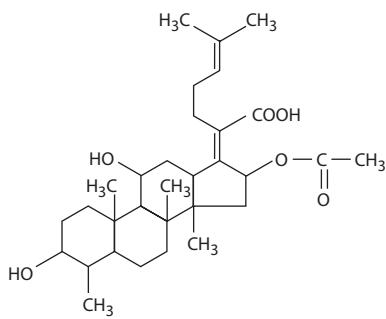

David Greenwood

The fusidanes are antibiotics with a steroid-like structure, but the stereochemistry differs from that of metabolically active steroids and they do not exert any hormonal or anti-inflammatory activity. The group includes helvolic acid, cephalosporin P₁ and fusidic acid. Helvolic acid, a product of *Aspergillus fumigatus*, attracted some early attention because of its weak antimycobacterial activity; cephalosporin P₁ was a component of the antibiotic complex of the mold that also yielded the first true cephalosporin.

Fusidic acid is much the most active member of the group and is the only one commercially available. It was discovered in Denmark in 1960 as a product of *Fusidium coccineum*, a fungus originally isolated in Japan from monkey dung. The principal interest of fusidic acid lies in its antistaphylococcal activity.

FUSIDIC ACID

Molecular weight (sodium salt): 538.7.

Supplied as the sodium salt, which is readily soluble in water, or suspension of the acid. Intravenous preparations (sodium or diethanolamine salt) are dissolved in phosphate-citrate buffer. Several formulations are available for topical application. The dry powder is stable for 3 years.

ANTIMICROBIAL ACTIVITY

Fusidic acid is active against most Gram-positive bacteria, but all aerobic Gram-negative bacilli are resistant (Table 19.1). Streptococci and pneumococci are much less susceptible than staphylococci. *Bacteroides fragilis*, *Nocardia asteroides* (minimum inhibitory concentration [MIC] 0.5–4 mg/L), *Corynebacterium diphtheriae* (MIC <0.01 mg/L) and *Clostridium* spp. (MIC 0.01–0.5 mg/L) are susceptible. It is moderately active against many mycobacteria, including *Mycobacterium tuberculosis*, *M. bovis*, *M. malmoense* and *M. leprae*, but other species are resistant. Fusidic acid shows some activity against certain protozoa, including *Giardia lamblia* and *Plasmodium falciparum*.

In 50% serum, the MIC may double and it is slightly more effective at pH 6–7 than at pH 8. It is bactericidal in concentrations close to the MIC.

ACQUIRED RESISTANCE

Large inocula of *Staphylococcus aureus* contain a small number of chromosomal mutants, designated *fusA*, which emerge rapidly in vitro and sometimes during therapy. Other bacterial properties, such as growth rate and coagulase production remain unimpaired. Plasmid-mediated resistance caused by acquisition of *fusB*, *fusC* and *fusD* determinants also occur in *Staph. aureus* and other staphylococci and may, indeed, be more common in clinical isolates. The end result in all cases seems to be the prevention of binding of the drug at the target site, the EFG-ribosome complex (see p. 16). Genes for β-lactamase production and fusidic acid resistance are commonly carried on the same plasmid.

Despite the ease of emergence of resistance in vitro, resistance remained uncommon in clinical isolates (1–2%) for many years, but has risen significantly. Topical applications are liable to facilitate the emergence of resistant mutants and

Table 19.1 Activity of sodium fusidate against some common pathogenic bacteria

Species	MIC (mg/L)
<i>Staphylococcus aureus</i>	0.03–0.1
<i>Streptococcus pyogenes</i>	4–16
<i>Str. pneumoniae</i>	2–16
<i>Enterococcus faecalis</i>	1–4
<i>Neisseria</i> spp.	0.03–1
<i>Escherichia coli</i>	R
<i>Klebsiella pneumoniae</i>	R
<i>Pseudomonas aeruginosa</i>	R
<i>Bacteroides fragilis</i>	2
<i>Mycobacterium tuberculosis</i>	8–32

R, resistant (MIC >64 mg/L).

there is evidence that increased use has contributed to the pool of resistant strains in circulation.

PHARMACOKINETICS

Oral absorption:sodium salt	>90%
suspension	70%
C_{\max} 500 mg oral	30 mg/L after 2–3 h
500 mg i.v. infusion	50 mg/L end infusion
Plasma half-life	c. 9 h
Volume of distribution	c. 12 L
Plasma protein binding	97%

Absorption

The suspension is less well absorbed than the sodium salt of the tablet formulation. In children absorption is more rapid than in adults. Milk appears to delay absorption, peak concentrations not being reached for 4–8 h. Because of slow elimination, accumulation of the drug occurs on repeated administration of both oral and intravenous formulations.

Distribution

It is well distributed in the tissues and most organs of the body. It does not reach the cerebrospinal fluid, but penetrates into cerebral abscesses. Inhibitory levels are obtained in muscle, kidney, lungs and pleural exudate. Bone concentrations in samples taken at operation from patients with chronic osteomyelitis treated for at least 5 days were 1.7–14.9 mg/g in patients receiving 1.5 g per day and 3.4–14.8 mg/g in patients receiving 3 g per day.

Levels in excess of 7 mg/L have been found in aspirated synovial fluid from patients with osteo- or rheumatoid arthritis

after 3–7 days' treatment with 0.75 g or 1.5 g per day. The drug has been detected in brain, milk and placenta, which it crosses to reach the fetus. In patients treated with 1.5 g per day, levels of 0.08–0.84 mg/L were found in the aqueous humor after 1 day and 1.2–2.0 mg/L after 3 days' treatment. In the post-distribution phase, about half of the drug is in the peripheral compartment, in keeping with the known ability of the drug to penetrate into tissues including bone.

Metabolism and excretion

It is extensively metabolized in the liver and is excreted in the bile in the form of glucuronides and various other metabolites. Only about 2% of the administered dose can be recovered in active form in the feces. Less than 1% of active drug is excreted in the urine. Very little is removed by dialysis.

TOXICITY AND SIDE EFFECTS

Mild gastrointestinal disturbance and occasional rashes have been reported. Some patients develop abnormalities in liver function tests and jaundice which resolve on withdrawal of therapy. Jaundice is less common with oral than with parenteral therapy. The drug is not recommended in hepatic insufficiency. Rapid infusion of diethanolamine fusidate may lead to venospasm or thrombosis, and occasionally to hypocalcemia, possibly as an effect of the buffer.

CLINICAL USE

Systemic formulations

Severe staphylococcal infections, particularly bone and joint infections (in combination with other antistaphylococcal agents)

Prosthetic valve endocarditis due to 'diphtheroids' (in combination with erythromycin)

Topical formulations

Skin infections, principally those involving staphylococci, but including erythrasma

Acute staphylococcal conjunctivitis

Preparations and dosage

Proprietary name: Fucidin.

Preparations: Tablets, suspension, injection, topical preparations.

Dosage: Adults, oral (as sodium fusidate): 500 mg every 8 h, doubled for severe infections. Children (as fusidic acid) ≤1 year, 50 mg/kg per day in three divided doses; 1–5 years, 250 mg every 8 h; 5–12 years, 500 mg every 8 h.

Intravenous infusion (as sodium fusidate): adults >50 kg, 500 mg every 8 h; adults <50 kg and children, 6–7 mg/kg every 8 h.

Widely available; not available in the USA.

CHAPTER

20 Glycopeptides

Neil Woodford

The natural glycopeptides are a group of chemically complex anti-bacterial compounds obtained originally from various species of soil actinomycetes. They all contain a core heptapeptide to which are attached sugar moieties, some of which are unique. Vancomycin and teicoplanin, the only representatives presently in clinical use, are used for the treatment of serious infections caused by Gram-positive bacteria, particularly *Staphylococcus aureus*. Three semisynthetic glycopeptides – dalbavancin, oritavancin and telavancin – are presently undergoing clinical trial (see p. 271).

Among other glycopeptides, avoparcin and actaplanin have been used as animal feed additives, while actinoidin and ristocetin have been used as investigational aids in the diagnosis of von Willebrand's disease and platelet aggregation dysfunction.

A naturally occurring lipoglycodepsipeptide, ramoplanin, shares many of the microbiological properties of vancomycin and teicoplanin. It is, however, chemically distinct and has a different mode of action. It is too toxic for systemic use, but remains under investigation as a topical agent, as a component of oral gut decontamination regimens, and for the oral therapy of antibiotic-associated colitis.

ANTIMICROBIAL ACTIVITY

The activity of glycopeptides is essentially restricted to Gram-positive organisms, notably staphylococci and streptococci of all kinds. However, *Lactobacillus*, *Leuconostoc*, *Pediococcus* and *Erysipelothrix* spp. are inherently resistant. Their large molecular size prevents them from penetrating the Gram-negative outer membrane and, with rare exceptions (e.g. some *Prevotella* and *Porphyromonas* spp.), they are inactive against Gram-negative bacteria.

ACQUIRED RESISTANCE

ENTEROCOCCI

Seven distinct resistance genotypes are recognized, of which the first two are most prevalent, especially in *Enterococcus faecium* (see also p. 30).

- VanA resistance is associated with the substitution of D-alanyl-D-alanine by D-alanyl-D-lactate at the carboxy terminus of the pentapeptide side chain of N-acetylmuramic acid (see p. 11; Figure 2.2), with a consequent loss of binding affinity for both vancomycin and teicoplanin. The modification is brought about by the functioning of an inducible cluster of genes that are on a transposable element and may be present on a transferable plasmid.
- VanB resistance also results from a D-lac substitution that is inducible by vancomycin but not by teicoplanin, to which susceptibility is retained. It is usually chromosomally mediated and transferability has been shown in some cases.
- VanC resistance is an intrinsic characteristic of *Ent. gallinarum* and *Ent. casseliflavus*, which are infrequently encountered as pathogens. It is non-transferable, chromosomally mediated, expressed constitutively and is conferred by substitution of D-alanyl-D-alanine by D-alanyl-D-serine. It is characterized by low-level resistance to vancomycin alone.
- VanD resistance has been found in a few strains of *E. faecium*. It results from a D-lac substitution, is usually expressed constitutively, and confers non-transferable resistance to vancomycin and reduced susceptibility to teicoplanin.
- VanE resistance has been described in a few strains of *E. faecalis* that display reduced susceptibility to vancomycin alone and harbor a D-ser substitution. Resistance may be expressed inducibly or constitutively.
- VanG and VanL resistance have also been found in a few strains of *E. faecalis*. Isolates have low-level resistance to vancomycin, but not to teicoplanin, owing to a D-ser substitution. The inducible resistance genes are located on the chromosome, but may be transferable from some strains.

None of the newer glycopeptides has increased binding to peptidoglycan precursors with D-lac or D-ser substitutions.

STAPHYLOCOCCI

Low-level resistance is described in clinical isolates and laboratory mutants of staphylococci, usually in *Staph. epidermidis* and *Staph. haemolyticus*, less often in *Staph. aureus*. Most glycopeptide-non-susceptible staphylococci show resistance to teicoplanin, but retain susceptibility to vancomycin, at least in vitro. This phenotype has not been reported in enterococci. Isolates of *Staph. aureus* with intermediate vancomycin resistance and reduced teicoplanin susceptibility are reported; in some such strains a raised minimum inhibitory concentration (MIC) is displayed by only a small subpopulation of cells.

The various resistance phenotypes each result from chromosomal mutation(s), rather than horizontal acquisition of resistance genes, and have been variously attributed to alterations in cell wall structure, overproduction of the cell-wall peptidoglycan and binding to cell-wall sites other than the primary target. However, the genetic basis has not yet been precisely defined and it seems probable that there are several genetic paths to low-level glycopeptide resistance.

There are several substantiated reports from the USA of high-level resistance to glycopeptides in *Staph. aureus* mediated by horizontal transfer of the enterococcal *vanA* gene cluster, but these isolates remain rare and the resistance often unstable.

DETECTION OF GLYCOPEPTIDE RESISTANCE

The routine detection of glycopeptide resistance may present problems, especially with strains exhibiting low-level resistance, such as glycopeptide-intermediate *Staph. aureus*. Disk tests are notoriously unreliable for this purpose and problems may occur with automated systems. In general, quantitative methods are recommended for accurate determination of MICs whenever possible. Population analysis may aid confirmation of strains showing intermediate resistance.

TEICOPLANIN

Molecular weight: (A₂-1): 1877.7; (A₂-2 and A₂-3): 1879.7; (A₂-4 and A₂-5): 1893.7.

A complex of several molecules of similar antibiotic potency produced by *Actinoplanes teichomyceticus*. It is formulated as the sodium salt for intramuscular or intravenous administration.

ANTIMICROBIAL ACTIVITY

In general, teicoplanin is 2–4 times more active than vancomycin against susceptible strains (Table 20.1). However, against some coagulase-negative staphylococci, especially *Staph. haemolyticus*, it may be less active (MIC 16–64 mg/L compared with ≤4 mg vancomycin/L). For these strains, the MIC of teicoplanin, but not vancomycin, is greatly affected by the composition of the medium, including the presence of lysed horse blood, and the bacterial inoculum density. Isolates inhibited by ≤4 mg/L are usually considered susceptible.

ACQUIRED RESISTANCE

Vancomycin-resistant enterococci of the VanA type are resistant, as are *Staph. aureus* strains with intermediate or full resistance to vancomycin. Strains of other resistance genotypes are usually susceptible, although resistance may develop in VanB enterococci by mutations that cause the resistance genes to be expressed constitutively. Coagulase-negative

Table 20.1 Comparative in vitro activity of glycopeptides against some common pathogenic bacteria: MIC range (mg/L)

Species	Vancomycin	Teicoplanin	Dalbavancin	Oritavancin	Telavancin
<i>Staphylococcus aureus</i>	1–2	0.12–1	≤0.008–2	≤0.008–4	≤0.015–2
<i>Streptococcus pyogenes</i>	0.12–0.25	0.03–0.12	≤0.008–0.06	0.015–0.5	0.03–0.12
<i>Str. pneumoniae</i>	0.12–0.25	0.03–0.12	≤0.008–0.25	≤0.008–0.5	≤0.008–0.06
<i>Enterococcus faecalis</i> and <i>E. faecium</i>	1–4	0.12–0.5	≤0.015–4	≤0.008–0.5	≤0.015–4
<i>Haemophilus influenzae</i>	16–R	R	R	R	R
<i>Neisseria</i> spp.	8–32	No data	No data	No data	No data
<i>Escherichia coli</i>	R	R	R	R	R
<i>Klebsiella pneumoniae</i>	R	R	R	R	R
<i>Pseudomonas aeruginosa</i>	R	R	R	R	R
<i>Clostridium difficile</i>	0.06–1	0.03–0.25	0.125–0.5	0.06–1	0.125–0.5
<i>Bacteroides fragilis</i>	R	R	R	R	R

R, resistant (MIC >32 mg/L).

staphylococci exhibiting low-level glycopeptide resistance are usually more resistant to teicoplanin than vancomycin even when they emerge during vancomycin therapy.

PHARMACOKINETICS

Oral absorption	Very low
C_{\max} 400 mg intravenous bolus 6 mg/kg intramuscular	25–40 mg/L after 1 h c. 10 mg/L after 2 h
Plasma half-life (terminal)	90 h (mean)
Volume of distribution (steady state)	0.9–1.6 L/kg
Plasma protein binding	>90%

Absorption

It is very poorly absorbed from the gastrointestinal tract. Bioavailability after intramuscular administration is about 90%. The area under the concentration–time curve (AUC) is similar after intravenous or intramuscular administration. In children, a dose of 6 mg/kg per day produced a mean trough concentration of 4.6 mg/L and a peak concentration of 19.1 mg/L. After a dose of 10 mg/kg the corresponding concentrations were 15.8 and 36.9 mg/L, respectively.

Distribution

Teicoplanin is widely distributed and penetrates readily into tissues, peritoneal fluid, synovial fluid and bone. It crosses the placenta, but not the blood–brain barrier.

Metabolism and excretion

No metabolic products have been identified. The drug is removed from the body almost entirely by glomerular filtration. The terminal half-life ranges from 33 to 190 h or longer, depending upon the pharmacokinetic model used for analysis and the last sampling time. The half-life may be shorter in children and is substantially altered in patients with renal failure (and the elderly), so that adjustment of dosage may be necessary. It is not removed during hemodialysis or hemofiltration and clearance by peritoneal dialysis is less than 20% of total body clearance. In all three procedures, management of plasma concentration is best achieved by giving a loading dose followed by monitoring at appropriate intervals.

TOXICITY AND SIDE EFFECTS

Unlike vancomycin, teicoplanin does not cause significant histamine release and the ‘red-man’ syndrome is very seldom seen. Nephrotoxicity is uncommon and, when it does occur, is not related to dose, plasma concentration or concomitant therapy with an aminoglycoside. Ototoxicity has been reported rarely and is not dose related.

Other, reversible, adverse effects include allergy, local intolerance, fever and altered liver function. Thrombocytopenia has been seen in patients with raised trough levels (about 60 mg/L). None of these effects occurs with a frequency greater than 3%. Teicoplanin should be used with caution in patients with a history of hypersensitivity to vancomycin.

Safety in pregnancy has not been established. Accidental overdosing in two children, in whom plasma levels in excess of 300 mg/L were found, was not associated with symptoms or laboratory abnormalities.

CLINICAL USE

Infections caused by *Staph. aureus* and other Gram-positive pathogens (especially those caused by methicillin-resistant staphylococci and in patients hypersensitive to β -lactam antibiotics)

Treatment of infections caused by vancomycin-resistant enterococci (other than VanA strains)

Treatment and prophylaxis of endocarditis caused by Gram-positive species (often in combination with an aminoglycoside)

Peritonitis associated with continuous ambulatory peritoneal dialysis (intraperitoneal)

Preparations and dosage

Proprietary name: Targocid.

Preparation: Injection.

Dosage: Adults, i.v., 400 mg initial loading dose on day 1 then 200 mg per day; severe infections, 400 mg loading dose every 12 h for the first three doses, then 400 mg per day. Children ≥ 2 months, 10 mg/kg every 12 h for three doses then 6 mg/kg per day; severe infections, 10 mg/kg every 12 h for three doses, then 10 mg/kg per day. Neonates, 16 mg/kg initial loading dose on day 1, subsequently 8 mg/kg per day.

Widely available; not available in the USA.

VANCOMYCIN

Molecular weight (free base): 1449; (hydrochloride): 1485.7.

A tricyclic glycopeptide isolated from the fermentation products of the actinomycete, *Amycolatopsis orientalis* (formerly *Streptomyces orientalis*). It is formulated as the water-soluble hydrochloride for intravenous infusion or oral administration.

ANTIMICROBIAL ACTIVITY

The antibacterial activity is essentially restricted to Gram-positive species (Table 20.1), including methicillin-resistant strains of staphylococci; viridans streptococci, *Listeria monocytogenes*, *Propionibacterium acnes* and corynebacteria are all susceptible (MIC 0.25–2 mg/L), as are Gram-positive anaerobes, including *Clostridium difficile* (MIC 0.06–1 mg/L) and *C. perfringens* (MIC 0.12–0.5 mg/L). Mycobacteria are resistant.

Vancomycin is slowly bactericidal for most susceptible bacteria. However, against isolates of *Enterococcus* spp., some viridans streptococci and *Staph. haemolyticus* it is effectively bacteriostatic. Gentamicin enhances the bactericidal effect, provided the isolate is susceptible (staphylococci) or lacks high-level resistance (enterococci and streptococci). There is growing evidence that vancomycin is less effective against methicillin-resistant *Staph. aureus* (MRSA) infections caused by strains with MICs at the high end of the susceptible range.

ACQUIRED RESISTANCE

Resistance is uncommon, except in enterococci. In this genus, acquired resistance is far more common in *E. faecium* than in *E. faecalis* or other species, and has emerged in response to widespread use of vancomycin in hospitals. The use of avoparcin (a related glycopeptide) as a growth promoter in animal husbandry may also have played a part in encouraging resistance in enterococci.

Low-level resistance (MIC 8–32 mg/L) has been described in coagulase-negative staphylococci, usually *Staph. epidermidis* or *Staph. haemolyticus*, sometimes emerging during protracted treatment. Strains of *Staph. aureus* exhibiting intermediate vancomycin susceptibility (MIC 8–16 mg/L) have been found, but the prevalence of these strains, many of which exhibit heteroresistance, appears to be very low, though they may be under-reported owing to the difficulties in detecting them in vitro. Rare strains of *Staph. aureus* highly resistant to glycopeptides (MIC: 32–128 mg vancomycin/L; 8–32 mg teicoplanin/L) have been reported from the USA, India and Iran.

PHARMACOKINETICS

Oral absorption	Very low
C_{max} 500 mg slow intravenous infusion (>1 h)	10–25 mg/L 1 h after end infusion
1 g slow intravenous infusion (>1 h)	20–50 mg/L 1 h after end infusion
Plasma half-life	5–11 h
Volume of distribution	0.6 L/kg
Plasma protein binding	c. 55%

Rapid infusion (<1 h) or bolus administration is dangerous. The intramuscular route of administration causes pain and necrosis and is not used. Slow intravenous infusion over at least 100 min is recommended. Dosage should be adjusted to give a peak concentration of 25–40 mg/L and a trough of 5–10 mg/L. In some centers, continuous infusion is used and may be pharmacodynamically optimal.

Absorption

It is very poorly absorbed from the gastrointestinal tract and large concentrations of unaltered drug are found in the feces after oral administration.

Distribution

After slow intravenous infusion vancomycin is distributed widely, reaching therapeutic concentrations in most body compartments. It does not penetrate appreciably into the cerebrospinal fluid of subjects with normal meninges, but levels may approach therapeutic concentrations in patients with meningitis; however, intrathecal administration may be necessary to achieve adequate levels.

Metabolism and excretion

Vancomycin is not metabolized and 90% of an intravenous dose is eliminated in the urine, almost exclusively by glomerular filtration. The elimination half-life in patients with normal renal function is usually 6–8 h, but is altered substantially in patients with impaired renal function, necessitating dosage modification. This can be predicted to some extent by creatinine clearance values but adequately optimized only by monitoring plasma concentrations.

Renal clearance may be more rapid in intravenous drug abusers and children (with the exception of neonates in whom the half-life may be prolonged) and plasma monitoring is indicated in such patients, particularly those receiving therapy for endocarditis or other life-threatening sepsis. A prolonged half-life has been observed in some patients with hepatic failure. Plasma monitoring is also indicated in these patients.

It is not removed efficiently by hemodialysis or hemofiltration. Patients undergoing these procedures should be given an appropriate loading dose and the frequency and size of further doses determined by monitoring plasma concentrations. Vancomycin crosses the peritoneal membrane in both directions with a transfer half-life of about 3 h, resulting in about 75% equilibration over a 6 h dialysis period. Because of the large dilution effect, many exchanges may be required before the plasma concentration reaches that of the dialysate, and to achieve rapid equilibration a loading dose of about three times the maintenance dose has been suggested. Thus, in patients on continuous ambulatory peritoneal dialysis, incorporation of 50 mg vancomycin/L of dialysate eventually produces plasma concentrations of 5–20 mg/L.

Alternatively, a loading dose of 0.5 g vancomycin, administered by intravenous infusion, followed by 7.5 mg/L dialysate with exchange every 4–6 h, produces plasma concentrations of 6.5–37 mg/L.

INTERACTIONS

Gentamicin, also furosemide (frusemide) or other loop diuretics, may increase the potential for nephrotoxicity and ototoxicity. Owing to the acidic nature of solutions, vancomycin is incompatible in vitro with various agents, including β -lactam antibiotics, aminophylline and heparin.

TOXICITY AND SIDE EFFECTS

Rapid administration (<60 min) may result in release of histamine from basophils and mast cells, leading to the so-called ‘red-man’ or ‘red-neck’ syndrome, characterized by one or more of pruritus, erythema, flushing of the upper torso, anaphylactoid reaction, angioedema and, rarely, cardiovascular depression and collapse.

Vancomycin is potentially nephrotoxic and ototoxic, although the highly purified drug preparations in current use are safer than early preparations. Increased risk of nephrotoxicity has been associated with treatment for longer than 3 weeks, trough plasma concentrations continually in excess of 10 mg/L, and concurrent therapy with an aminoglycoside or a loop diuretic. Ototoxicity, often irreversible, used to be seen particularly in elderly patients and in patients receiving excessive dosage, but is unusual with the more highly purified preparations. The risk of ototoxicity is minimized if the peak serum level is kept below 50 mg/L and is very unusual if the level is less than 30 mg/L, unless the patient has prior auditory nerve damage or is receiving another potentially ototoxic drug. Reversible neutropenia and/or thrombocytopenia, which can be profound, may occur, notably in patients with renal impairment.

CLINICAL USE

Infections caused by *Staph. aureus* and other Gram-positive pathogens (especially those caused by methicillin-resistant staphylococci and in patients hypersensitive to β -lactam antibiotics)

Empirical therapy of febrile and profoundly neutropenic patients (in combination with agents active against Gram-negative bacteria)

Treatment and prophylaxis of endocarditis caused by Gram-positive species (often in combination with an aminoglycoside)

Peritonitis associated with continuous ambulatory peritoneal dialysis (intraperitoneal)

Oral formulation: Antibiotic-associated colitis

Oral formulation: Suppression of bowel flora in neutropenic patients (in combination with other agents)

Preparations and dosage

Proprietary name: Vancocin.

Preparations: Injection, capsules.

Dosage: Adults, oral, 125 mg every 6 h for 7–10 days, up to 2 g per day in severe infections; i.v., 500 mg every 6 h or 1 g every 12 h. Children, oral, 5–10 mg/kg every 6 h; >5 years, half the adult dose. Children, i.v., >1 month, 15 mg/kg every 8 h; infants 1–4 weeks, 15 mg/kg initially then 10 mg/kg every 8 h; neonates up to 1 week, 15 mg/kg initially then 10 mg/kg every 12 h.

Widely available.

INVESTIGATIONAL GLYCOPEPTIDES

DALBAVANCIN

A teicoplanin-like lipoglycopeptide derived from a product of the actinomycete *Nomonura* spp.

It displays excellent activity in vitro, especially against staphylococci (Table 20.1) and including many strains with mutational resistance to teicoplanin. Activity against glycopeptide-resistant enterococci is similar to that of teicoplanin (Table 20.1). Activity against strains of enterococci and *Staph. aureus* with VanA resistance is much reduced. Susceptibility testing is complicated since dalbavancin binds to surfaces of labware, which may result in artificially high MICs. This can be overcome by the addition of 0.002% polysorbate-80 to liquid media.

The serum half-life of 6–11 days allows once weekly dosing, which may facilitate outpatient intravenous therapy.

- Zhanell GG, Trapp S, Gin AS, et al. Dalbavancin and telavancin: novel lipoglycopeptides for the treatment of Gram-positive infections. *Expert Rev Anti Infect Ther*. 2008;6:67–81.

ORITAVANCIN

A semisynthetic vancomycin-like derivative of chloroeremomycin, which has an alkyl side chain that promotes strong dimerization and membrane anchoring, both of which enhance its complex antibacterial activity.

It is highly active against a wide range of Gram-positive organisms in vitro (Table 20.1). It remains active against many strains with reduced susceptibility or resistance to vancomycin or teicoplanin, although strains with VanA resistance are usually less susceptible. Like dalbavancin, it binds rapidly to labware; susceptibility testing media (broth) should be supplemented with 0.002% polysorbate-80.

It is in development as a once-daily injectable agent.

 Poulakou G, Giannarelli H. Oritavancin: a new promising agent in the treatment of infections due to Gram-positive pathogens. *Expert Opin Investig Drugs*. 2008;17:225–243.

TELAVANCIN

A bactericidal, vancomycin-like lipoglycopeptide currently under clinical trial for injectable treatment of infections caused by Gram-positive pathogens, including hospital-acquired pneumonia and complicated skin and skin structure infections. It exhibits excellent activity in vitro against enterococci and staphylococci (Table 20.1), though it has reduced activity against many glycopeptide-resistant strains, especially VanA strains. The half-life is 7–9 h, which allows once-daily dosing. Telavancin was approved by the US Food and Drug Administration (FDA) in September 2009 for the treatment of adult patients with complicated skin and skin structure infections (cSSSI) caused by susceptible Gram-positive bacteria, including *Staph. aureus*, both methicillin-resistant (MRSA) and methicillin-susceptible (MSSA) strains.

Preparations and dosage

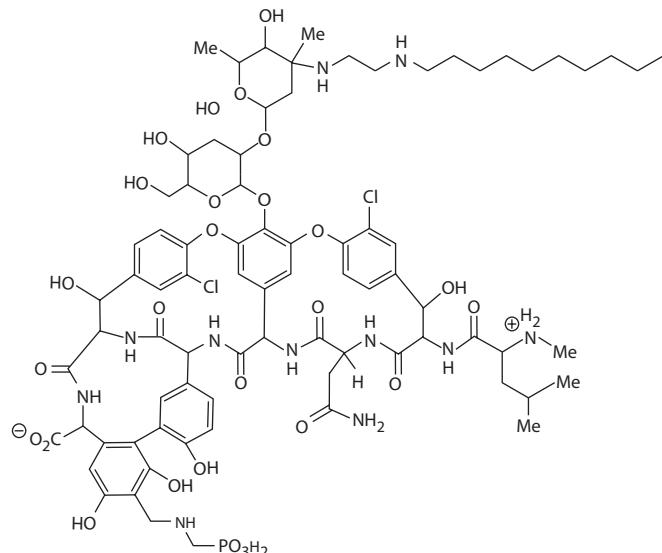

Proprietary Name: Vibativ.

Preparation: Injection

Dosage: Adults, i.v., 10 mg/kg infused over 60 minutes, once every 24 hours for 7 to 14 days. Adjustment is needed for patients with reduced renal function. No adjustment is needed for those with reduced hepatic function.

Animal data suggest that telavancin may cause adverse developmental outcomes in the fetus if given to pregnant women. A pregnancy test should be performed in all women of childbearing age and use should be avoided in pregnant women unless the benefits for the mother outweigh the risks to the fetus.

Available in US.

CHAPTER

21 Lincosamides

David Greenwood

The lincosamides are a small group of agents with a novel structure unlike that of any other antibiotic. The naturally occurring members of the group are lincomycin and the much less active celesticetin. Attempts to prepare semisynthetic derivatives with improved properties have been largely unsuccessful, with the exception of the chlorinated derivative, clindamycin, and pirlimycin, which is used in bovine mastitis.

Lincosamides are widely active against Gram-positive bacteria and most anaerobes, but not Gram-negative aerobes. They are also active against some mycoplasmas and protozoa. Their principal therapeutic indications are staphylococcal infections, particularly of bones and joints, and anaerobic infections, including mixed infections for which they must be combined with an agent active against aerobic Gram-negative bacilli. They are moderately well absorbed when administered by mouth and distributed widely to tissues, including penetration into cells and bone. They are generally well tolerated, except for the relative frequency with which they have been associated with severe diarrhea, including *Clostridium difficile*-associated pseudomembranous colitis.

CLINDAMYCIN

7-Chloro-7-deoxylincomycin. Molecular weight (anhydrous free base): 425.

A semisynthetic derivative of lincomycin. Aqueous suspensions are stable for up to 2 weeks at room temperature. Capsules contain clindamycin hydrochloride, which has a very bitter taste, detectable in concentrations as low as 8 mg/L; the syrup contains a suspension of the ester, clindamycin palmitate, which is palatable for children. Clindamycin phosphate, which is more soluble at neutral pH and less irritating than the hydrochloride, is used parenterally. The palmitate and phosphate salts are inactive *in vitro* and must be hydrolyzed to liberate clindamycin.

ANTIMICROBIAL ACTIVITY

The spectrum includes most Gram-positive organisms, notably staphylococci (including many methicillin-resistant strains) and streptococci, but not enterococci (Table 21.1). Aerobic Gram-negative rods are uniformly resistant, but most anaerobic bacteria are highly susceptible. Typical minimum inhibitory concentrations (MICs) are: *Prevotella* and *Porphyromonas* spp., 0.1–2 mg/L; *Fusobacterium* spp., <0.5 mg/L; *Peptostreptococcus* spp., 0.1–0.5 mg/L. Clostridia, with the notable exception of *Clostridium perfringens* (MIC <0.1–8 mg/L) are less susceptible. Corynebacteria, *Bacillus anthracis* and *Nocardia asteroides* are all susceptible, but mycobacteria are resistant. The MIC for *Chlamydia trachomatis* is 16 mg/L, that for *Mobiluncus* spp. is 0.5 mg/L, and that for *Gardnerella vaginalis* is 0.03 mg/L. *Mycoplasma hominis* is susceptible (MIC <1 mg/L), *M. pneumoniae* somewhat less so (MIC 1–4 mg/L). Ureaplasmas are resistant. Clindamycin exhibits useful activity against some protozoa, including *Toxoplasma gondii*, *Plasmodium falciparum* and *Babesia* spp. and against the fungus *Pneumocystis jirovecii*.

ACQUIRED RESISTANCE

Resistant strains of staphylococci, streptococci (including pneumococci) and *Bacteroides* spp. are found with variable frequency and are commonly also resistant to erythromycin. Resistance may be caused by changes in a ribosomal protein

Table 21.1 Susceptibility of common pathogenic bacteria:
MIC (mg/L)

	Clindamycin	Lincomycin
<i>Staphylococcus aureus</i>	0.1–1	0.5–2
<i>Streptococcus pyogenes</i>	0.01–0.25	0.05–1
<i>Str. pneumoniae</i>	0.05	0.1–1
<i>Enterococcus faecalis</i>	4–R	2–R
<i>Haemophilus influenzae</i>	0.5–16	4–16
<i>Neisseria</i> spp.	0.5–4	8–64
<i>Escherichia coli</i>	R	R
<i>Klebsiella pneumoniae</i>	R	R
<i>Pseudomonas aeruginosa</i>	R	R
<i>Bacteroides fragilis</i>	0.02–2	2–4

R, resistant (MIC >64 mg/L).

or, less commonly, by enzymic inactivation. There is complete cross-resistance to lincomycin. A form of resistance that embraces macrolides, lincosamides and type B streptogramins is associated with methylation of adenine residues at a common binding site. The methylase is inducible by macrolides, but not lincosamides (or streptogramins), which consequently remain active in the absence of macrolides.

PHARMACOKINETICS

Oral absorption	80–90%
C_{\max} : hydrochloride 300 mg oral	3.6 mg/L after 1–2 h
palmitate 300 mg oral	1.4–4.2 mg/L after 1 h
phosphate 300 mg intramuscular	4–5 mg/L after 2 h
phosphate 300 mg intravenous	5–6 mg/L end infusion
Plasma half-life	c. 2–3 h
Volume of distribution	43–74 L/m ²
Plasma protein binding	94%

Absorption

Oral absorption is not depressed or delayed by food. The palmitate is rapidly and completely hydrolyzed in the gut. In contrast, clindamycin phosphate is absorbed intact after intramuscular injection and relatively slowly hydrolyzed by alkaline phosphatases. A substantial amount of unhydrolyzed clindamycin phosphate (1–2 mg/L) is detectable in the serum at 30–60 min and up to 10% of the dose may still be present as phosphate after 8 h. The bioavailability in relation to dose is linear, but not proportional.

Plasma levels in pregnant women following a single 450 mg oral dose were similar to those in non-pregnant women. After intravaginal administration of 5 mL of 2% clindamycin

phosphate cream (100 mg) to healthy women and women suffering from bacterial vaginosis, less than 5% of the dose was subsequently found in the plasma.

Distribution

After hydrolysis in the serum, clindamycin phosphate is rapidly and widely distributed, but cerebrospinal fluid (CSF) concentrations are low (0.14–0.46 mg/L after a single 150 mg dose) and levels in brain are low or absent.

The drug is excreted in breast milk and crosses the placenta. In patients undergoing cesarean section, mean peak fetal plasma concentrations (*c.* 3 mg/L) were 46% of the maternal level after a 600 mg intravenous dose of the phosphate.

Therapeutic concentrations are achieved in cancellous and cortical bone. The tissue:serum concentration ratio has been found to be 1.0 in bone marrow, 0.5–0.75 in spongy bone and 0–0.15 in compact bone. Hydroxyapatite binds clindamycin and probably also the ester.

Uptake of clindamycin phosphate into neutrophils is rapid, temperature dependent, saturable and depressed by acid pH. Clindamycin is accumulated by lysosomes to active concentrations around 40 times those of the extracellular fluid. After an initially high rate of hydrolysis by intracellular alkaline phosphatase, enzyme activity declines; after 4 h around half of the drug is still unhydrolyzed. Similar product inhibition may prevent the complete hydrolysis of the phosphate in pus where alkaline phosphatase is liberated from neutrophils.

Metabolism

It is extensively metabolized in the liver to clindamycose, desmethyl clindamycin, and sulfoxide derivatives. Desmethyl clindamycin and clindamycin sulfoxide retain antibacterial activity, but clindamycose and desmethyl clindamycin sulfoxide are much less active than the base.

Excretion

About 13% of an oral dose is excreted unchanged in urine, somewhat less after a parenteral dose of the phosphate. Bioactivity persists in the urine for up to 4 days, suggesting slow release of the drug or its active metabolites from tissues or body fluids. In patients with severe renal disease, plasma levels may be 3–4 times normal and persist for over 24 h. Urinary recovery of the drug can fall below 1% in severe renal failure. Clindamycin is not removed by hemodialysis or peritoneal dialysis.

The liver plays a significant part in the metabolism and elimination of the drug. Concentrations 2–3 times those in serum have been found in the bile gallbladder wall and liver of patients with patent common ducts undergoing biliary tract surgery, most of the activity being due to the desmethyl metabolite. Where the common duct was obstructed, none could be detected in bile and the level was lower in gallbladder wall, but the concentration in liver was slightly higher than in those without obstruction. Patients with proven hepatic cirrhosis show significant impairment of clindamycin elimination. Clindamycin

phosphate may be slowly converted to the base in patients with hepatic impairment. Less than 5% of an oral dose can be recovered from the feces, but excretion of bioactive drug persists for several days and may continue to affect the normal gut flora.

The plasma half-life in premature infants (8.7 h) is significantly longer than in term infants (3.6 h).

TOXICITY AND SIDE EFFECTS

Up to 30% of patients experience diarrhea, especially when taking the drug orally. This is often due to *C. difficile* toxins and in a small proportion of cases leads to pseudomembranous colitis. Diarrhea is more common in women and in patients over 60 years of age. Diarrhea may abate if treatment is continued; however, because of the risk of pseudomembranous colitis, administration of the drug should be stopped.

Parenteral administration can cause elevation of transaminases and serum alkaline phosphatase, but these are generally reversible. Intravenous administration may be complicated by thrombophlebitis.

Rashes occur in about 10% of patients, but severe eruptions are rare. Isolated episodes of toxic epidermal necrolysis, blood dyscrasias and erythema multiforme have been reported and there is a single report of prolonged neuromuscular blockade after an accidental intravenous overdose.

CLINICAL USE

Staphylococcal soft tissue, bone and joint infection

Streptococcal infection (as a penicillin substitute in allergic patients, including prophylaxis of endocarditis in special risk patients undergoing dental procedures)

Prophylaxis and treatment of anaerobic infections (with appropriate agents where infection is likely to include aerobic Gram-negative rods)

Bacterial vaginosis

Acne

Toxoplasmosis

Babesiosis (in combination with quinine)

Pneumocystis jirovecii pneumonia (in combination with primaquine)

Preparations and dosage

Proprietary names: Dalacin C, Dalacin T.

Preparations: Capsules, suspension, injection.

Dosage: Adults, oral, 150–300 mg every 6 h, increased to 450 mg every 6 h for severe infections. Children, oral, 3–6 mg/kg every 6 h. Adults, i.m., i.v., 600 mg to 1.2 g per day in 2–4 equal doses; more severe infections, 1.2–2.7 g per day in 2–4 equal doses; life-threatening infections, up to 4.8 g per day. Children >1 month, i.m., i.v., 15–25 mg/kg per day in 3–4 divided doses; severe infections, 25–40 mg/kg per day in 3–4 divided doses; in severe infections it is recommended that children are given no less than 300 mg per day, regardless of body weight. Neonates have been given 15–20 mg/kg per day in 3–4 divided doses.

Widely available.

LINCOMYCIN

Molecular weight (hydrochloride monohydrate): 461.

A fermentation product of *Streptomyces lincolnensis* var. *lincolnensis* supplied as the hydrochloride. The dry crystalline hydrochloride is very soluble in water and very stable.

ANTIMICROBIAL ACTIVITY

The spectrum closely resembles that of clindamycin, but it is generally less potent (Table 21.1).

ACQUIRED RESISTANCE

There is complete cross-resistance between clindamycin and lincomycin. Clinical isolates of streptococci and enterococci are commonly cross-resistant to erythromycin. A transposon carrying a lincomycin resistance gene similar to that found in *Staphylococcus aureus* has been reported in *Bacteroides* strains.

PHARMACOKINETICS

Oral absorption (fasting)	20–35%
C_{\max} 500 mg oral	2–3 mg/L after 2–4 h
600 mg intramuscular	8–18 mg/L after 1–2 h
600 mg intravenous	18–20 mg/L end infusion
Plasma half-life	4–6 h
Plasma protein binding	72%

Absorption

It is less well absorbed than clindamycin. Food significantly delays and decreases absorption, the mean peak plasma level from a dose given immediately after a meal being only about half the fasting levels.

Distribution

It is widely distributed in a volume approximating to the total body water. Levels in normal CSF are low, but in the presence of inflammation, CSF:serum concentration ratios around 0.4 have been found. Penetration occurs into cerebral abscesses. Concentrations in saliva and sputum approximate to the simultaneous serum level. Concentrations of 1.5–6.9 mg/L have been found in cord serum or amniotic fluid after the mother received 600 mg intramuscularly, and 0.5–2.4 mg/L in human milk after the second of two maternal 500 mg doses.

In patients undergoing total hip replacement given 600 mg intramuscularly 6 h preoperatively, and again by intravenous infusion perioperatively, mean concentrations achieved were: capsule 9.4 mg/kg; synovial fluid 5.4 mg/L; cancellous bone 7.2 mg/kg; cortical bone 5.4 mg/kg.

Peak concentrations of 30–135 mg/L have been found in aqueous humor 1–2 h after subconjunctival injection of 75 mg; plasma levels were around 2–3 mg/L within 10 min.

Metabolism and excretion

Like clindamycin, it is metabolized in the liver and excreted in the bile. About 40% of an oral dose can be recovered from the feces. Less than 5% of an oral dose appears in the urine over 24 h, but up to 60% after intravenous administration, mostly in the first 4 h. In patients with severe hepatic dysfunction the plasma half-life is approximately doubled and the proportion of the dose appearing in the urine increases. It is not removed by dialysis.

TOXICITY AND SIDE EFFECTS

Nausea, vomiting and abdominal cramps may occur. Diarrhea affects at least 10% of patients, usually within a

few days of oral or parenteral administration. It is more common in older patients and uncommon in children. Symptoms range from watery diarrhea without fever or leukocytosis to severe, often bloody, diarrhea, with abdominal pain progressing to profound shock and dehydration with high mortality.

Hypersensitivity reactions are rare. Transient changes occur in liver function tests, probably due to interference with the tests, since abnormalities in specific enzyme tests and clinical evidence of hepatic dysfunction are rare.

In some patients receiving large doses by rapid intravenous injection, the blood pressure falls precipitately with nausea, vomiting, arrhythmias and, exceptionally, cardiac arrest. It can transiently depress neuromuscular transmission and might weakly depress respiration after anesthesia.

There is no evidence of risk in pregnancy.

CLINICAL USE

Uses are similar to those of clindamycin, by which it has been generally superseded.

Preparations and dosage

Proprietary name: Lincocin.

Preparations: Capsules, syrup, injection.

Dosage: Adults, oral, 500 mg, every 6–8 h; i.m., 600 mg, every 12–24 h; i.v. infusion, 600 mg to 1 g, every 8–12 h, up to 8 g per day in severe infections. Children >1 month, oral, 30–60 mg/kg per day in divided doses; i.m., i.v., 10–20 mg/kg per day in divided doses.

Limited availability; available in the USA, but not available in the UK.

CHAPTER

22 Macrolides

André Bryskier

The macrolides form a large group of closely related antibiotics produced mostly by *Streptomyces* and related species. They are characterized by a macrolactone ring (to which they owe their generic name), to which typically two sugars, one an amino sugar, are attached. The original macrolide complex, erythromycin A, was isolated in 1952 as a natural product of *Saccharopolyspora erythraea* (formerly *Streptomyces erythreus*). Other natural products followed. The search for analogs has focused on compounds with an extended antibacterial spectrum (notably against fastidious Gram-negative pathogens), improved pharmacokinetic properties (e.g. increased acid stability) and reduced gastrointestinal intolerance.

The most important therapeutic macrolides are characterized by a 14-, 15- or 16-membered lactone ring. Macrolides with a 12-membered ring are also known, but only as research compounds. In the group that includes erythromycin A, the lactone ring contains 14 atoms and one or two sugar groups attached by α - or β -glycosidic linkages to the aglycone. In the 16-membered-ring macrolides, two sugars are linked together and attached to the lactone ring through the amino sugar.

Insertion of a nitrogen atom into the erythronolide A ring of erythromycin A yielded a chemical subclass with a 15-membered ring, known as azalides, one of which, azithromycin, is used clinically. It shares the properties of other macrolide antibiotics, but exhibits increased potency against fastidious Gram-negative bacteria and some Enterobacteriaceae, and has a longer elimination half-life.

A further development came with the ketolides, semisynthetic derivatives of erythromycin A in which α -L-cladinose at position 3 of the erythronolide A ring is replaced with a ketone function and a cyclic carbamate

residue is present at C11–C12. Ketolides are highly stable, even at pH 1.0, and remain active against many erythromycin-resistant Gram-positive cocci. They do not induce resistance to macrolides, lincosamides and streptogramins caused by methylation of the ribosomal binding site (see below). One such compound, telithromycin, is clinically available.

More than 100 other ketolide derivatives have been reported. Three – cethromycin, modithromycin and CEM 101 – are in clinical development at the time of writing. Modithromycin has a bicyclic bridge between positions 6 and 11 of the lactone ring, and because of this structure the name 'bicyclolide' has been proposed for this type of ketolide.

Several macrolides, including tylosin, mycinamycin, tilimicosin (a derivative of tylosin), tulathromycin and gamithromycin are used only in veterinary medicine and are not discussed further here.

ANTIBACTERIAL ACTIVITY

The 14-, 15- and 16-membered-ring macrolides share the same antibacterial spectrum, including most Gram-positive organisms, *Neisseria* spp., *Haemophilus* spp., *Bordetella pertussis*, *Moraxella catarrhalis* and both Gram-positive and Gram-negative anaerobes. Activity against common pathogenic bacteria is shown in Table 22.1. They are inactive or poorly active against Enterobacteriaceae and non-fermentative Gram-negative bacteria such as *Pseudomonas aeruginosa*.

Group 1 14-membered ring compounds	Group 2 16-membered ring compounds	Group 3 Azalides (15-membered ring)	Group 4 Ketolides (14-membered ring)
Clarithromycin ^a	Josamycin	Azithromycin ^a	Cethromycin ^a
Dirithromycin ^a	Kitasamycin (leucomycin)		Modithromycin ^a
Erythromycin A	Midecamycin		Telithromycin ^a
Flurithromycin ^a	Miokamycin ^a		CEM 101 ^a
Oleandomycin	Rokitamycin ^a		
Roxithromycin ^a	Spiramycin		

^aSemisynthetic compounds

The semisynthetic macrolides do not provide a significant advantage over erythromycin A against staphylococci and streptococci, and are poorly active against enterococci. They are active against *Mor. catarrhalis*, *B. pertussis*, *Neisseria gonorrhoeae*, *Campylobacter jejuni*, *Rhodococcus equi*, *Haemophilus ducreyi*, *Gardnerella vaginalis*, *Mobiluncus* spp., *Propionibacterium acnes*, *Borrelia burgdorferi* and *Treponema pallidum*. The minimum inhibitory concentrations (MICs) against *H. influenzae* range from 0.25 to 8 mg/L, the azalide azithromycin being the most active. Variable susceptibilities are reported for *B. bronchiseptica*, *Listeria monocytogenes*, *Corynebacterium jeikeium*, *Eikenella corrodens*, *Pasteurella multocida*, *Bacteroides fragilis*, *Prevotella melaninigenica*, *Fusobacterium* spp. and *Clostridium perfringens*.

In-vitro activity against common respiratory pathogens is shown in Table 22.2. The ketolide, telithromycin, is the most active compound and retains activity against erythromycin-resistant strains.

The semisynthetic macrolides exert important activity against intracellular pathogens, including *Chlamydia trachomatis* (MIC₅₀ clarithromycin 0.007 mg/L; azithromycin 0.125 mg/L; roxithromycin 0.06 mg/L), *Chlamydophila* (formerly

Chlamydia pneumoniae, *Legionella pneumophila* and other *Legionella* spp., the *Mycobacterium avium* complex (MIC: clarithromycin 0.25–4.0 mg/L; azithromycin and roxithromycin 4–32 mg/L), *M. leprae* and *Rickettsia* spp. (MIC 1–2 mg/L). Azithromycin appears to be the most active of the compounds against *Brucella melitensis* and atypical pathogens such as *Ureaplasma urealyticum* and *Mycoplasma* spp. They are inactive against *M. tuberculosis*.

ACQUIRED RESISTANCE

Widespread use of erythromycin and semisynthetic analogs has led to the emergence of resistance in *Staphylococcus aureus*, *Streptococcus pneumoniae* and Lancefield group A streptococci (*Str. pyogenes*). Chromosomal or plasmid-mediated resistance to erythromycin may be inducible or constitutive. Intrinsic resistance of Gram-negative bacilli is probably due to the relative impermeability of the outer membrane to the hydrophobic compounds and/or to an efflux mechanism of resistance.

Table 22.1 Susceptibility (MIC range: mg/L) of some common pathogenic bacteria to macrolides

	Azithromycin	Erythromycin A	Josamycin	Midecamycin	Oleandomycin	Roxithromycin	Spiramycin	Telithromycin

Acquired resistance to macrolides involves three mechanisms: modification of the target, active efflux or inactivation. In the first type, a single alteration in 23S ribosomal RNA in the 50S ribosomal subunit confers cross-resistance to macrolides, azalides, lincosamides and streptogramin-B-type antibiotics (the so-called MLS_B phenotype); the other types confer resistance to structurally related antibiotics only.

Modification of the 50S ribosomal targets is a complex mechanism. Several types have been described:

- Monomethylation of adenine 2058, located in the 23S rRNA, results in blockade of the N⁶ amino group of adenine and inhibition of binding of erythromycin A or its derivatives. It can be induced by 14-membered-ring macrolides and azalides, but not by 16-membered-ring macrolides or ketolides. Monomethylation or bimethylation of adenine 2058 or 2059 may be constitutive and affects all available macrolides. Monomethylation does not affect telithromycin.
- Mutation of adenine 2058 to guanine has been described in many bacterial species, such as staphylococci, streptococci (including *Str. pneumoniae* and *Str. pyogenes*), *Helicobacter pylori*, the *M. avium* complex and *T. pallidum*. Other point mutations on the peptidyltransferase site, such as adenine 2611 to guanine, lead to resistance to 14- and 15-membered-ring macrolides.
- Mutations at ribosomal proteins L4 and L22, which are close to the exit channel, have been reported in clinical isolates of *Str. pneumoniae*, *Str. oralis* and *Str. pyogenes*.

An efflux pump, Mef, encoded by a *mef* gene, accounts for resistance in over 50% of *Str. pneumoniae* or *Str. pyogenes* isolates in certain geographic areas. It has been described in all streptococci, including the viridans group. Other pumps involved in macrolide resistance include Msr A/B in staphylococci, Acr-like in *H. influenzae*, Mre A in *Str. agalactiae* and Mtr (which also removes penicillin G) in *N. gonorrhoeae*.

Macrolide-inactivating esterases that hydrolyze the lactone ring are found mainly in *Escherichia coli*. Enzymes that fix either a glucose or a phosphate at the 2' OH group of D-desosamine have been reported in *Nocardia* spp., which are resistant to all macrolides having a D-desosamine substituent. Inactivation mechanisms have also been reported in 16-membered-ring macrolides.

PHARMACOKINETICS

Erythromycin is characterized by poor water solubility and rapid inactivation by stomach acidity, resulting in widely varying bioavailability after oral administration. Derivatives of erythromycin A have improved pharmacological properties, including bioavailability, gastrointestinal tolerance, higher peak plasma levels, longer apparent elimination plasma half-lives and improved tissue concentrations.

Oral absorption is rapid, with plasma peaks varying between 0.4 mg/L (azithromycin) and 11 mg/L (roxithromycin). Maximum concentrations are reached between 0.5 h (rokita-mycin) and 3 h (clarithromycin) and are dose dependent.

The apparent elimination half-life varies from 1 h (miokamycin) to 44 h (dirithromycin); the absolute bioavailability varies between 10% (dirithromycin) and 55–60% (roxithromycin, clarithromycin). The main elimination route is via the bile and feces; a proportion of clarithromycin is excreted via the intestinal mucosa. A substantial part of the administered dose of clarithromycin is eliminated in urine. The long apparent elimination half-lives of roxithromycin, azithromycin and dirithromycin allow them to be administered as single daily oral doses.

INTRACELLULAR CONCENTRATION

Rates of uptake into cells and efflux vary for each compound (Table 22.3). Azithromycin, dirithromycin and telithromycin concentrate progressively, with a high concentration after 3 h. Macrolides usually concentrate in the granule zone of polymorphonuclear neutrophils. They are concentrated in the bronchial mucosa and tonsils (Table 22.4).

INTERACTIONS

Erythromycin A and oleandomycin induce hepatic microsomal enzymes and interfere via the cytochrome P₄₅₀ system with clearance of other drugs such as theophylline, antipyrine and carbamazepine, increasing their plasma levels. The induced isoenzymes of cytochrome P₄₅₀ rapidly demethylate and oxidize macrolides to nitrosoalkanes, which combine with the iron of the enzymes, thereby inactivating them. The 16-membered-ring macrolides such as josamycin and

Table 22.3 Uptake of macrolides into polymorphonuclear neutrophils

Macrolide	Uptake ^a	Efflux ^b	Percentage in granule
Azithromycin	>300	≤20	60

^aRatio of intracellular: extracellular concentration; ^bover 60 min.

Table 22.4 Concentration of macrolides in respiratory tissue

Macrolide	Dose (mg)	Plasma (mg/L)	Bronchial mucosa (mg/kg)	Tonsils (mg/kg)
Azithromycin	500 (S)	–	3.9	–
Clarithromycin	500 (R)	2.5	–	1.9
Dirithromycin	500 (R)	0.22	1.9	3.5
Erythromycin	500 (R)	3.08	7.2	2.9
Josamycin	1000 (R)	0.39	–	21.4
Oleandomycin	2000 (S)	–	–	4.1
Miokamycin	600 (R)	2.3	–	3.2
Roxithromycin	150 (R)	6.3	–	2.9
Spiramycin	2000 (R)	2.4	13–36	21.5–40
Telithromycin	800 (S)	1.9–2.7	0.7–3.9	0.7–3.95

S, single dose; R, repeated dose.

spiramycin have no such effect. Erythromycin base, estolate and stearate, and a metabolite of triacetyloleandomycin all form stable complexes with cytochrome P₄₅₀. Josamycin base forms an unstable complex. Josamycin propionate and spiramycin (base and adipate) do not bind.

TOXICITY AND SIDE EFFECTS

Macrolides are generally safe and serious adverse events are rare. A notable exception is erythromycin estolate, which is hepatotoxic and may cause severe hepatitis, probably as a result of the mixture of lauryl sulfate and the 2'-propionyl ester. Gastrointestinal complaints (nausea, vomiting, abdominal pain or, less frequently, diarrhea) are most common; they present a problem mainly with erythromycin doses higher than those recommended and are partly due to a hemiketal degradation product that acts on motilin, an intestinal endopeptide.

The semisynthetic 14- and 15-membered-ring macrolides are more acid stable than erythromycin A and are better tolerated.

CLINICAL USE

The macrolides retain the classic clinical applications of erythromycin, including activity against Gram-positive cocci and intracellular pathogens such as *Legionella*, *Chlamydia* and *Rickettsia* spp. The improved pharmacokinetic properties and tissue distribution of some semisynthetic compounds may prove useful in more unusual settings such as infections due to mycobacteria (*M. avium* complex) and protozoa (e.g.

Toxoplasma gondii, *Entamoeba histolytica*, *Plasmodium falciparum*). Other target infections are chronic gastritis (*H. pylori*) and borreliosis.

GROUP 1: 14-MEMBERED RING MACROLIDES

CLARITHROMYCIN

Molecular weight: 748.

A semisynthetic erythromycin A derivative (6-O-methylerythromycin A) formulated for oral and intravenous use.

ANTIBACTERIAL ACTIVITY

Activity against susceptible common pathogens is two to four times greater than that of erythromycin A (Table 22.1). Most respiratory pathogens, with the exception of *H. influenzae*, are inhibited at a concentration of ≤ 0.25 mg/L. It inhibits *Mycoplasma pneumoniae* at 0.004 mg/L and *Mor. catarrhalis* at 0.06 mg/L. It is eight times more active than erythromycin A against *Legionella* spp., *C. trachomatis* and *Ch. pneumoniae*. Against anaerobic species, activity is similar to that of erythromycin A. Against *H. influenzae* the 14-hydroxy metabolite is twice as active as the parent compound.

PHARMACOKINETICS

Oral absorption	55%
C_{\max} 250 mg oral	0.75 mg/L after 1.7 h
500 mg oral	1.65 mg/L after 2 h
Terminal half-life	2.7–3.5 h
Volume of distribution	250 L
Plasma protein binding	80%

Absorption and distribution

It is more stable to gastric acid than erythromycin, but internal ketalization between the 9-keto group and the C-12 hydroxyl group has been described resulting in an inactive product: pseudo clarithromycin. It is rapidly absorbed orally and absorption is not affected by food.

Concentrations in tonsil and lung tissues exceed the simultaneous plasma level by a factor of two and four, respectively.

Metabolism and excretion

The primary metabolic pathway is *N*-demethylation of the D-desosamine and stereospecific hydroxylation at the 14-position of the erythronolide A ring. Metabolism to the 14-hydroxy derivative is saturable above 800 mg.

Around 20–40% of the administered dose is eliminated in urine. The apparent elimination half-life of the 14-hydroxy metabolite is around 7 h. The parent compound and its principal metabolite are retained in renal impairment, resulting in long apparent elimination half-lives, exceeding 30 and 45 h, respectively, in patients whose creatinine clearance is less than 30 mL/min.

TOXICITY AND SIDE EFFECTS

Clarithromycin is well tolerated, producing little gastrointestinal disturbance and only transient changes in some liver function tests.

Upper and lower respiratory tract infections, including streptococcal pharyngitis, acute bacterial maxillary sinusitis, bacterial exacerbations of chronic bronchitis and community-acquired pneumonia
Skin and soft-tissue infections
H. pylori infection (in combination with other agents)

Preparations and dosage

Proprietary names: Klaricid, Biaxin.

Preparations: Tablets, suspension, granules, injection.

Dosage: Adults, oral, 250–500 mg every 12 h for 7–14 days, depending on severity of infection. Children, oral, <8 kg, 7.5 mg/kg every 12 h; 8–11 kg, 62.5 mg every 12 h; 12–19 kg, 125 mg every 12 h; 20–29 kg, 187.5 mg every 12 h; 30–40 kg, 250 mg every 12 h. Adults, i.v. infusion, 500 mg every 12 h. Widely available.

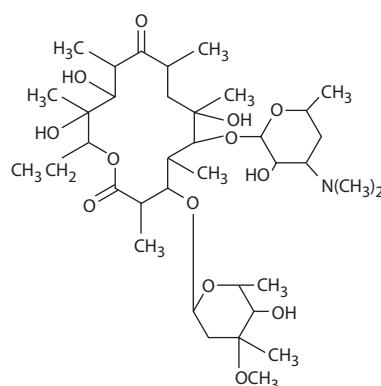

Further information

Anonymous. Clarithromycin. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C248–C253.

ERYTHROMYCIN

Molecular weight (erythromycin A base): 733.9; (ethyl succinate): 862.1; (stearate): 1018.4; (estolate): 1056.4.

A natural antibiotic produced as a complex of six components (A–F) by *Saccharopolyspora erythraea*. Only erythromycin A has been developed for clinical use. It is available in a large number of forms for oral administration: the base compound (enteric- or film-coated to prevent destruction by gastric acidity); 2'-propionate and 2'-ethylsuccinate esters; a stearate salt; estolate and acistrate salts of 2'-esters. The 2'-esters and their salts have improved pharmacokinetic and pharmaceutical properties and are less bitter than erythromycin. It is also formulated as the lactobionate and gluceptate for parenteral use.

ANTIBACTERIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 22.1 (p. 277). Gram-positive rods, including *Clostridium* spp. (MIC_{50} 0.1–1 mg/L), *C. diphtheriae* (MIC_{50} 0.1–1 mg/L), *L. monocytogenes* (MIC_{50} 0.1–0.3 mg/L) and *Bacillus anthracis* (MIC_{50} 0.5–1.0 mg/L), are generally susceptible. Most strains of *M. scrofulaceum* and *M. kansasii* are susceptible (MIC_{50} 0.5–2 mg/L), but *M. intracellularare* is often and *M. fortuitum* regularly resistant. *Nocardia* isolates are resistant. *H. ducreyi*, *B. pertussis* (MIC_{50} 0.03–0.25 mg/L), some *Brucella*, *Flavobacterium*, *Legionella* (MIC_{50} 0.1–0.5 mg/L) and *Pasteurella* spp. are susceptible. *H. pylori* (MIC 0.06–0.25 mg/L) and *C. jejuni* are usually susceptible, but *C. coli* may be resistant. Most anaerobic bacteria, including *Actinomyces* and *Arachnia* spp., are susceptible or moderately so, but *B. fragilis* and *Fusobacterium* spp. are resistant. *T. pallidum* and *Borrelia* spp. are susceptible, as are *Chlamydia* spp. ($\text{MIC} \leq 0.25$ mg/L), *M. pneumoniae* and *Rickettsia* spp. *M. hominis* and *Ureaplasma* spp. are resistant. Enterobacteriaceae are usually resistant.

Activity rises with increasing pH up to 8.5. Incubation in 5–6% CO_2 raises the MIC for *H. influenzae* from 0.5–8 to 4–32 mg/L; MICs for *Str. pneumoniae* and *Str. pyogenes* also rise steeply. Activity is predominantly bacteriostatic.

ACQUIRED RESISTANCE

In Europe, the USA and other countries the incidence of resistance in *Str. pneumoniae* ranges from 5% to over 60%. In *Str. pneumoniae* strains resistant or intermediately susceptible to penicillin G, resistance rates above 80% have been reported. Increasing rates of resistance in clinical isolates of *Str. pyogenes* have also been reported, threatening its use as an alternative to penicillin G in allergic patients.

Lower rates of resistance have been reported in other bacterial species, including methicillin-resistant *Staph. aureus*, coagulase-negative staphylococci, *Str. agalactiae*, Lancefield group C and G streptococci, viridans group streptococci, *H. pylori*, *T. pallidum*, *C. diphtheriae* and *N. gonorrhoeae*.

PHARMACOKINETICS

Oral absorption	Variable
C_{\max}	
base 250 mg oral	1.3 mg/L after 3–4 h
500 mg oral	2 mg/L after 2–4 h
1000 mg oral	1.3–1.5 mg/L after 4 h
stearate 250 mg oral (fasting)	0.88 mg/L after 2.2 h
500 mg oral (fasting)	2.4 mg/L after 2–4 h
500 mg oral (after food)	0.1–0.4 mg/L after 2–4 h
2'-propionate 500 mg oral (fasting)	0.4–1.9 mg/L after 2–4 h

500 mg oral (after food)	0.3–0.5 mg/L after 4 h
2'-estolate 250 mg oral (fasting)	0.36–3 mg/L after 2–4 h
500 mg oral (fasting)	1.4–5 mg/L after 1–2 h
250 mg oral (after food)	1.1–2.9 mg/L after 2–4 h
500 mg oral (after food)	1.8–5.2 mg/L after 2–4 h
lactobionate 500 mg intravenous	11.5–30 mg/L end infusion
gluceptate 250 mg intravenous	3.5–10.7 mg/L end infusion
Plasma half-life:	
base	1.6–2 h
stearate	1.6–4 h
2'-propionate	3–5 h
2'-estolate	2–4 h
lactobionate/gluceptate	1–2 h
Volume of distribution	0.75 L/kg
Plasma protein binding:	
base	70%
propionate	93%

Absorption and metabolism

The acid lability of erythromycin base necessitates administration in a form giving protection from gastric acid. In acid media it is rapidly degraded (10% loss of activity at pH 2 in less than 4 s) by intramolecular dehydrogenation to a hemiketal and hence to anhydroerythromycin A, neither of which exerts antibacterial activity. Delayed and incomplete absorption is obtained from coated tablets and there is important inter- and intra-individual variation, adequate levels not being attained at all in a few subjects. Food delays absorption of erythromycin base. After 500 mg of the 2'-ethylsuccinyl ester, mean peak plasma levels at 1–2 h were 1.5 mg/L. In subjects given 1 g of the 2'-ethylsuccinate every 12 h for seven doses, the mean plasma concentration 1 h after the last dose was around 1.4 mg/L. Intra- and inter-subject variation and delayed and erratic absorption in the presence of food have not yet been eliminated by new formulations. Improved 500 mg preparations of erythromycin stearate are claimed to produce peak plasma levels of 0.9–2.4 mg/L that are little affected by the presence of food. 2'-Esters of erythromycin are partially hydrolyzed to erythromycin; 2'-acetyl erythromycin is hydrolyzed more rapidly than the 2'-propionyl ester, but more slowly than the 2'-ethylsuccinate.

The stoichiometric mixture with stearate does not adequately protect erythromycin from acid degradation. After an oral dose of erythromycin stearate, equivalent concentrations of erythromycin and its main degradation product, anhydroerythromycin, could be detected.

Doses of 10 mg/kg produced mean peak plasma concentrations around 1.8 mg/L in infants weighing 1.5–2 kg and 1.2 mg/L in those weighing 2–2.5 kg. In infants less than 4 months old, doses of 10 mg/kg of the 2'-ethylsuccinate every 6 h produced steady state plasma levels of around 1.3 mg/L. The apparent elimination half-life was 2.5 h. In children given 12.5 mg/kg of erythromycin 2'-ethylsuccinate every 6 h, the concentration in the plasma 2 h after the fourth dose was around 0.5–2.5 mg/L.

Distribution

Very low levels are obtained in cerebrospinal fluid (CSF), even in the presence of meningeal inflammation, and after parenteral administration. Levels of 0.1 mg/L in aqueous humor were found when the serum level was 0.36 mg/L, but there was no penetration into the vitreous. In children with otitis media given 12.5 mg/kg of erythromycin 2'-ethylsuccinate every 6 h, concentrations in middle ear exudate were 0.25–1 mg/L. In patients with chronic serous otitis media given 12.5 mg/kg up to a maximum of the equivalent of 500 mg, none was detected in middle ear fluid, but on continued treatment levels up to 1.2 mg/L have been described.

Penetration also occurs into peritoneal and pleural exudates. Mean concentrations of 2.6 mg/L have been found in sputum in patients receiving 1 g of erythromycin lactobionate intravenously every 12 h and 0.2–2 mg/L in those receiving an oral stearate formulation. Levels in prostatic fluid are about 40% of those in the plasma. Salivary levels of around 4 mg/L were found in subjects receiving doses of 0.5 g every 8 h at 5 h after a dose, when the plasma concentration was around 5.5 mg/L. Intracellular:extracellular ratios of 4–18 have been found in polymorphonuclear neutrophils.

Fetal tissue levels are considerably higher after multiple doses; when the mean peak maternal serum level was 4.94 (0.66–8) mg/L, the mean fetal blood concentration was 0.06 (0–0.12) mg/L. Concentrations were more than 0.3 mg/L in amniotic fluid and most other fetal tissues, but the concentrations were variable and unmeasurable in some. Erythromycin appears to be concentrated by fetal liver.

Excretion

Erythromycin is excreted both in urine and in the bile but only a fraction of the dose can be accounted for in this way. Only about 2.5% of an oral dose or 15% of an intravenous dose is recovered unchanged in the urine. It is not removed to any significant extent by peritoneal dialysis or hemodialysis. Reported changes in apparent elimination half-life in renal impairment may be related to the saturable nature of protein binding. Fairly high concentrations (50–250 mg/L) are found in the bile. In cirrhotic patients receiving 500 mg of the base, peak plasma levels were higher and earlier than in healthy volunteers (2.0 and 1.5 mg/L at 4.6 and 6.3 h, respectively). The apparent elimination half-life was 6.6 h. It is possible that the smaller excretion of the 2'-propionyl ester in the bile in comparison to the base accounts in part for its better-maintained serum levels. There is some enterohepatic recycling, but some of the administered dose is lost in the feces, producing concentrations of around 0.5 mg/g.

INTERACTIONS

Interaction with the hepatic metabolism of other drugs can result in clinically significant potentiation of the action of carbamazepine, ciclosporin (cyclosporine), methylprednisolone,

theophylline, midazolam, terfenadine and warfarin, and in adverse responses to digoxin and ergot alkaloids.

TOXICITY AND SIDE EFFECTS

Oral administration, especially of large doses, commonly causes epigastric distress, nausea and vomiting, which may be severe. Solutions are very irritant: intravenous infusions almost invariably produce thrombophlebitis. Cholestatic hepatitis occurs rarely. Transient auditory disturbances have been described after intravenous administration of the lactobionate salt, and occasionally in patients with renal and hepatic impairment in whom oral dosage has produced high plasma levels. Sensorineural hearing impairment can occur and, although this is usually a reversible effect which occurs at high dosage, can be permanent. Prolongation of the apparent elimination half-life of carbamazepine, due to inhibition of its conversion to the epoxide, usually results in central nervous system (CNS) disturbances. Nightmares are troublesome in some patients. Allergic effects occur in about 0.5% of patients.

The estolate is particularly prone to give rise to liver abnormalities, consisting of upper abdominal pain, fever, hepatic enlargement, a raised serum bilirubin, pale stools and dark urine and eosinophilia. The condition is rare and usually seen 10–20 days after the initiation of treatment, with complete recovery on stopping the drug. Recurrence of symptoms can be induced by giving the estolate but not the base or stearate. There is evidence that erythromycin estolate is more toxic to isolated liver cells than is the 2'-propionate or the base, and it is suggested that the essential molecular feature responsible for toxicity is the propionyl-ester linkage. The relative frequency of the reaction, its rapidity of onset (within hours) after second courses of the drug, evidence of hypersensitivity and the histological appearance suggest a mixture of hepatic cholestasis, liver cell necrosis and hypersensitivity. Abnormal liver function tests in patients receiving the estolate must be interpreted with caution, since increased levels of transaminases is often the only abnormality and some metabolites of the estolate can interfere with the measurement commonly used. Elevated levels of transaminases return to normal after cessation of treatment. Serum bilirubin is generally unchanged in these patients, but γ -glutamyl transpeptidase may also be affected.

Lower and upper respiratory tract infections (including those caused by atypical and intracellular pathogens)

Legionellosis (alone or in combination with rifampicin [rifampin])

Skin and soft-tissue infections

Campylobacter infection

Syphilis (penicillin-allergic patients)

Whooping cough

Diphtheria (including treatment of carriers)

Concentrations found in middle ear exudate are unlikely to be sufficient to inhibit *H. influenzae* isolates, which is a common cause of otitis media in children.

Preparations and dosage

Proprietary names: Erythrocin, Ilosone and many generic forms.

Preparations: Film-coated tablets (as ethyl succinate and stearate), suspension (as ethyl succinate), capsules, injection (as lactobionate).

Dosage: Adults and children >8 years, oral, 250–500 mg every 6 h or 0.5–1 g every 12 h, up to 4 g per day for severe infections. Children up to 2 years, oral, 125 mg every 6 h; 2–8 years, 250 mg every 6 h; doses doubled for severe infection. Adults, children, i.v., 50 mg/kg per day by continuous i.v. infusion or in divided doses every 6 h for severe infections; 25 mg/kg per day for mild infections when oral treatment is not possible.

Widely available.

ROXITHROMYCIN

Molecular weight: 837.04.

A semisynthetic derivative of erythromycin A formulated for oral use.

ANTIBACTERIAL ACTIVITY

Activity against common pathogens (Table 22.1, p. 277) is comparable to that of erythromycin. It is active against *L. monocytogenes*, *C. jejuni*, *H. ducreyi*, *G. vaginalis*, *Bord. pertussis*, *C. diphtheriae*, *B. burgdorferi*, *H. pylori*, the *M. avium* complex, *Chlamydia* spp., and *U. urealyticum*. Activity against respiratory pathogens is shown in Table 22.2 (p. 277).

PHARMACOKINETICS

Oral absorption	50–55%
C_{max} 150 mg oral	7.9 mg/L after 1.9 h
300 mg oral	10.8 mg/L after 1.5 h
Plasma half-life	10.5–11.9 h
Plasma protein binding	c. 90%

Absorption

Absorption is not affected by food. Oral administration with antacids or H₂-receptor antagonists does not significantly affect bioavailability. In a direct comparison, the area under the time-concentration curve (AUC) produced by a 150 mg dose was 16 times greater than that produced by 250 mg erythromycin A. Behavior in children is broadly similar to that in adults, repeated doses of 2.5 mg/kg producing age-independent mean peak plasma concentrations around 10 mg/L at 1–2 h, but the apparent elimination half-life was longer (approximately 20 h).

It is saturably bound to α-acid glycoprotein in plasma. The plasma clearance appears to be dose dependent or plasma concentration dependent.

Distribution

It is widely distributed, but does not reach the CSF. Concentrations close to the simultaneous serum level have been found in tonsillar, lung, prostatic and other tissues. It achieves high levels in skin.

Metabolism and excretion

Less than 5% of the administered dose is eliminated as degradation products. Rather more than half the dose appears in the feces and only 7–10% (including metabolites) in the urine; up to 15% is eliminated via the lungs. Renal clearance increased in volunteers as the dose was raised from 150 to 450 mg, and is decreased in elderly subjects. In patients in whom the creatinine clearance was <10 mL/min, the apparent elimination half-life rose to around 15.5 h and total body clearance was significantly reduced. The apparent elimination half-life was somewhat increased in patients with hepatic cirrhosis.

INTERACTIONS

The half-life of simultaneously administered theophylline is increased by about 10%, but there is no effect on that of carbamazepine and no interaction with warfarin or ciclosporin.

TOXICITY AND SIDE EFFECTS

It is generally well tolerated, adverse effects being described in 3–4% of patients, mostly gastrointestinal disturbance (abdominal pain, nausea and diarrhea). Headache, weakness, dizziness, rash and reversible changes in liver function tests and increased eosinophils and platelets have also been described.

- Upper and lower respiratory tract infections
- Skin and soft-tissue infections
- Urogenital infections
- Orodental infections

Preparations and dosage

Proprietary names: Rulid, Surlid.

Preparations: Tablets, oral suspension.

Dosage: Adults, oral, 150 mg every 12 h or 300 mg per day. Children, oral, 2.5–5 mg/kg every 12 h.

Widely available. Not available in the UK or the USA.

OTHER GROUP 1 MACROLIDES

DIRITHROMYCIN

A prodrug of erythromycylamine, a semisynthetic erythromycin A derivative, formulated for oral administration. Activity against respiratory pathogens (Table 22.2, p. 277) is generally poorer than that of erythromycin A.

The long apparent elimination half-life (30–44 h) allows once-daily administration. Around 60–90% of a dose is converted to erythromycylamine within 35 min after intravenous administration. After oral administration of single doses of 500–1000 mg to healthy volunteers, the peak plasma concentrations ranged from 0.29 to 0.64 mg/L after 4–5 h. The absolute bioavailability after oral administration is about 10%. It achieves a higher concentration than erythromycin in some

tissues. After a 500 mg single oral dose, the mean peak biliary concentration was 139 mg/L. Renal and non-renal clearance was lower in patients with biliary disease than in other patients or healthy volunteers.

About 60–80% of an oral dose and over 80% of an intravenous dose are eliminated in the feces, predominantly as erythromycylamine. Dosage adjustments do not appear necessary in patients with mild or moderate hepatic, biliary or renal impairment. Negligible amounts of the drug are removed during hemodialysis.

Adverse events are similar to those found with other macrolides. Gastrointestinal events are most common; around 5% of patients experience abdominal pain, diarrhea or nausea.

It has been used in community-acquired infections of the respiratory tract and skin and soft-tissue infections. It is no longer widely available.

Further information

Brogden RN, Peters DH. Dirithromycin – a review of its antimicrobial activity, pharmacokinetic properties and therapeutic efficacy. *Drugs.* 1994;48:599–616.

FLURITHROMYCIN

A semisynthetic derivative of erythromycin A, supplied for oral administration. It is stable at acid pH due to the presence of the fluorine atom at C-8 of the erythronolide A ring.

It is active against most streptococci (including *Str. pneumoniae* and *Str. agalactiae*; MIC₅₀ 0.03 mg/L), *Mor. catarrhalis*, *N. gonorrhoeae* (MIC₅₀ 0.04 mg/L), *C. trachomatis* (MIC 0.06–0.125 mg/L), *M. genitalium* (MIC₅₀ 0.007 mg/L) and *U. urealyticum* (MIC₅₀ 0.03 mg/L). It has little or no activity against *H. influenzae* and *M. hominis*. Activity against anaerobes is similar to that of erythromycin A. It displays cross-resistance with erythromycin A.

A single 500 mg oral dose achieved a mean peak plasma concentration of 1.2–2 mg/L after 1–2 h. The apparent elimination half-life was 8 h and the volume of distribution 5.5 L/kg. With repeated doses (500 mg orally every 8 h for 10 doses), plasma concentrations were 0.72 mg/L immediately before and 0.67 mg/L at 4 h after the last dose. Absorption is not significantly affected by food. After administration of a single 375 mg tablet of flurithromycin ethylsuccinate, the mean serum levels at 0.5 h were 0.43 ± 0.35 mg/L. The mean peak serum concentration (1.41 ± 0.49 mg/L) was achieved at 1 h. At 8 and 12 h, the serum levels were 0.14 (± 0.05) and 0.04 (± 0.04) mg/L, respectively. The apparent elimination half-life is 3.94 (± 1.42) h. The apparent half-life in artificial gastric juice was about 40 min.

It is generally well tolerated and has been used successfully for the treatment of lower respiratory tract infections. Availability is limited.

OLEANDOMYCIN

A natural 14-membered-ring macrolide produced by *Streptomyces antibioticus*. It is stable in acid conditions. It is less active than erythromycin A in vitro, but four times more active than spiramycin (Table 22.1, p. 277). Several attempts have been made to improve its potency by chemical modification while retaining its relative acid stability.

It is incompletely absorbed, but an ester, triacetyloleandomycin, gives improved plasma levels. Following doses of 0.5 g, mean peak serum levels around 0.8 mg/L were reached by the base and 2 mg/L by the triacetyl ester. A single oral dose of 1 g of the ester produced a mean plasma oleandomycin concentration of 4 mg/L at 1 h after dosing, with an AUC of 14 mg.h/L. The apparent elimination half-life was 4.2 h. Significant quantities of mostly inactivated compound are eliminated in the bile. About 10% of the dose appears in the urine after administration of the base and about 20% after the ester.

Nausea, vomiting and diarrhea are common. Like erythromycin estolate, triacetyloleandomycin can cause liver damage. Abnormal liver function tests were found in about one-third of patients treated for 2 weeks. Hepatic dysfunction resolved when treatment was discontinued. The action of drugs eliminated via the cytochrome P₄₅₀ system may be potentiated.

Its uses are similar to those of erythromycin. It is of restricted availability.

GROUP 2: 16-MEMBERED-RING MACROLIDES

SPIRAMYCIN

Molecular weight (spiramycin 1): 843.

A fermentation product of *Streptomyces ambofaciens*, composed of several closely related compounds. Spiramycin 1 is the major component (c. 63%); spiramycins 2 and 3 are the acetate and monopropionate esters, respectively. It is available for oral administration and as spiramycin adipate for intravenous infusion. Spiramycins are relatively stable in acid conditions. A derivative, acetylspiramycin, is available in Japan.

ANTIBACTERIAL ACTIVITY

Activity against common pathogens is shown in Table 22.1 (p. 277). *L. pneumophila* is inhibited by 1–4 mg/L and *Campylobacter* spp. by 0.5–16 mg/L. Enterobacteriaceae are resistant. Spiramycin is also active against anaerobic species: *Actinomyces israelii* (MIC 2–4 mg/L), *Cl. perfringens* (MIC 2–8 mg/L) and *Bacteroides* spp. (MIC 4–14 mg/L). It is also active against *Tox. gondii*.

PHARMACOKINETICS

Oral absorption	Variable
C _{max} 1 g oral	2.8 mg/L after 2 h
Plasma half-life	4–8 h
Volume of distribution	383 L
Plasma protein binding	15%

In healthy volunteers given 2 g orally followed by 1 g every 6 h, peak plasma levels were 1.0–6.7 mg/L. After 1 g orally the AUC was 10.8 mg.h/L, with an apparent elimination half-life of 2.8 h. It is widely distributed in the tissues. It does not reach the CSF. Levels 12 h after a dose of 1 g were 0.25 mg/L in serum, 5.3 mg/L in bone and 6.9 mg/L in pus. Levels of 10.6 mg/L have been found 4 h after dosing in saliva, and concentrations at least equal to those in the serum are seen in bronchial secretions. A concentration of 27 mg/g was found in prostate tissues after repeated dosage. Only 5–15% is recovered from the urine. Most is metabolized, but significant quantities are eliminated via the bile, in which concentrations up to 40 times those in the serum may be found.

TOXICITY AND SIDE EFFECTS

Spiramycin is generally well tolerated, the most common adverse reactions being gastrointestinal disturbances, notably abdominal pain, nausea and vomiting, rashes and sensitization following contact.

Respiratory tract infections
Toxoplasmosis (especially in pregnancy)

Preparations and dosage

Proprietary name: Rovamycine.

Preparations: Tablets, capsules, intravenous formulation (spiramycin adipate).

Dosage: Adults, oral, 2–4 g per day in two divided doses; i.v., 0.5–1 g every 8 h. Children, oral, 50–100 mg/kg per day in divided doses.

Limited availability.

Further information

Anonymous. Spiramycin. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:S85–S88.

Davey P, Speller D, Daly PJ, eds. Spiramycin reassessed. *J Antimicrob Chemother*. 1988;22(suppl B).

OTHER GROUP 2 MACROLIDES

JOSAMYCIN

A naturally occurring antibiotic produced by *Streptomyces narbonensis* var. *josamyceticus* and belonging to the leucomycin group of macrolides. It is formulated for oral administration.

Activity is comparable to that of erythromycin A (Table 22.1, p. 277), susceptible organisms being inhibited by ≤ 2 mg/L. Many Gram-positive and Gram-negative anaerobes are susceptible, including *Peptostreptococcus* spp., *Propionibacterium* spp., *Eubacterium* spp. and *Bacteroides* spp.

After a single 1 g oral dose, a peak serum concentration of 2.74 mg/L was achieved 0.75 h after dosing. The AUC was 4.2 mg.h/L, and the apparent elimination half-life 1.5 h. Several inactive metabolites could be detected. It penetrates into saliva, tears and sweat, and achieves high levels in bile and lungs. It is mostly metabolized and excreted in the bile in an inactive form. Less than 20% of the dose appears in the urine, producing levels of around 50 mg/L.

The drug is generally well tolerated, producing only mild gastrointestinal disturbance. Its uses are similar to those of erythromycin. It is of limited availability.

Further information

Chabbert YA, Modai J. Perspectives josamycine – Symposium International du 16–18 mai 1985, Lisboes. *Médecine et Maladies Infectieuses*. 1985;(suppl).

KITASAMYCIN (LEUCOMYCIN)

A naturally occurring product of *Streptomyces kitasatoensis*, available in Japan for parenteral and oral use, and as acetylkitasamycin for topical application. Elsewhere it is chiefly used in veterinary medicine.

MIDECAMYCIN

A naturally occurring metabolite of *Streptomyces mycarofaciens*, supplied as the native compound and as midecamycin acetate for oral administration.

The antibacterial spectrum is comparable to that of erythromycin A, but it is less active (Table 22.1, p. 277). It is rapidly and extensively metabolized and is said to exhibit less toxicity than earlier macrolides. It is of limited availability.

Further information

Neu HC. In vitro activity of midecamycin, a new macrolide antibiotic. *Antimicrob Agents Chemother*. 1983;24:443–444.

MIOKAMYCIN

A semisynthetic diacetyl derivative of midecamycin A₁. It is generally less active than erythromycin and some strains of *H. influenzae* and *E. faecalis* are resistant. It is rapidly and extensively metabolized, though some metabolites retain antibacterial activity.

Absorption of the dry formulation is unaffected by food, whereas that of the oral suspension is delayed. In various studies the peak plasma concentration was 1.65, 1.31–3 and 1.3–2.7 mg/L after doses of 400, 600 and 800 mg, respectively.

It is said to exhibit less toxicity than earlier macrolides. Attention has been paid to its interaction with theophylline, which resembles that of other macrolides. It is of limited availability.

ROKITAMYCIN

3-Propionyl leucomycin A₅. A semisynthetic macrolide. Unstable in acid media.

The antibacterial spectrum is identical to that of erythromycin, but it is less active against Gram-positive cocci. It is poorly active against *H. influenzae* (MIC_{50} 8 mg/L) and *Mor. catarrhalis* (MIC_{50} 4 mg/L). It displays good activity against *Campylobacter* spp. (MIC_{50} 0.1 mg/L), *L. pneumophila* (MIC_{50} 0.1 mg/L) and *M. pneumoniae* (MIC_{50} 0.003 mg/L). It is active

against anaerobes, including some *Bacteroides* spp. ($\text{MIC}_{50} < 0.05 \text{ mg/L}$).

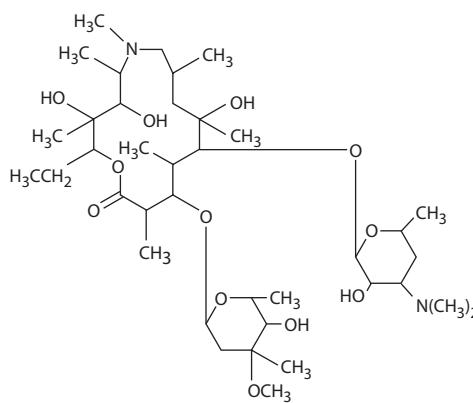

After a single oral dose of 600 mg, the peak plasma concentration was 1.9 mg/L after 0.6 h. Oral doses of 5, 10 and 15 mg/kg of a syrup formulation given to children achieved plasma concentrations of 0.26, 0.55 and 0.79 mg/L, respectively, after about 40 min. The half-life is around 2 h.

It is mainly eliminated in the bile; only about 2% appears in the urine. Its major metabolites are leucomycin A₇, 10"-OH-rokitamycin (which show some antibacterial activity) and leucomycin V. In healthy adult volunteers, the proportions of rokitamycin and its metabolites in serum 30 min after a single oral dose of 1200 mg were 18% (leucomycin A₇), 33% (10"-OH-rokitamycin) and 9% (leucomycin V). The pharmacokinetic behavior is not altered in patients with liver cirrhosis. It is available in Italy and Japan.

GROUP 3: AZALIDES

AZITHROMYCIN

Molecular weight (dihydrate): 785.

A semisynthetic derivative of erythromycin A, supplied as the dihydrate for oral administration.

ANTIBACTERIAL ACTIVITY

Activity in vitro against common bacterial pathogens is shown in Table 22.1 (p. 277). It is less potent than erythromycin A against Gram-positive isolates, but is more active against Gram-negative bacteria. It is four times more potent than erythromycin A against *H. influenzae*, *N. gonorrhoeae* and *Campylobacter* spp., and twice as active against *Mor. catarrhalis*. It also exhibits superior potency against Enterobacteriaceae, notably *Esch. coli*, *Salmonella enterica* serotypes, and *Shigella* spp. It is active against *Mycobacteria*, notably the *M. avium* complex and against intracellular micro-organisms such as *Legionella* and *Chlamydia* spp.

PHARMACOKINETICS

Oral absorption	37%
C_{\max} 250 mg oral	0.17 mg/L after 2.2 h
500 mg oral	0.4 mg/L after 2 h
Plasma half-life (terminal)	11–40 h
Volume of distribution	31 L/kg
Plasma protein binding	7–50%

Chemical modification at the 9 position of the erythronolide A ring of erythromycin A blocks the internal ketalization and markedly improves acid stability. At pH 2, loss of 10% activity occurred in less than 4 s with erythromycin A, but took 20 min with azithromycin. The AUC at 0–24 h is 4.5 mg.h/L. The level is only slightly increased on repeated dosing.

Binding to plasma protein varies with the concentration, from around 50% at 0.05 mg/L to 7.1% at 1 mg/L. The apparent elimination half-life is dependent upon sampling interval: between 8 and 24 h it ranged from 11 to 14 h; between 24 and 72 h it was 35–40 h.

It rapidly penetrates the tissues, reaching levels that approach or, in some cases, exceed the simultaneous plasma levels and persist for 2–3 days. Only about 6% of the dose is found in urine in the first 24 h.

TOXICITY AND SIDE EFFECTS

Azithromycin is well tolerated with little gastrointestinal disturbance.

Lower and upper respiratory tract infections
Skin and soft-tissue infections
Uncomplicated urethritis/cervicitis associated with <i>N. gonorrhoeae</i> , <i>C. trachomatis</i> or <i>U. urealyticum</i>
Trachoma

Preparations and dosage

Proprietary name: Zithromax.

Preparations: Capsules, tablets, suspension.

Dosage: Adults, oral, 500 mg per day for 3 days. Children >6 months, 10 mg/kg per day for 3 days; 15–25 kg, 200 mg per day for 3 days; 26–35 kg, 300 mg per day for 3 days; 36–45 kg, 400 mg per day for 3 days. Widely available.

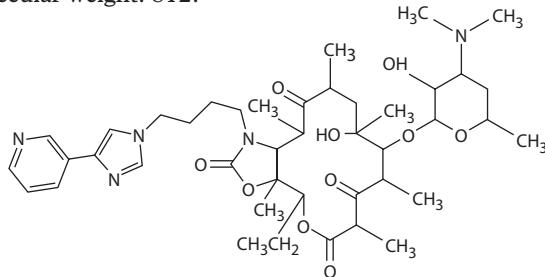

Further information

Anonymous. Azithromycin. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:A261–A265.
Leigh DA, Ridgway GL, Leeming JP, Speller DCE. Azithromycin (CP 62,993): the first azalide antimicrobial agent. *J Antimicrob Chemother*. 1990;25(suppl A).

GROUP 4: KETOLIDES

TELITHROMYCIN

Molecular weight: 812.

A 14-membered-ring ketolide, obtained by semisynthesis from erythromycin A. Formulated for oral administration.

ANTIBACTERIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 22.1 (p. 277). The spectrum covers Gram-positive and Gram-negative cocci, Gram-positive bacilli, fastidious Gram-negative bacilli, atypical mycobacteria, *M. leprae*, *H. pylori*, anaerobes, *T. pallidum*, intracellular pathogens and atypical organisms.

It exhibits bactericidal activity in vitro against isolates of *Str. pneumoniae* regardless of the underlying resistance to penicillin G, erythromycin A and other agents. It is 2–4 times more active than clarithromycin against erythromycin A-susceptible isolates of *Str. pneumoniae* and other streptococci. Against *H. influenzae* the MIC range is 1–4 mg/L. It also exhibits good in-vitro activity against *Coxiella burnetii* (MIC 1 mg/L) and various Gram-positive species, including viridans streptococci (MIC \leq 0.015–0.25 mg/L), *C. diphtheriae* (MIC 0.004–0.008 mg/L) and *Listeria* spp. (MIC 0.03–0.25 mg/L).

ACQUIRED RESISTANCE

It retains activity against isolates resistant to erythromycin A, *Str. pneumoniae* and *Str. pyogenes* isolates for which the MIC of telithromycin is above the resistance breakpoint of 2 mg/L are presently rare. It is not active against *Staph. aureus* isolates that owe their resistance to erythromycin to constitutive methylation of adenine 2058 on domain V of the peptidyl transferase loop.

PHARMACOKINETICS

Oral absorption	90%
C_{\max} 800 mg oral	1.9–2.27 mg/L (steady state after 2–3 days)
Plasma half-life	10–12 h
Volume of distribution	210 L
Plasma protein binding	60–70%

After oral administration the absolute bioavailability is 57% in both young and elderly subjects. The rate and extent of absorption are not influenced by food. In a study of ascending doses administered to healthy volunteers, peak plasma concentration ranged from 0.8 mg/L (400 mg dose) to 6 mg/L (2400 mg dose). The peak plasma concentration was reached after 1–2 h. The apparent elimination half-lives ranged from 10 to 14 h, with an AUC of 2.6 mg.h/L (400 mg dose) to 43.3 mg.h/L (2400 mg dose). After repeated oral doses the ratios between day 1 and day 10 ranged from 1.3 to 1.5. After once-daily oral dosing with 800 mg, the AUC is 8.25 mg.h/L. Concentrations in alveolar macrophages, epithelial lining fluid and bronchial tissue are shown in Table 22.5.

TOXICITY AND SIDE EFFECTS

It is generally well tolerated. The main adverse event is diarrhea.

Lower and upper respiratory tract infections in adult patients (community-acquired pneumonia, acute exacerbations of chronic bronchitis, acute bacterial maxillary sinusitis and pharyngitis)

Preparations and dosage

Proprietary name: Ketek.

Preparation: Tablet (400 mg).

Dosage: Adults, oral, 800 mg per day.

Widely available.

Table 22.5 Telithromycin concentration in respiratory tissue (800 mg oral daily dose)

	Mean concentrations (mg/L)			
	2–3 h	6–8 h	12 h	24 h
Epithelial lining fluid	5.4–14.9	4.2	3.3	0.8–1.2
Alveolar macrophages	65–69	100	3.8	41–162
Bronchial tissues	0.68–3.9	2.2	1.4	0.7
Tonsils	3.95	–	0.9	0.7

OTHER KETOLIDES

CETHROMYCIN (ABT 773)

A semisynthetic derivative of erythromycin A. It is a C11–C12 carbamate ketolide and has an unsaturated chain with a quinoline ring at the C-6 position. It has the same antibacterial spectrum as telithromycin and exhibits comparable activity against respiratory tract pathogens (Table 22.2, p. 277). Erythromycin-susceptible *Staph. aureus* strains are inhibited by 0.015–0.06 mg/L irrespective of susceptibility to methicillin.

The apparent elimination half-life ranges from 3.6 to 6.7 h. In an escalating oral dose study, the peak plasma concentration ranged from 0.14 mg/L (100 mg dose) to 1.2 mg/L (1200 mg dose) after 0.5–5.1 h. The AUC ranged from 0.63 mg.h/L (100 mg dose) to 11.0 mg.h/L (1200 mg dose) with a total clearance of 183–254 L/h.

Clinical efficacy in respiratory tract infections is under investigation.

MODITHROMYCIN (EDP 420)

A bicyclolide ketolide with a 9-substituted oxime group and a bicyclic substituted (pyridine and imidazole rings) bridge between position 6 and position 11 of the lactone ring. It exhibits good antipneumococcal activity (MIC 0.008–0.25 mg/L). Typical MICs for *Staph. aureus* are 0.125–32 mg/L and for

H. influenzae 1–64 mg/L. In-vitro activity against intracellular pathogens (*Legionella*, *Chlamydophila* spp.) and atypical pathogens such as *M. pneumoniae* is good. Gram-positive cocci resistant to erythromycin A by an efflux mechanism remain susceptible; those resistant by methylation (*erm* gene) exhibit variable susceptibility.

After a single oral ascending dose to healthy volunteers, the peak plasma concentrations were c. 0.2 mg/L (100 mg dose) and 1 mg/L (1200 mg dose) after 1.75–5 h (average 3 h). The lag time between administration and first detection in plasma was about 0.25 h. The apparent elimination half-life is around 15 h. Approximately 6–12% of the administered dose is eliminated in urine.

CEM 101

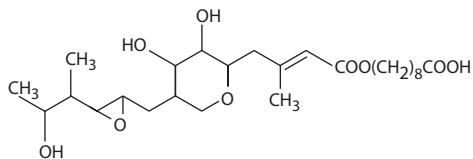

A 2-fluoroketolide. The side chain substituting the C11–C12 carbamate is composed of a substituted triazolyl (amino-phenyl) ring. It displays good in-vitro and in-vivo activity against *Streptococcus* spp., including *Str. pneumoniae* (MIC 0.0015–0.25 mg/L), *Str. pyogenes* (MIC ≤0.008–0.015 mg/L) and viridians group streptococci (MIC ≤0.008–0.06 mg/L). Activity against *H. influenzae* is close to that of azithromycin (MIC 1.0–2.0 mg/L). Vancomycin-susceptible strains of *E. faecalis* are inhibited by 0.003–2.0 mg/L and *E. faecium* by 0.25–2.0 mg/L. It exhibits good activity against *Ch. pneumoniae* (MIC 0.25–1.0 mg/L), *C. trachomatis* (MIC 0.123–0.5 mg/L) and *Mycoplasma* spp. (MIC ≤0.0008 mg/L). In vitro *H. pylori* is susceptible (MIC 0.006–0.25 mg/L), but *C. jejuni* less so (MIC 1–4 mg/L). It is extremely active in vitro against *B. anthracis* (MIC <0.008–0.015 mg/L) and other agents of bioterrorism such as *Francisella tularensis* (MIC <0.08–4.0 mg/L), *Yersinia pestis* and *Burkholderia mallei* (MIC 0.25–2.0 mg/L). It exhibits a good activity against the *M. avium* complex.

In healthy adult volunteers the proposed therapeutic dose of 400 mg achieved a peak plasma concentration of 0.78 mg/L after 4 h. The apparent elimination half-life was 5.1 h.

23 Mupirocin

Adam P. Fraise

Mupirocin is an antimicrobial substance originally derived from *Pseudomonas fluorescens*. It is a mixture of pseudomonic acids with more than 90% of the commercial product being pseudomonic acid A:

It has activity predominantly against Gram-positive bacteria and its main use is as a topical agent for the eradication of carriage of methicillin-resistant *Staphylococcus aureus* (MRSA). It is also used as a topical treatment for superficial skin infections caused by Gram-positive organisms such as impetigo.

ANTIMICROBIAL ACTIVITY

Activity against common pathogens is shown in Table 23.1. It is active against staphylococci and streptococci, but also *Neisseria* and *Haemophilus* spp. *Enterococcus faecalis* tends to be sensitive whereas *E. faecium* is usually resistant. Activity against *Staph. aureus* is affected by inoculum such that a 10-fold increase in the inoculum causes doubling of the minimum inhibitory concentration (MIC) in vitro. Activity also decreases as pH increases above the normal skin pH of 5.5.

ACQUIRED RESISTANCE

Before the introduction of mupirocin, resistance in *Staph. aureus* was uncommon, with a natural mutation frequency of 1 in 10^9 . However, shortly after the agent was introduced, mupirocin-resistant strains began to emerge. They are of two types: low level (MIC 8–256 mg/mL) and high level (MIC >256 mg/mL).

Table 23.1 Activity of mupirocin against some common pathogenic bacteria: MIC (mg/L)

Species	MIC
<i>Staphylococcus aureus</i> (including MRSA)	0.01–0.25
Coagulase-negative staphylococci	0.01–4.0
<i>Streptococcus pyogenes</i>	0.06–0.5
<i>Str. pneumoniae</i>	0.06–0.5
<i>Enterococcus faecalis</i>	16–R
<i>E. faecium</i>	1.0–4.0
<i>Neisseria gonorrhoeae</i>	0.03–0.25
<i>N. meningitidis</i>	0.03–0.25
<i>Haemophilus influenzae</i>	0.003–0.25
<i>Enterobacter</i> spp.	R
<i>Pseudomonas aeruginosa</i>	R
<i>Bacteroides fragilis</i>	R

R, resistant (MIC >64 mg/L).

Low-level resistance appears to be due to mutations in the target enzyme, isoleucyl-tRNA synthetase (see p. 16); it is probably not transmissible and seems of little clinical significance as these strains respond to standard treatment.

High-level resistance, in contrast, is linked to the acquisition of a transmissible resistance gene *MupA* that may co-transfer with other antimicrobial resistance genes. Strains that express *MupA* are not clinically susceptible to mupirocin.

Several studies suggest that widespread use of prophylactic mupirocin may result in increased levels of resistance. In Canada increasing use of mupirocin across the country led to high-level mupirocin resistance, rising from 1.6% to 7% over a 9-year period.

PHARMACOKINETICS

Following parenteral administration, mupirocin is rapidly destroyed by non-specific esterases (possibly in renal or liver tissues since it is reasonably stable in blood) to inactive monic acid and its conjugates. It is strongly protein bound. About 0.25% is absorbed from intact skin. The skin ointment, but not the cream, contains polyethylene glycol, which may be absorbed significantly when applied to open wounds or damaged skin, including burns.

TOXICITY AND SIDE EFFECTS

Topical applications are well tolerated. Conjunctival application is contraindicated as it may cause irritation. Minor side effects such as irritation and unpleasant or abnormal taste have been recorded for very few patients following nasal application.

Polyethylene glycol from the ointment base may, if absorbed from application to open wounds or damaged skin, cause renal toxicity.

CLINICAL USE

Mupirocin is mainly used as a nasal cream as part of the regimen to decolonize patients who have been found to carry methicillin-resistant *Staph. aureus*. It can also be applied to tracheostomy, gastrostomy and other sites that are frequently colonized with MRSA.

The use of mupirocin as a means of controlling outbreaks of infection due to MRSA appears to be of only marginal benefit in an endemic situation.

A Cochrane Review of nine randomized controlled trials of use of mupirocin to prevent subsequent *Staph. aureus* infections in nasal carriers of the organism found a statistically significant reduction in such infections at any site.

A small study of local therapy to reduce the risk of peritonitis in patients on continuous ambulatory peritoneal dialysis (CAPD) found that mupirocin applied three times weekly to the dialysis catheter exit site resulted in a 92% reduction in the rate of peritonitis.

Preparations and dosage

Proprietary name: Bactroban.

Preparations: 2% mupirocin as ointment, cream or nasal ointment.

Dosage: Topical application, up to three times daily for a maximum of 10 days. Nasal application, up to three times daily for 3–5 days.

Widely available.

CHAPTER

24 Nitroimidazoles

Peter J. Jenks

An imidazole ring is an important feature of many natural compounds with a wide range of biological activities. Nitroimidazoles with antimicrobial activity emerged from a search for a drug that would provide an effective treatment for infections caused by protozoa of the *Trichomonas* genus, including the human pathogen, *Trichomonas vaginalis*. The first active compound was an antibiotic, azomycin (2-nitroimidazole) produced by a streptomycete. It was soon abandoned, but led to the synthesis of several hundred related compounds, one of which, the 5-nitroimidazole metronidazole, combined activity against the parasites with acceptable animal toxicity. The compound was marketed in 1960 and 2 years later was fortuitously found also to possess potent activity against anaerobic bacteria.

Numerous 5-nitroimidazoles were subsequently developed. Metronidazole and tinidazole are in widespread clinical use; others include nimorazole, ornidazole and secnidazole. The 2-nitroimidazole, benznidazole, is uniquely used in the treatment of South American trypanosomiasis (Chagas disease); fexinidazole is under investigation in African trypanosomiasis (sleeping sickness). Carnidazole, dime-tridazole, ipronidazole and ronidazole are used in veterinary medicine and are not discussed further here.

Other imidazole derivatives are used as antifungal agents (Chapter 32) and anthelmintics (Chapter 34). Some, chiefly 2-nitroimidazoles, have been examined as possible radiosensitizers for the treatment of hypoxic tumors.

ANTIMICROBIAL ACTIVITY**BACTERIA**

The 5-nitroimidazoles exhibit excellent potency against anaerobic bacteria (Table 24.1), including *Bacteroides* spp., *Clostridium* spp., *Prevotella* spp. and *Fusobacterium* spp. Most isolates of *Mobiluncus curtisi* are resistant to metronidazole and its hydroxy metabolite, while *Mobiluncus mulieris* is often sensitive. Other susceptible bacteria include *Capnocytophaga* spp. and *Campylobacter fetus*. Most *Actinomyces* and

Propionibacterium spp. are resistant. Among facultative anaerobes, *Actinobacillus actinomycetemcomitans* and *Eikenella corrodens* are usually resistant, while *Gardnerella vaginalis* is frequently sensitive, more so to the hydroxy metabolite of metronidazole.

PROTOZOA

Susceptible protozoa include *T. vaginalis*, *Giardia lamblia*, *Entamoeba histolytica*, *Balantidium coli* and *Blastocystis hominis*. The spectrum of benznidazole is restricted to *Trypanosoma cruzi*.

FACTORS AFFECTING ACTIVITY IN VITRO

All nitroimidazoles exert their antimicrobial activity via reduction of the nitro group, which only occurs at low redox potentials. The major factor affecting in-vitro activity is therefore the failure to achieve anaerobic conditions, which can lead to reporting of false resistance. The presence of traces of oxygen may inhibit or reverse reduction of the drug through 'futile cycling'. It is essential, therefore, to ensure that fully anaerobic conditions are maintained during susceptibility testing.

All nitroimidazoles are capable of being photodegraded and should be protected from light.

ACQUIRED RESISTANCE**PROTOZOA**

While resistant strains of *E. histolytica* and *T. vaginalis* are rarely encountered, up to 20% of *G. lamblia* isolates may be resistant in general clinical practice. Although resistance rates of *T. vaginalis* are low, millions of cases of infection occur each

Table 24.1 Activity of nitroimidazoles against anaerobic bacteria: MIC (mg/L)

	Metronidazole	Ornidazole	Tinidazole
<i>Bacteroides fragilis</i>	0.5–4	<0.1–4	0.1–4
<i>B. melaninogenicus</i>	<0.1	<0.1	<0.1
<i>Fusobacterium</i> spp.	<0.1–1	<0.1–1	0.1–2
<i>Clostridium perfringens</i>	0.25–2	0.25–2	0.25–2
<i>Peptococcus</i> and <i>Peptostreptococcus</i> spp.	<0.1–4	<0.1–2	<0.1–2
<i>Veillonella</i> spp.	1–2	0.5–1	0.5–2
<i>Eubacterium</i> spp.	0.5–2	0.5–1	0.5–2
<i>Propionibacterium</i> spp.	R	R	R

R, resistant (MIC >16 mg/L).

year and the number of treatment failures due to resistance is significant. The minimum inhibitory concentration (MIC) of metronidazole for strains of *T. vaginalis* from refractory vaginitis is frequently 3–8 times the value for susceptible strains.

The development of high-level resistance is frequently multifactorial and many protozoa develop nitroimidazole resistance either by reducing or by abolishing activity of elements of the electron transport reactions, particularly ferredoxin oxidoreductase (FOR) and ferredoxin, with appropriate compensatory modifications of the normal fermentative pathway. Reduced or abolished FOR activity and decreased transcription of the ferredoxin gene resulting in decreased levels of a functional pyruvate:ferredoxin oxidoreductase (PFOR) system have been reported in both *Trichomonas* and *Giardia* spp. The consequences are that pyruvate oxidation is diverted to alternative pathways which favor the formation of lactate (in *T. vaginalis*) or ethanol (in *T. fetus*). Decreased levels of the PFOR system with compensatory changes in the electron transport chain are also associated with resistance in *Giardia* spp.

Increased expression of superoxide dismutase without a reduction of PFOR activity has been reported in metronidazole-resistant ameba and appears to contribute to the resistant phenotype, rather than being the result of a general stress response.

BACTEROIDES AND CLOSTRIDIUM SPP

Reduced susceptibility to metronidazole and other nitroimidazoles has been described in *B. fragilis*, *B. distasonis* and *B. bivius*. Mechanisms such as reduced uptake of nitroimidazoles, reduced nitroreductase activity or decreased PFOR activity have been proposed. Reduction in PFOR activity is compensated by increased pyruvate dehydrogenase activity, and results in reduced activation and hence uptake of

nitroimidazoles. Resistance in *Bacteroides* spp. may also be associated with specific nitroimidazole (nim) resistance genes that can be either plasmid or chromosomally encoded. These are thought to encode a nitroimidazole reductase which converts nitroimidazole to aminoimidazole, preventing formation of bactericidal nitroso residues.

Metronidazole-resistant strains of clostridia have not been reported clinically, but a laboratory strain of *Clostridium perfringens* made resistant by mutation possessed decreased levels of PFOR.

HELICOBACTER SPP

Most nitroimidazole-resistant strains of *H. pylori* contain mutations within the gene encoding the oxygen-insensitive NADPH nitroreductase, RdxA. This usually arises by de-novo mutation of the *rdaA* gene, but resistance transfer may occur in patients infected with two strains of *H. pylori*.

Inactivation of other reductase-encoding genes, including *frxA* (which encodes NADPH flavin oxidoreductase) and *fxbA* (which encodes a ferredoxin-like protein), are also occasionally associated with resistance to metronidazole. Mutations in these genes often result in transition to high-level resistance once inactivation of the *rdaA* gene has occurred, but resistance may also arise as a result of inactivation of *frxA* alone.

Other mechanisms of metronidazole resistance may remain to be discovered in *H. pylori*. These are most likely to involve inactivation of other nitroreductase enzyme-encoding genes, but mutations affecting membrane transport and DNA repair may also contribute to the resistant phenotype. Combinations of these factors are likely to account for wide interstrain differences in susceptibility of *H. pylori*.

PHARMACOKINETICS

Nitroimidazoles are generally well absorbed following oral administration. Following rectal or vaginal administration, bioavailability is approximately 60% and 20%, respectively, with considerable variation between individuals. Binding to proteins is low. Peak plasma levels are achieved 3–5 h after an oral dose. The decay from the peak is exponential, with the rate depending on the half-life of the drug. Dose-proportional kinetics are observed for clinically relevant doses. The concentrations after normal oral doses are well above the MICs for anaerobes but are borderline for *G. vaginalis*. The nitroimidazoles are well distributed to peripheral compartments, including brain tissue and cerebrospinal fluid, but concentrations in subcutaneous fat are 15% or less of concurrent serum levels.

Nitroimidazoles are metabolized mainly by the liver and excreted in the urine. Derivatives with a 2-methyl group (except nimorazole) are metabolized to the corresponding methoxy derivative and those with an alcohol side chain are metabolized to the corresponding acid metabolite. All can form glucuronide conjugates and, occasionally, the ethereal sulfate conjugate.

TOXICITY AND SIDE EFFECTS

The most common side effects are gastrointestinal (including nausea and diarrhea) and a metallic taste, especially when high doses are used. A reversible peripheral neuropathy may occur in patients receiving high doses for prolonged periods, particularly in the treatment of hypoxic tumors. Central neurotoxicity has also been reported and the drug should be discontinued if any abnormal neurological symptoms are reported. If combined with alcohol, metronidazole may cause a disulfiram-like reaction, with nausea, vomiting, flushing of the skin, tachycardia, hypotension and palpitations.

Although nitroimidazoles have been found to be mutagenic and carcinogenic in animal studies, there is no evidence that they are carcinogenic to humans. Nevertheless, they should only be used in pregnancy when the benefits outweigh the risks, and should be avoided altogether in the first trimester. Because the concentrations in breast milk are similar to those in serum, a risk assessment should be performed before use in lactating mothers.

CLINICAL USE

Nitroimidazoles are the most active antibiotics for the treatment and prevention of infections involving anaerobic bacteria. They are therefore important in the treatment of intra-abdominal and gynecological sepsis, abscesses and specific clinical syndromes such as tetanus. They are also an important component of prophylactic regimens for surgical procedures where contamination with anaerobic flora is likely. They are used to treat bacterial vaginosis (frequently associated with *G. vaginalis*) and dental infections, including acute necrotizing ulcerative gingivitis (Vincent's angina). Metronidazole is the treatment of choice for antibiotic-associated diarrhea caused by *C. difficile* for all but those with recurrent, complicated or fulminant disease, for whom oral vancomycin is recommended. Metronidazole and tinidazole are also used as part of eradication regimens for *H. pylori*, although resistance may affect 10–50% of strains isolated in developed countries and virtually all strains from developing countries.

The nitroimidazoles provide the first-line treatment for giardiasis, amebiasis and trichomonal vaginitis, and may also be used to treat balantidiasis. Benznidazole is used for the treatment of *Trypanosoma cruzi* infections (Chagas disease).

These drugs have also been used as hypoxic cell sensitizers in the radiotherapy of tumors, in the treatment of bacterial overgrowth syndromes and in the prevention of recurrence of Crohn's disease.

BENZNIDAZOLE

Molecular weight: 260.26.

A synthetic 2-nitroimidazole, formulated for oral administration. Solubility in water 400 mg/L.

ANTIMICROBIAL ACTIVITY

It exhibits antiprotozoal activity, particularly against *Trypanosoma cruzi*.

PHARMACOKINETICS

Oral bioavailability	High
C_{\max} 100 mg oral	2.2–2.8 mg/L after 3–4 h
Plasma half-life	10.5–13.6 h
Volume of distribution	c. 0.56 L/kg
Plasma protein binding	c. 44%

The 2-nitro group undergoes reduction to the amine and hydrolysis to the hydroxy derivative.

TOXICITY AND SIDE EFFECTS

Adverse effects are more common in the elderly and include nausea, vomiting, abdominal pain, peripheral neuropathy and severe skin reactions.

CLINICAL USE

Benznidazole is used in treatment of South American trypanosomiasis (Chagas disease).

Preparations and dosage

Preparation: Tablets.

Dosage: Adults, 5–10 mg/kg per day for 30–60 days. Children, 5–10 mg/kg per day for 30–60 days.

Available in South America.

zoa include *T. vaginalis*, *G. lamblia*, *E. histolytica*, *Balanitidium coli* and *Blastocystis hominis*, which are inhibited by concentrations of 0.2–0.25 mg/L. *Clostridium* spp. (including *C. difficile*) are inhibited at concentrations of 0.5–8 mg/L. It is also active against the microaerophilic *H. pylori* (MIC for susceptible strains <8 mg/L). The 2-methoxy metabolite of metronidazole is more active (MIC about 0.3 mg/L), but the acid metabolite shows less activity than the parent drug (MIC about 3 mg/L). *G. vaginalis* shows similar susceptibility (MIC 1–8 mg/L); the methoxy metabolite is more active (MIC 0.02–2 mg/L).

ACQUIRED RESISTANCE

Although resistance in *Bacteroides* spp. and *T. vaginalis* is well documented, it is uncommon. Resistance occurs more frequently in *H. pylori* and failure of treatment with triple drug regimens may be associated with resistance to the metronidazole component.

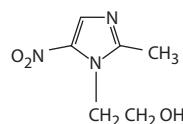

PHARMACOKINETICS

Oral absorption	>90%
C_{max} 400 mg oral	c. 10 mg/L after 3–5 h
Plasma half-life	6–11 h
Volume of distribution	0.6–1.1 L/kg
Plasma protein binding	<20%

METRONIDAZOLE

Molecular weight (free compound): 171.16; (hydrochloride): 207.6; (benzoate): 275.3.

A 5-nitroimidazole available for oral administration or as a suppository; also formulated as the hydrochloride for intravenous use, and as the benzoate in an oral suspension and a dental gel. Aqueous solubility: 10 g/L at 20°C. Soluble in dilute acids. It is photolabile and preparations should be protected from light. Metronidazole hydrochloride has a low pH (0.5–2.0) when reconstituted, and reacts with aluminum in equipment, including needles, to produce a reddish-brown discolouration. It is incompatible with several agents and other drugs should not be added to intravenous solutions.

ANTIMICROBIAL ACTIVITY

It is a potent inhibitor of obligate anaerobic bacteria (Table 24.1, p. 293) and protozoa, but not of any organism that is aerobic or incapable of anaerobic metabolism. Susceptible proto-

Absorption

Peak plasma concentrations after oral administration are proportional to the dose. Plasma levels are usually lower in men because of weight differences. In patients treated intravenously with a loading dose of 15 mg/kg followed by 7.5 mg/kg every 6 h, peak steady state plasma concentrations averaged 25 mg/L with minimum trough concentrations averaging 18 mg/L.

The bioavailability of metronidazole in rectal suppositories is around 60%. Effective blood concentrations occur 5–12 h after the first suppository and are maintained by an 8 h regimen.

There are conflicting data on the effects of age on absorption. One study, which did not distinguish between metronidazole and its metabolites, indicated that the area under the curve (AUC) for plasma was almost doubled in the elderly. However, the general consensus is that there is no requirement for a decreased dosage for the elderly, unless there is significant renal impairment.

Distribution

It is widely distributed in body tissues after oral or intravenous administration. It appears about 90 min after an oral dose in brain tissue, cerebrospinal fluid (CSF), saliva and breast milk in concentrations similar to those found in plasma; and in

vaginal secretions, pleural and prostatic fluid at levels about 40% of those of the plasma. In patients receiving 500 mg every 12 h or 1 g every 6 h, CSF levels of up to 2 and 8 mg/L, respectively, have been found. Bactericidal concentrations of metronidazole are achieved in pus from hepatic abscesses. Concentrations in placenta and fetal tissue are related to the corresponding maternal plasma levels: concentrations of 3.5 mg/kg (placenta) and 9 mg/kg (fetus) when the plasma concentration was 13.5 mg/L.

Metabolism

It is metabolized in the liver to a glucuronide conjugate and to acid and hydroxy derivatives. The acid metabolite, produced by oxidation of the N-1 ethanol side-chain, is microbiologically inactive and appears in the urine because of its high water solubility. The hydroxy derivative, which is as active as the parent drug against *G. vaginalis*, is formed by oxidation of the methyl group on C-2 of the imidazole ring, first to the hydroxymethyl derivative and subsequently to the carboxylic acid. Hydroxymetronidazole has a half-life of 10–13 h. Both metronidazole itself and the hydroxymethyl metabolite can form sulfate or glucuronide conjugates; the acid metabolite may be excreted as the glycine conjugate. Traces of metabolites derived from reduction of the nitro group are found in urine and are assumed to be formed by the intestinal flora.

Excretion

About 60–80% of the dose appears in the urine and 6–15% in the feces. The hydroxy and acid metabolites are also excreted in the urine. Glucuronide conjugates account for approximately 20% of the total. Renal clearance is approximately 10 mL/min per 1.73 m². Decreased renal function does not alter the single-dose kinetics and dose adjustment is not normally required in patients with renal impairment. However, the hydroxy metabolite may accumulate in patients with end-stage disease and dose reduction may be necessary. Elimination is prolonged in patients with impaired liver function necessitating dose reduction. Hemodialysis increases the clearance of metronidazole, shortening the half-life to 2–3 h.

Newborn infants possess a decreased capacity to eliminate metronidazole. In one study, the elimination half-life measured during the first 3 days of life was inversely related to gestational age. In premature newborns and infants whose gestational ages were between 28 and 40 weeks, the corresponding half-life elimination rates ranged from 10.9 to 22.5 h.

TOXICITY AND SIDE EFFECTS

Precautions

Alcohol should not be taken during and for 48 h after therapy because of a possible disulfiram-like reaction, nor should it be combined with formulations containing alcohol. It should not be given in cases of known hypersensitivity to nitroimidazoles.

It enhances the anticoagulant effect of warfarin and may impair the clearance of phenytoin and lithium. Phenytoin may increase the metabolism of metronidazole. Plasma concentrations are decreased by the concomitant administration of phenobarbital (phenobarbitone). The drug may also mask the immunological response of untreated early syphilis cases because of its antitreponemal activity.

It should be used with care in patients with blood dyscrasias or with any central nervous system (CNS) disease.

The drug should be avoided in pregnancy, especially during the first trimester and particularly if high doses are being administered. Use during the second and third trimesters may be acceptable if alternative therapies for trichomoniasis have failed, but single-dose (2 g oral) therapy should be avoided. The drug may cause the breast milk to taste bitter. Breast feeding should be discontinued until 24 h after the last dose to allow excretion of the drug. It appears safe when given to nursing mothers at doses of up to 400 mg every 8 h.

Adverse effects

An unpleasant sharp, metallic taste is not unusual. Furry tongue, glossitis and stomatitis have occurred; stomatitis may be associated with overgrowth of *Candida* spp. during treatment. Gastrointestinal disturbances include nausea, vomiting, abdominal discomfort and diarrhea, and occur with intravenous and oral preparations. Pseudomembranous colitis has also been reported.

Nervous system effects associated with intravenous and oral preparations include convulsive seizures, peripheral neuropathy, dizziness, vertigo, incoordination, ataxia, confusion, irritability, depression, weakness and insomnia. Peripheral neuropathy was found in 11 of 13 patients aged 12–22 years treated for Crohn's disease. The symptoms disappeared when the dose was discontinued or markedly reduced. Peripheral neuropathy or CNS toxicity is more likely in patients treated for 10 days or more and treatment should be discontinued. The co-administration of cimetidine increases plasma levels of metronidazole and may increase the risk of neurological side effects.

Reversible neutropenia has been reported after administration of both intravenous and oral preparations. Bone marrow aplasia and thrombocytopenia are rare. Hemolytic uremic syndrome was reported in six children who had been given metronidazole for non-specific diarrhea or for prophylaxis after bowel surgery.

Erythematous rash and pruritus have been reported after use of the intravenous preparation. The risk of thrombophlebitis can be minimized by avoiding prolonged indwelling catheters for intravenous infusion.

Rarely, flattening of the T wave may be seen in electrocardiographic tracings. A number of cases of deafness have been reported. Myopia related to 11 days' oral treatment for trichomoniasis disappeared 4 days after treatment was stopped, but returned when treatment was resumed. There have been isolated reports of pancreatitis and gynecomastia.

Mutagenicity and carcinogenicity

Metronidazole and some of its metabolites are weakly mutagenic by the Ames test, but only under anaerobic or microaerophilic conditions that lead to reduction of the nitro group, an essential prerequisite for its bactericidal action. Other mutagenicity and genotoxicity studies in experimental animals and in-vitro tests of human cells have proved negative.

Several large studies have found no increase in the incidence of cancer.

CLINICAL USE

Trichomonal vaginitis, giardiasis and amebiasis
Treatment and prophylaxis of anaerobic infections
Acute necrotizing ulcerative gingivitis (Vincent's stomatitis)
Bacterial vaginosis
C. difficile-associated disease
Gastric colonization with *H. pylori* (in combination with other agents)
Surgical prophylaxis (abdominal and gynecological)

It is also used in acne rosacea, balantidiasis and Guinea worm infection. *T. vaginalis* infections resistant to the usual dosage require special treatment (p. 836).

Preparations and dosage

Proprietary names: Flagyl and numerous generic preparations.

Preparations: Tablets, suppositories, topical gel and cream, i.v. infusion, oral suspension.

Dosage:

Trichomonal vaginitis: Adults, 2 g as a single oral dose or a 7-day course of 400 mg every 12 h. All sexual partners should be treated concomitantly. Children aged 1–3 years, 50 mg every 8 h for 7 days; aged 3–7 years, 100 mg every 12 h for 7 days; aged 7–10 years, 100 mg every 8 h for 7 days; aged 10–18 years, 200 mg every 8 h for 7 days or 2 g as a single dose. *In the USA:* 250–500 mg every 8 h for 7 days or 2 g as a single dose.

Anaerobic bacterial infections: Adults, an initial dose of 800 mg orally followed by 400 mg every 8 h, for 7–10 days; i.v. administration is 500 mg every 8 h. Children: 7.5 mg/kg every 8 h orally or i.v. By rectal suppository: child 1 month–1 year, 125 mg every 8 h for 3 days, then every 12 h thereafter; child 1–5 years, 250 mg every 8 h for 3 days, then every 12 h thereafter; child 5–12 years, 500 mg every 8 h for 3 days, then every 12 h thereafter; child 12–18 years, 1 g every 8 h for 3 days, then every 12 h thereafter. *In the USA:* Adults 500 mg every 6–12 h orally or 15 mg/kg by i.v. infusion over 1 h, followed by 7.5 mg/kg every 6 h. No more than 4 g in 24 h.

Surgical prophylaxis. Adults, 400 mg orally or 500 mg i.v. as a single dose, repeated every 3 h for prolonged procedures. Children, 7.5 mg/kg administered as above. Alternatively, rectal suppositories of 500 mg may be used for children 5–10 years and 1 g for children 10–18 years. *In the USA:* Adults 15 mg/kg by i.v. infusion over 30–60 min and completed about 1 h before surgery, followed by two further i.v. doses of 7.5 mg/kg infused at 6 and 12 h after the initial dose.

C. difficile-associated disease: 800 mg orally then 400 mg every 8 h for 10–14 days. *In the USA:* 250 mg every 6 h or 500 mg every 8 h.

Intestinal amebiasis: Adults, 800 mg orally every 8 h for 5–10 days. Children aged 1–3 years, 200 mg every 8 h for 5 days; aged 3–7 years, 200 mg every 6 h; aged 7–10 years, 400 mg every 8 h for 5 days; aged 10–18 years, 800 mg every 8 h for 5 days. *In the USA:* 500–750 mg every 8 h for 10 days.

Extraintestinal amebiasis: Adults, 800 mg orally every 8 h for 10 days. Children aged 1–3 years, 100–200 mg every 8 h for 5–10 days; aged 3–7 years, 100–200 mg every 6 h for 5–10 days; aged 7–10 years, 200–400 mg every 8 h for 5–10 days; aged 10–18 years, 400–800 mg every 8 h for 5–10 days. *In the USA:* 500–750 mg every 8 h for 10 days.

Symptomless cyst passers: Adults, 400–800 mg orally every 8 h for 5–10 days. Children aged 1–3 years, 100–200 mg every 8 h for 5–10 days; aged 3–7 years, 100–200 mg every 6 h for 5–10 days; aged 7–10 years, 200–400 mg every 8 h for 5–10 days. Similar doses to those given for amebiasis may be used for balantidiasis and *Blastocystis hominis* infections.

Giardiasis: Adults, 2 g metronidazole orally per day as a single dose for 3 days; alternatively, 400 mg every 8 h for 5–7 days. Children aged 1–3 years, 500 mg once per day for 3 days; aged 3–7 years, 600–800 mg once per day for 3 days; aged 7–10 years, 1 g once per day for 3 days; aged 10–18 years, 2 g once per day for 3 days or 400 mg every 8 h for 5 days. *In the USA:* 250 mg every 8–12 h.

Acute ulcerative gingivitis: Adults, 200 mg orally every 8 h for 3 days. Children aged 1–3 years, 50 mg every 8 h for 3 days; aged 3–7 years, 100 mg every 12 h for 3 days; aged 7–10 years, 100 mg every 8 h for 3 days; aged 10–18 years, 200 mg every 8 h for 3 days.

Bacterial vaginosis: 400 mg orally every 12 h for 5–7 days or 2 g as a single dose. *In the USA:* 500 mg every 12 h.

*Gastroduodenal ulcers (*H. pylori*):* 400 mg every 8 h for 7–14 days (in combination with other agents). *In the USA:* 250 mg every 6 h.

Widely available.

TINIDAZOLE

Molecular weight: 247.3.

A 5-nitroimidazole available for oral administration and, in some countries, for intravenous infusion.

ANTIMICROBIAL ACTIVITY

Its antibacterial and antiprotozoal activity is similar to that of metronidazole. Activity against the common anaerobic bacterial pathogens is shown in Table 24.1 (p. 293). The MIC against *G. vaginalis* is 0.2–2 mg/L; the hydroxy metabolite is significantly more active than that of metronidazole. *H. pylori* is inhibited by 0.5 mg/L. *T. vaginalis* and *T. fetus* at 2.5 mg/L and *E. histolytica* is inhibited by about 0.3–2.5 mg/L.

PHARMACOKINETICS

Oral absorption	>95%
C_{\max} 2 g oral 800 mg (30-min infusion)	40 mg/L after 2 h 12 mg/L 6 min after end infusion
Plasma half-life	12–14 h
Volume of distribution	0.64 L/kg
Plasma protein binding	12%

Absorption and distribution

After a 2 g oral dose, concentrations remain at c. 10 mg/L at 24 h and 2.5 mg/L at 48 h. Daily doses of 1 g maintain plasma levels in excess of 8 mg/L, irrespective of whether the dose is oral or intravenous.

It is well distributed, with concentrations in bile, CSF, breast milk and saliva similar to those reached in plasma. The drug readily crosses the placenta. In women undergoing first trimester abortion, concentrations of 4.9 mg/kg (placenta) and 7.6 mg/kg (fetus) were found when the plasma concentration was 13.2 mg/L.

Metabolism and excretion

Metabolites include the 2-hydroxymethyl derivative, its glucuronide and two unidentified minor derivatives. In urine about half the drug remains unmetabolized.

The parent drug and its metabolites are excreted primarily in the urine and to a minor extent in the feces. The clearance rate is about 0.73 mL/min per kg and the urinary excretion is about 21% of the dose. Total clearance of the drug is 51 mL/min, renal clearance 10 mL/min. In healthy volunteers given an intravenous

infusion of 800 mg [¹⁴C]tinidazole over 30 min, a mean of 44% of the dose was excreted in the urine during the first 24 h, increasing to 63% over 5 days; only 12% of the dose appeared in the feces. Unchanged tinidazole comprised 32% of urinary ¹⁴C in 0–12 h urine. The 2-hydroxymethyl metabolite accounted for about 9% of the urinary ¹⁴C and was also present in plasma.

In renal failure the pharmacokinetics are not significantly different from those in healthy individuals. It is rapidly removed by hemodialysis and a normal dose should be given after each dialysis; if treatment precedes dialysis a half dose should be infused after the end of the procedure.

TOXICITY AND SIDE EFFECTS

Tinidazole is generally well tolerated. Infrequent and transient effects include nausea, vomiting, diarrhea and a metallic taste. Disulfiram-like reactions may occur and rare neurological disturbances and transient leukopenia have been described. Rash, which may be severe, urticaria and angioneurotic edema can occur.

CLINICAL USE

Anaerobic bacterial infections (prophylaxis and treatment)
Trichomoniasis
Giardiasis (single dose)
Amebiasis (including amebic liver abscess)
Bacterial vaginosis
Gastric colonization with <i>H. pylori</i> (in combination with other agents)

Preparations and dosage

Proprietary names: Fasigin, Fasigyn, Fasigyne Simplotan, Sorquetan, Tricolam, Tindamax.

Preparations: Tablets, intravenous infusion.

Dosage: In general, tinidazole in tablet form is taken with or after food.

Trichomoniasis, giardiasis, bacterial vaginosis and acute necrotizing gingivitis:

Adults, 2 g as a single oral dose. In trichomoniasis all sexual partners should be treated. Children, 50–75 mg/kg, repeating the dose once if necessary.

Anaerobic bacterial infection: 2 g orally, then 1 g per day as a single dose or two divided doses for 5–6 days; i.v. infusion: 800 mg as 400 mL of a 2 mg/mL solution at 10 mL/min, followed by 800 mg per day or 400 mg every 12 h until oral therapy can be substituted.

Surgical prophylaxis: 2 g orally about 12 h before surgery; alternatively, 1.6 g as a single i.v. infusion before surgery, or in two divided doses, one just before surgery, the other during or not longer than 12 h after surgery.

Intestinal amebiasis: Adults, 2 g per day as a single dose for 2–3 days. Children, 50–60 mg/kg per day as a single dose for 3 days.

Liver amebiasis: Adults, 1.5–2 g per day as a single dose for 3–6 days. Children, 50–60 mg/kg per day as a single dose for 5 days.

*Gastroduodenal ulcers (*H. pylori*):* 500 mg every 12 h for 7 days in combination with other drugs.

Widely available as tablets; restricted availability as infusion.

OTHER NITROIMIDAZOLES

NIMORAZOLE (NITRIMIDAZINE)

An orally administered 5-nitroimidazole. It is slightly soluble in water at room temperature, soluble in alcohols, acetone and chloroform. The spectrum includes *T. vaginalis*, *G. lamblia*, *E. histolytica*, anaerobic bacteria and *G. vaginalis*. Activity against *B. fragilis* and *Fusobacterium* spp. is similar to or slightly less than that of metronidazole (mean MIC 0.25–1 mg/L).

A peak blood concentration of about 32 mg/L occurs within 2 h of a 500 mg oral dose. High concentrations are achieved in saliva and vaginal secretions. Excretion is principally via the urine where the drug appears as metabolites which display antimicrobial and antiprotozoal activity less than that of the parent drug.

It is generally well tolerated even at the high doses required in conjunction with radiotherapy for the treatment of head and neck tumors. Adverse effects are the same as those of metronidazole. Disulfiram-like reactions appear to be rare.

Clinical uses are similar to those of metronidazole. It is also used as a hypoxic radiosensitizer in the radiotherapy of head and neck tumors.

Preparations and dosage

Proprietary names: Eslama, Naxogin, Naxogyn.

Preparation: Tablets.

Dosage:

Trichomoniasis: 2 g as a single dose with a main meal; can be repeated after 1 month. Sexual partners should be treated concomitantly.

Giardiasis or amebiasis: Adults, 500 mg to 1 g every 12 h for 5–10 days. Children >10 kg body weight, 500 mg per day for 5 days; <10 kg body weight, 250 mg per day for 5 days.

Ulcerative gingivitis: 500 mg every 12 h for 2 days.

Available in continental Europe and South Africa.

ORNIDAZOLE

A 5-nitroimidazole available for oral administration, intravenous infusion and as a vaginal pessary. Its activity closely parallels that of metronidazole and tinidazole (Table 24.1, p. 293).

Peak plasma levels after a single 750 mg or 1.5 g oral dose reach 11 mg/L and 30 mg/L, respectively, within about 2 h. The half-life is 12–14 h. It is well absorbed from the vagina, with peak plasma concentrations of 5 mg/L being reached 12 h after the insertion of a 500 mg vaginal pessary. After a single 1 g intravenous infusion for colorectal surgery, serum levels reached about 24 mg/L after 15 min and about 6 mg/L after 24 h. It has wide tissue distribution, including CSF. Plasma protein binding is 10–15%.

It is metabolized in the liver, mainly to hydroxymethyl derivatives. The plasma clearance rate decreases in hepatic failure because of reduced liver metabolism and decreased biliary elimination. About 60% of an oral dose is recovered in the urine and 20% in the feces. The dosing interval should be doubled in patients with severe hepatic impairment, but it is unnecessary to reduce the dose in patients with impaired renal function. It is removed by hemodialysis.

Toxicity and side effects are similar to those of metronidazole and tinidazole and it has similar clinical uses. It has been shown to be effective for the prevention of recurrence of Crohn's disease after ileocolonic resection.

Preparations and dosage

Preparations: Tablets, vaginal pessary, i.v. infusion.

Dosage:

Amebiasis: Adults, oral, 500 mg every 12 h for 5–10 days; 1.5 g as a single dose for 3 days for amebic dysentery. Children, 25 mg/kg per day as a single dose for 5–10 days; 40 mg/kg per day in amebic dysentery. In severe cases of amebic dysentery or severe amebic liver abscess, 0.5–1 g i.v. over 15–30 min, followed by 500 mg every 12 h for 3–6 days. Children, 20–30 mg/kg per day.

Giardiasis: Adults, oral, 1–1.5 g per day as a single dose for 1–2 days. Children, 30–40 mg/kg per day.

Trichomonial vaginitis: Adults, oral, a single 1.5 g tablet, or 1 g orally together with 500 mg vaginally; alternatively, 500 mg every 12 h for 5 days with or without a 500 mg vaginal pessary. Children, 25 mg/kg per day.

Anaerobic bacterial infections: Adults, an initial dose of 0.5–1.0 g i.v., followed by 500 mg every 12 h for 5–10 days. Oral therapy with 500 mg every 12 h should be substituted as soon as possible. Children, 10 mg/kg every 12 h.

Surgical prophylaxis: 1 g i.v. about 30 min before surgery.

Restricted availability. Not available in the UK or the USA.

Turcant A, Granny JC, Allain P, Cavellat M. Pharmacokinetics of ornnidazole in neonates and infants after a single intravenous infusion. *Eur J Clin Pharmacol*. 1987;32:111–113.

SECNIDAZOLE

A 5-nitroimidazole with properties similar to those of metronidazole. It is rapidly absorbed after oral administration and is distinguished by having the longest plasma half-life (18 h) of clinically used nitroimidazole drugs. It is used in the treatment of intestinal amebiasis, giardiasis, trichomoniasis and bacterial vaginosis.

Preparations and dosage

Proprietary name: Flagentyl.

Preparation: Tablets.

Dosage: Adults, oral, 2 g as a single dose. Children, 30 mg/kg as a single dose. In invasive amebiasis, 15 g per day for 5 days. Children, 30 mg/kg per day for 5 days.

Available in France.

CHAPTER

25 Oxazolidinones

Una Ni Riain and Alasdair P. MacGowan

The oxazolidinones are a novel class of synthetic antimicrobial agents unrelated to any other antibacterial drug class. They were originally developed as monoamine oxidase inhibitors for treatment of depression, with subsequent recognition of their antimicrobial properties. The first members of the group to emerge exhibited potent activity against Gram-positive organisms, but were not developed for human use owing to toxicity in animal models. In the 1990s two less toxic oxazolidinones were developed: eperezolid, a piperazine derivative, and linezolid, a morpholine derivative. Linezolid exhibited the more favorable pharmacokinetic profile and was subsequently licensed for human use.

Numerous chemical analogs have been screened in a search for compounds with enhanced potency, a broader spectrum of activity or a more favorable side effect profile. Several promising candidates have been described, but linezolid remains the only oxazolidinone currently available.

These drugs are characterized by activity against Gram-positive organisms including methicillin-resistant *Staphylococcus aureus*, penicillin-resistant pneumococci and vancomycin-resistant enterococci. They are inactive against most Gram-negative species, although some investigational compounds are active against fastidious Gram-negative bacteria including *Haemophilus influenzae*. They have potentially useful activity against mycobacteria, including multiresistant isolates of *Mycobacterium tuberculosis*. Resistance among Gram-positive organisms remains very uncommon (<0.5%) among clinical isolates.

LINEZOLID

Molecular weight: 337.35.

A synthetic oxazolidinone available for oral or intravenous administration. Soluble in water at a pH range of 5–9. Aqueous solutions (2 g/L) are stable at 25°C, 4°C and –20°C for at least 3 months.

ANTIMICROBIAL ACTIVITY

The in-vitro activity against common pathogenic bacteria is shown in Table 25.1. It exhibits potent activity against a wide range of Gram-positive organisms, including those that are resistant to other antimicrobial agents. Methicillin-resistant *Staph. aureus* and coagulase-negative staphylococci are susceptible, as are enterococci, including vancomycin-resistant *Enterococcus faecalis* and *Ent. faecium*. Penicillin-sensitive and resistant isolates of *Streptococcus pneumoniae* are equally susceptible. Less common Gram-positive pathogens are also susceptible; the minimum inhibitory concentrations (MICs) for *Bacillus* spp., *Corynebacterium* spp., *Listeria monocytogenes*, *Aerococcus* spp., *Micrococcus* spp. and *Rhodococcus equi* are all ≤2 mg/L. *M. tuberculosis* is susceptible, with typical MICs ≤1 mg/L for sensitive and multidrug-resistant strains.

All enterobacteria, *Pseudomonas* spp. and other non-fermentative aerobic Gram-negative bacilli, including *Acinetobacter* spp., are resistant. *Moraxella catarrhalis*, *Legionella* spp.,

Table 25.1 Activity of linezolid against common pathogenic bacteria: MIC (mg/L)

	MIC
<i>Staphylococcus aureus</i> (methicillin susceptible)	0.06–4
(methicillin resistant)	0.12–4
Coagulase-negative staphylococci	0.5–2
<i>Streptococcus pyogenes</i>	0.5–2
<i>Str. pneumoniae</i> (penicillin susceptible)	0.12–2
(penicillin resistant)	0.5–2
<i>Enterococcus faecalis</i> (vancomycin susceptible)	0.5–4
(vancomycin resistant)	1–4
<i>E. faecium</i> (vancomycin susceptible)	1–4
(vancomycin resistant)	0.5–4
<i>Haemophilus influenzae</i>	8–16
<i>Neisseria gonorrhoeae</i>	4–>16
<i>Escherichia coli</i>	R
<i>Klebsiella pneumoniae</i>	R
<i>Pseudomonas aeruginosa</i>	R
<i>Bacteroides fragilis</i>	1–8

R, resistant (MIC >32 mg/L).

Mycoplasma spp. and *Chlamydia* spp. are inhibited by 4–8 mg/L. Activity against *Haemophilus influenzae* is modest.

Among anaerobes, *Clostridium perfringens* and *Peptostreptococcus* spp. are inhibited by <2 mg/L. Typical MICs (mg/L) for Gram-negative anaerobes include: *Bacteroides* spp., 4–8; *Prevotella* spp., 1–4; *Fusobacterium* spp., 0.125–1.

Activity is bacteristatic against most susceptible species, but modest bactericidal activity has been demonstrated against some strains of *Str. pneumoniae*, *C. perfringens* and *Bacteroides fragilis*. Inhibition of toxin production by staphylococci and streptococci in the presence of sub-MIC concentrations has been described.

Linezolid may antagonize the bactericidal action of some antibiotics (e.g. gentamicin). No evidence of synergy has been found in various experimental systems with gentamicin against vancomycin-resistant *Enterococcus* spp. or with vancomycin, gentamicin, ciprofloxacin, fusidic acid or rifampicin (rifampin) against methicillin-resistant *Staph. aureus*.

ACQUIRED RESISTANCE

Isolates of *Staph. aureus* and *E. faecalis* for which the MIC of linezolid is raised have been obtained following serial exposure to gradients of the drug. However, induction of resistance requires many passages over several weeks. Resistance in these laboratory mutants is associated with modifications of the 23S rRNA gene.

Overall, resistance rates in clinical isolates are very low at <0.5%. Resistance is reported primarily in coagulase-negative staphylococci (1.77%) and enterococci (1.13%; mostly *E. faecium*), with exceptionally low resistance rates in *Staph. aureus* (0.06%). Risk factors for emergence of resistance include prolonged use of the drug, the presence of irremovable indwelling devices, sequestered sites of infection and low-dose therapy for infections caused by vancomycin-resistant enterococci or methicillin-resistant *Staph. aureus*. Resistance in clinical isolates is most often associated with gene mutations in which guanosine is replaced by uracil in the 23S rRNA. Nosocomial clonal spread of such mutants has been described in coagulase-negative staphylococci and enterococci. Resistance conferred by a novel mobile element, *cfr*, has been described in two isolates of staphylococci.

PHARMACOKINETICS

Oral absorption	>95%
C_{\max} 400 mg oral	11–12 mg/L after 1–2 h
600 mg oral	18–21 mg/L after 1–2 h
600 mg intravenous	>15 mg/L after 1 h
Plasma half-life	c. 5.5 h
Volume of distribution	45–50 L
Plasma protein binding	31%

Absorption

Bioavailability after oral administration is almost complete. Plasma trough concentrations following oral doses of 400 mg and 600 mg every 12 h are >3.0 and >4.0 mg/L, respectively. With the higher dose, administered orally or intravenously, plasma concentrations remain above the MIC for most susceptible species throughout a 12 h dosage interval. After administration with high fat content food the maximum serum concentration achieved is lower and the peak delayed, but the area under the concentration–time curve (AUC) is unaltered.

Distribution

Linezolid is distributed widely in tissues and fluids. In human volunteers, maximum concentrations in inflammatory blister fluid averaged over 16 mg/L, with a mean penetrance of 104%. In patients undergoing hip arthroplasty, linezolid rapidly penetrates into bone, fat and muscle, achieving levels in excess of the MICs for susceptible organisms, with therapeutic concentrations maintained in the perioperative site hematoma fluid for more than 16 h. Mean penetration of linezolid into inflamed diabetic foot infection tissue is 101%, producing a concentration of 9.6 µg/g. Studies with human volunteers have also indicated good concentrations in pulmonary alveolar fluid with a mean fluid to plasma ratio of 3.2:1. When the meninges are not inflamed, the concentration in cerebrospinal fluid (CSF) is lower than that of plasma, with a CSF:plasma ratio of approximately 0.7:1. The concentration in sweat is about half that of plasma.

Other sites at which local concentrations exceed corresponding plasma concentrations, based on animal studies, include kidney, adrenal, liver and gastrointestinal tract. In a rat model of endocarditis, heart valve tissue and plasma concentrations were approximately equivalent.

Pharmacokinetic properties are unaltered in elderly patients and dose adjustment is unnecessary. Single-dose pharmacokinetic studies indicate that plasma clearance and volume of distribution are greater in children than in adults, while peak and trough serum concentrations are lower. Shorter dosing intervals (every 8 h) are therefore recommended for most therapeutic indications in children.

Metabolism

Linezolid undergoes non-renal as well as renal metabolism. Non-renal metabolism is by slow chemical oxidation in a process that does not discernibly interact with the hepatic cytochrome P₄₅₀ system. The oxidants contributing to metabolism of the drug have not yet been fully elucidated, but in-vivo studies suggest the process is mediated by reactive oxygen species produced throughout the body. The metabolites produced following non-renal metabolism are an aminoethoxyacetic acid and a hydroxyethylglycine metabolite, neither of which has any significant antimicrobial activity. Non-renal clearance rates are 120 mL/min and account for almost 65% of total body clearance. Since it does not appear to act as an inducer or inhibitor of cytochrome P₄₅₀ enzymes, interactions with drugs metabolized by these enzymes are unlikely to occur.

Excretion

Renal clearance accounts for approximately 50 mL/min of the total body clearance of 170 mL/min. Under steady-state conditions, approximately 30% of the dose is excreted unchanged in the urine.

In populations with varying degrees of renal function (creatinine clearance range of 10–>80 mL/min) there is no evidence of alteration in total body clearance, and adjustment of dose in patients with renal insufficiency is not recommended. However, accumulation of metabolites, up to 10-fold, occurs in patients with severe renal impairment (creatinine clearance <30 mL/min). The clinical significance of this is unknown, but linezolid should be used with caution in patients with severe renal impairment. Approximately one-third of the dose is removed by hemodialysis and since total apparent clearance is increased during dialysis, one of the 12-hourly doses should be administered after the procedure. Accumulation of metabolites also occurs in patients on dialysis, with unknown clinical significance, and caution in use in hemodialysis is advised. There are no available data on pharmacokinetics in patients undergoing peritoneal dialysis or hemofiltration.

In patients with mild to moderate hepatic impairment there is no significant change to the pharmacokinetic profile. Accordingly, dosage adjustment is not recommended in patients with mild to moderate liver disease. The pharmacokinetics of linezolid in severe hepatic failure have not been

studied, but as its metabolism is predominantly non-enzymatic, the pharmacokinetics would not be expected to alter significantly.

PHARMACODYNAMICS

Human and animal studies indicate that the parameters that best correlate with efficacy are AUC divided by MIC and the period for which the drug concentration remains above the MIC. In 288 patients with significant infection caused by Gram-positive organisms, optimal efficacy was observed when plasma concentrations remained above the MIC for >85% of the dosage interval, and when the AUC:MIC ratio was 80–20.

A post-antibiotic effect, which was more prolonged at 4 × MIC than at 1 × MIC, has been demonstrated for staphylococci and enterococci in vitro. A modest post-antibiotic effect of 3–4 h has been described in a mouse thigh model of infection with *Staph. aureus*.

TOXICITY AND SIDE EFFECTS

Most reported adverse events are mild or moderate, with reactions severe enough to lead to withdrawal of therapy occurring in less than 3% of patients. The most common adverse events are shown in Table 25.2. The most frequent side effects are gastrointestinal disturbances (diarrhea, nausea, vomiting and taste alteration) and headache. The reported incidence of *Clostridium difficile* complications is 0.2%.

Mild and transient abnormalities of liver function tests (elevation of transaminases and/or alkaline phosphatase) occur in more than 1% of patients. Skin reactions, including rashes, dermatitis, pruritus and diaphoresis, are uncommon.

Serious but infrequent adverse drug effects include myelosuppression, peripheral neuropathy, optic neuropathy and lactic acidosis. These adverse events, which probably result from inhibition of mitochondrial protein synthesis, occur primarily in patients treated for >28 days. Myelosuppression

Table 25.2 Common adverse drug reactions to linezolid

Adverse event	Frequency (%)
Diarrhea	4.3
Nausea	3.4
Headache	2.2
Vaginal candidiasis	1
Taste alteration (metallic taste)	0.9
Vomiting	1.2
Abnormal liver function tests	1.3

generally occurs only after more than 2 weeks of treatment and increases with longer durations. It occurs more frequently in patients with severe renal insufficiency and is reversible on discontinuation of therapy.

Reversal of cytopenias by concomitant administration of vitamin B₆ has been described. Weekly monitoring of full blood count is recommended for all patients, with more frequent monitoring of those in the following categories: pre-existing anemia or thrombocytopenia; receiving concomitant drugs that may cause anemia or thrombocytopenia; severe renal insufficiency; treatment for more than 10–14 days.

Peripheral and optic neuropathy are serious but infrequent. Most cases are associated with treatment for more than 28 days (median 5 months), but neuropathies have occurred with shorter courses. In most cases optic neuropathy improved or resolved on cessation of therapy but peripheral neuropathy did not.

Lactic acidosis can occur within a week of commencing therapy but is most often seen in patients receiving prolonged treatment (median 6 weeks).

Linezolid is a weak, reversible monoamine oxidase inhibitor (MAOI) with potential interaction with adrenergic and serotonergic drugs. Co-administration of sympathomimetics, vasoconstrictors or dopaminergic agents may lead to an enhanced pressor response. It should be co-administered with these drugs only under conditions where close observation and monitoring of blood pressure is available, and their initial doses should be reduced and then titrated to achieve the desired pressor effect. Similarly, concomitant administration of linezolid with agents that increase central nervous system serotonin concentrations can lead to serotonin toxicity (serotonin syndrome). This most commonly follows concurrent administration of selective serotonin receptor inhibitors, but can occur with tricyclic antidepressants or any MAOI. Since MAOIs and their active metabolites have long elimination half-lives, linezolid is contraindicated in patients who are taking these drugs or have taken them in the previous 2 weeks.

CLINICAL USE

- Community-acquired pneumonia
- Nosocomial pneumonia
- Skin and soft-tissue infections
- Vancomycin-resistant *E. faecium* infections, including cases with concurrent bacteremia

Linezolid is primarily used for the treatment of infections caused, or likely to be caused, by methicillin-resistant *Staph. aureus*, vancomycin-resistant enterococci and penicillin-resistant *Str. pneumoniae*. Combination therapy with an antimicrobial active against Gram-negative bacteria is indicated if concomitant infection with a Gram-negative pathogen is suspected or confirmed.

Outside of licensed indications, it has been used in the treatment of bone and joint infections, endocarditis, central nervous system infections, infections in neutropenic patients and drug-resistant tuberculosis.

Preparations and dosage

Proprietary name: Zyvox.

Preparations: Tablets, suspension, injection.

Dosage: Adults, oral or i.v. infusion over 30–120 min, 600 mg every 12 h. Children (unlicensed in the UK), oral or i.v. infusion over 30–120 min, neonate <7 days, 10 mg/kg every 8–12 h; neonate >7 days, 10 mg/kg every 8 h; 1 month–12 years, 10 mg/kg (max. 600 mg) every 8 h; 12–18 years, 600 mg every 12 h.

Widely available.

INVESTIGATIONAL OXAZOLIDINONES

Numerous chemical analogs have been described. Among the most promising candidates are:

- RWJ-416457, a pyrrolopyrazolyl-substituted oxazolidinone, with greater potency than that of linezolid against staphylococci and enterococci in vitro
- Radezolid (RX-1741), one of a family of biarylloxazolidinones that demonstrate improved potency against Gram-positive bacteria including methicillin-resistant *Staph. aureus* and vancomycin-resistant enterococci, and which are also active against *H. influenzae* and *Mor. catarrhalis*
- PF-00422602, an oxazolidinone with a novel C-5 side chain, which has antibacterial activities similar to those of linezolid but reduced in-vivo myelotoxicity in animal models.

26 Quinolones

Peter C. Appelbaum and André Bryskier

The pyridone- β -carboxylic acid derivatives or quinolones comprise a large and expanding number of synthetic compounds. Since the first analog, nalidixic acid, was synthesized in 1962, many types have been reported based on a few common structures: most are 1,8 naphthyridone or quinoline derivatives:

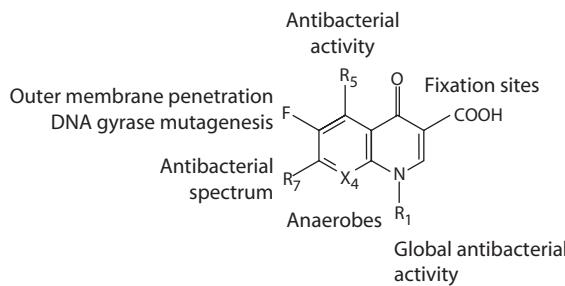

1,8 naphthyridone derivatives

Quinoline derivatives

Changes to various parts of the molecules confer different properties and this is the basis of the variation in activity of various members of the group. The main structure–activity relationships are shown in the accompanying figure:

The first 4-quinolone, nalidixic acid, is a 1,8-naphthyridinone with a narrow spectrum of activity, chiefly against Enterobacteriaceae. Several compounds with improved antibacterial activity were subsequently synthesized. These included pipemidic acid, which expanded the spectrum to include weak activity against *Pseudomonas aeruginosa*, and piromidic acid, which exhibited useful activity against *Staphylococcus aureus*. Further development led to the discovery in the late 1970s of fluorine-substituted derivatives with much enhanced intrinsic activity against both organisms, a group now known as the fluoroquinolones. Numerous fluoroquinolones with altered

pharmacokinetic properties and additional improvements in spectrum, including in some cases useful activity against *Mycobacterium tuberculosis* and *M. leprae*, became available in the next 30 years. Current research efforts are directed to overcome problems of resistance, which is increasingly encountered in both Gram-positive and Gram-negative bacteria.

CLASSIFICATION

The varied properties of the quinolones make them difficult to classify accurately. According to their antibacterial activity and spectrum, four broad groups are recognized:

Group 1:	Compounds with a narrow antibacterial spectrum directed mainly against Enterobacteriaceae.
Group 2:	Fluoroquinolones, which exhibit potent activity against Gram-negative bacilli including <i>Ps. aeruginosa</i> and many Gram-positive bacteria excluding <i>Streptococcus pneumoniae</i> . These compounds are characterized by a 6-fluorine atom and often by a 7-piperazinyl group.
Group 3:	Compounds with improved activity against <i>Str. pneumoniae</i> and <i>Staph. aureus</i> . Some derivatives do not contain a fluorine atom.
Group 4:	Compounds with properties similar to those of groups 2 and 3 and additional activity against anaerobes.

Group 1	Group 2	Group 3	Group 4
Cinoxacin	Ciprofloxacin	Garenoxacin	Gemifloxacin
Flumequine	Enoxacin	Gatifloxacin	Delafloxacin ^b
Nalidixic acid	Norfloxacin	Levofloxacin	Moxifloxacin
Oxolinic acid	Ofloxacin	Sparfloxacin ^a	Nemonoxacin ^b
Pipemidic acid	Pazufloxacin	Tosufloxacin	Sitaflloxacin ^b
Piromidic acid	Pefloxacin		Trovafloxacin ^a
Rosoxacin	Prulifloxacin		WCK 771 ^b
	Rufloxacin		Zabofloxacin ^b

^aCompounds withdrawn from use in the USA and Europe.

^bCompounds under development.

Two additional quinolones, besifloxacin and nadifloxacin, are marketed solely for topical use. Other derivatives, including danofoxacin, difloxacin, enrofloxacin, ibafloxacin, marbofloxacin, orbifloxacin and sarafloxacin, are used in veterinary medicine and are not dealt with here.

ANTIBACTERIAL ACTIVITY

Group 1 quinolones exhibit moderate activity against a wide range of Enterobacteriaceae as well non-fastidious Gram-negative bacilli such as *Haemophilus influenzae* and *Neisseria* spp. They have weak (pipemidic acid) or no activity against *Pseudomonas aeruginosa*, anaerobes and Gram-positive bacteria (Table 26.1).

Introduction of a fluorine atom and a nitrogen-containing heterocycle on the quinoline or a naphthyridone core resulted in compounds with greater potency and a broader antibacterial spectrum (Table 26.2). Minimum inhibitory concentrations (MICs) of the group 2 fluoroquinolones are up to 100-fold lower than those of group 1 compounds for Enterobacteriaceae, *Aeromonas* spp., *Campylobacter* spp. and *Yersinia* spp., as well as against fastidious Gram-negative bacilli such as *H. influenzae*, *Neisseria* spp. and *Moraxella catarrhalis*. Some of these compounds (such as ciprofloxacin) also exhibit significant antibacterial activity against *Pseudomonas aeruginosa*; some compounds presently under investigation are active against non-fermentative Gram-negative bacilli such as *Acinetobacter* spp. and *Stenotrophomonas maltophilia*. Fluoroquinolones display variable in-vitro activity against *Staph. aureus* and coagulase-negative staphylococci. Methicillin-resistant strains are often quinolone resistant.

Compounds of groups 3 and 4, including levofloxacin, moxifloxacin and gemifloxacin, are very potent against *Str. pneumoniae* but exhibit poor activity against *Enterococcus* spp.

Table 26.1 Activity of selected group 1 quinolones against common pathogenic bacteria: MIC (mg/L)

Species	Cinoxacin	Nalidixic acid	Pipemidic acid
<i>Staphylococcus aureus</i>	64-R	R	R
<i>Streptococcus pyogenes</i>	R	R	R
<i>Str. pneumoniae</i>	R	R	R
<i>Enterococcus faecalis</i>	R	R	R
<i>Neisseria gonorrhoeae</i>	1-8	1	2
<i>Haemophilus influenzae</i>	1	1	2
<i>Escherichia coli</i>	1-4	4-8	2
<i>Klebsiella pneumoniae</i>	2-32	8-16	2
<i>Pseudomonas aeruginosa</i>	R	R	8-32
<i>Acinetobacter</i> spp.	R	R	R
<i>Bacteroides fragilis</i>	R	R	32-R

R, resistant (MIC >64 mg/L).

and *Listeria monocytogenes*. Among group 4 compounds, some, such as moxifloxacin, claim to exert improved activity against anaerobes.

Most fluoroquinolones exhibit antibacterial activity against atypical bacteria (mycoplasmas, ureaplasmas) and intracellular pathogens including *Legionella* spp., *Chlamydophila* (formerly *Chlamydia*) *pneumoniae*, *Chlamydia trachomatis*, *Coxiella burnetii* and *Rickettsia* spp. Fluoroquinolones, particularly those with a quinoline core, exhibit variable activity against *Mycobacterium tuberculosis* and *M. leprae*, the most active being pefloxacin, ofloxacin, levofloxacin, gatifloxacin, sparfloxacin and moxifloxacin. Other mycobacteria, including organisms of the *M. avium* complex, are less susceptible.

Table 26.2 Activity of group 2 fluoroquinolones against common pathogenic bacteria: MIC (mg/L)

	Ciprofloxacin	Enoxacin	Fleroxacin	Lomefloxacin	Norfloxacin	Oflloxacin	Pefloxacin	Rufloxacin
<i>Staphylococcus aureus</i>	0.25-1	2	1-2	1-2	1	0.12-1	0.5-1	2
<i>Streptococcus pyogenes</i>	0.5-2	8-16	4-16	4-8	4	2	4-8	16
<i>Str. pneumoniae</i>	1-4	8-16	4-16	2-8	8	1-4	8	32
<i>Enterococcus faecalis</i>	0.5-2	≥8	4-16	8-16	8	2-4	4	32
<i>Neisseria</i> spp.	≥0.06	0.12	<0.06-0.5	<0.06-0.12	≥0.06	≥0.06	≥0.06	0.12
<i>Haemophilus influenzae</i>	≥0.06	0.12	<0.06-0.25	≥0.06-0.25	≥0.06	≥0.06	≥0.06	0.5
<i>Escherichia coli</i>	≥0.06	0.25	0.12-0.5	0.25	0.25	0.06-0.25	0.25	2
<i>Klebsiella pneumoniae</i>	0.06-0.25	0.25	0.12-2	0.25	0.5	0.25	0.5	32
<i>Pseudomonas aeruginosa</i>	0.25-2	2-8	1-8	0.25-4	1-2	2-4	2-4	8
<i>Bacteroides fragilis</i>	4-16	≥32	8-64	8-64	8-32	8	16	32
<i>Chlamydia trachomatis</i>	0.5-2	0.5-2	4-8	0.5-2	4-16	0.5-2	2-8	4-8
<i>Mycobacterium tuberculosis</i>	0.25-4	0.3-4	>4	>4	2-8	0.3-1.2	0.3-2	No data

Quinolones are rapidly bactericidal to most susceptible bacterial species at concentrations exceeding the MIC by no more than four-fold. However, there is usually an optimal bactericidal concentration above which the lethal action is diminished. This paradoxical effect is probably caused by dose-dependent inhibition of RNA synthesis.

Fluoroquinolones rapidly accumulate in polymorphonuclear neutrophils, monocytes, macrophages and other cells, achieving bactericidal concentrations. The ratio of cellular to extracellular concentrations is compound dependent and ranges from 2:1 to 10:1.

INTERACTIONS

Combinations of quinolones with carbapenems, aminoglycosides and polymyxin may interact synergistically in vitro, particularly against *Ps. aeruginosa* and *Acinetobacter* spp. Against *Sten. maltophilia*, marked synergy has been observed when quinolones are combined with cephalosporins such as ceftazidime, ceftriaxone and cefoperazone. Testing for synergy in vitro has not been standardized and there is no solid evidence of correlation between in vitro and clinical results.

ACQUIRED RESISTANCE

MECHANISMS

Four mechanisms of resistance within the quinolone family have been described:

- Mutations at the level of the gene targets (*gyrA*, *parC*, *gyrB* and *parE*).
- Decreased cellular uptake and/or active expulsion (efflux).
- Protection of DNA gyrase by plasmid-encoded pentapeptides.
- Inactivation of quinolones (rare).

The frequency with which bacteria develop resistance to the quinolones is much lower for the fluoroquinolones (10^{-12}) than for nalidixic acid (10^{-8}). Moreover, Gram-positive bacteria mutate to resistance at higher frequencies than do Gram-negative organisms. Single-step mutations generally lead to two- to eight-fold increases in MICs. There is cross-resistance within available quinolones. The species that are most likely to become resistant to group 2 fluoroquinolones in a single mutational step are those of borderline susceptibility (e.g. *Ps. aeruginosa*, *Serratia* spp., *Acinetobacter* spp., *Staphylococcus* spp.).

Gram-positive cocci (*Staph. aureus*, *Str. pneumoniae*) express fluoroquinolone efflux systems that utilize the energy of the proton motive force and generally provide modest resistance. In Gram-negative bacilli, efflux systems recognize fluoroquinolones and other antibacterial agents. An efflux pump, QepA in *Escherichia coli*, may decrease susceptibility of hydrophilic fluoroquinolones such as ciprofloxacin and norfloxacin by a factor of 8–32.

Plasmid-mediated resistance conferred by pentapeptides that protect DNA gyrase has become a worrying problem among Enterobacteriaceae and mycobacteria. It may be associated with other resistance genes. Inactivation of ciprofloxacin and norfloxacin by N-acetylation of the free N4' of the piperazinyl ring has also been described.

EPIDEMIOLOGY

Epidemiological surveys of fluoroquinolone resistance in *Str. pneumoniae* found a prevalence rate below 1% in Europe and North America, but a higher rate in Hong Kong ($\geq 3\%$). However, clinically significant resistance has been detected among bacterial species such as *Ps. aeruginosa*, *Staph. aureus* (particularly methicillin-resistant strains, for which resistance rates of up to 80% have been reported), coagulase-negative staphylococci and *Acinetobacter* spp. and *Esch. coli* (up to 20% in some countries and hospitals). Clinical isolates of *N. gonorrhoeae* with reduced susceptibility or resistance to fluoroquinolones are commonly isolated in many parts of the world.

PHARMACOKINETICS

ABSORPTION

Most quinolones are rapidly absorbed when given orally, although there is considerable variation among different compounds. Absorption is inhibited by co-administration with anti-acids containing divalent metals, such as magnesium, calcium and iron, with which they form insoluble chelates. When the oral bioavailability is absolute, fluoroquinolones may be administered by this route instead of intravenously in many diseases.

DISTRIBUTION

Protein binding of fluoroquinolones varies. They have large volumes of distribution; concentrations approximating those in the plasma are found in tissue fluid and they are highly distributed into bone and prostate. Concentrations in the bronchial mucosa, lung epithelial lining fluid and alveolar macrophages are usually higher than in plasma. Concentrations in cerebrospinal fluid (CSF) are about one-third to one-half the corresponding plasma level; the presence of inflammation does not appear to enhance penetration significantly.

ELIMINATION

Most available fluoroquinolones are eliminated by the renal route but many are metabolized, to a greater or lesser extent, in the liver. Liver metabolism of <5% occurs with ofloxacin and levofloxacin. Some metabolites exhibit antibacterial activity (pefloxacin metabolized to norfloxacin; prulifloxacin metabolized to ulifloxacin).

If the dominant elimination route is the kidney, adjustment of doses or times of administration may be needed depending upon the degree of renal impairment. In elderly subjects, changes in pharmacokinetics are drug dependent and usually low; dosage modification may sometimes be indicated.

TOXICITY AND ADVERSE EVENTS

Several quinolones (temafloxacin, sparfloxacin, grepafloxacin, trovafloxacin) have been withdrawn or their use severely limited soon after their clinical introduction owing to severe and sometimes life-threatening adverse events.

The frequency of mild adverse events in patients receiving ciprofloxacin, levofloxacin, moxifloxacin and gemifloxacin (particularly short courses) is comparable to that seen with other commonly used antibacterial agents. Rates of 6–10% have been described, with less than 1% being regarded as serious. Fluoroquinolones are not recommended during pregnancy, for lactating women or for children unless there are overriding reasons for their use.

The most common serious adverse events are:

- phototoxicity (lomefloxacin, sitafloxacin, pefloxacin); bone and joint arthropathies (occurring mainly in elderly patients when a steroid is co-administered)
- central nervous system abnormalities when administered with anti-inflammatory drugs such as ibuprofen; drug interactions (co-administration with theophylline)
- hypotension (garenoxacin)
- cardiotoxicity (QTc prolongation and/or torsade de pointes) resulted in withdrawal of grepafloxacin and restriction on the use of sparfloxacin; it may occur rarely with other fluoroquinolones
- hypoglycemia or interference with diabetic drugs (gatifloxacin)
- tendon rupture (especially of the Achilles tendon) rarely occurs with ciprofloxacin and levofloxacin.

CLINICAL USE

GROUP 1 QUINOLONES

The narrow Gram-negative spectrum of group 1 quinolones makes them suitable for treatment of urinary tract infection. Nalidixic acid is prescribed for enteric infection due to *Shigella* in some part of the world.

FLUOROQUINOLONES (GROUPS 2–4)

Many fluoroquinolones are available in both oral and parenteral formulations but because they are well absorbed when given by mouth, many infectious diseases can be treated

successfully with oral therapy. The following comprise common indications:

- Lower respiratory tract infections (i.e. acute bacterial exacerbations of chronic bronchitis, community-acquired pneumonia)
- Sinusitis
- Uncomplicated and some complicated urinary tract infections
- Bacterial prostatitis
- Community-acquired skin and soft-tissue infections
- Bone and joint infections
- Gastrointestinal tract infections, particularly infectious diarrhea caused by toxigenic *Esch. coli*, *Salmonella enterica* (including typhoid and paratyphoid fevers, and the chronic salmonella carrier state), *Shigella*, *Campylobacter*, *Aeromonas* and *Vibrio* species (including *Vibrio cholerae*), as well as *Plesiomonas shigelloides*
- Sexually transmitted diseases (including pelvic infections) other than syphilis, which does not respond to quinolones
- Tuberculosis, leprosy, plague.

Specific pharmaceutical formulations (eye drops and creams) are available for topical application.

GROUP 1 QUINOLONES

NALIDIXIC ACID

Molecular weight: 232.2.

A 1,8-naphthyridone derivative available for oral administration.

ANTIBACTERIAL ACTIVITY

It displays good activity in vitro against a wide range of Enterobacteriaceae. *Ps. aeruginosa*, Gram-positive bacteria and anaerobes are resistant (Table 26.1, p. 307).

PHARMACOKINETICS

Oral absorption	>90%
C_{\max} 1 g oral	c. 25 mg/L
Plasma half-life	c. 1.5 h
Volume of distribution	0.4 L/kg
Plasma protein binding	93%

The plasma concentrations achieved after oral administration vary widely. In infants with acute shigellosis, absorption is much impaired by diarrhea. Administration with an alkaline compound leads to higher plasma concentrations, partly as the result of enhanced solubility (nalidixic acid is much more soluble at higher pH) and absorption and partly because of reduced tubular reabsorption.

It is rapidly metabolized, principally to the hydroxy acid, which is bacteriologically active, and glucuronide conjugates, which are not. The entire administered dose appears in the urine over a 24 h period. Elimination is reduced by probenecid. In the presence of renal impairment there is little accumulation of the active compound because it continues to be metabolized. However, elimination of metabolites is progressively delayed as renal function declines. About 4% of a dose appears in the feces.

TOXICITY AND SIDE EFFECTS

Adverse reactions are generally those common to all quinolones: gastrointestinal tract and CNS disturbances and skin rashes, including eruptions related to photosensitivity. About half of the reported CNS reactions involve visual disturbances, hallucinations or disordered sensory perception. Severe excitatory states, including acute psychoses and convulsions, are usually observed in patients receiving high dosages. The drug should be avoided in patients with psychiatric disorders or epilepsy.

Acute intracranial hypertension has been observed in children, some of whom have also manifested cranial nerve palsies. Hemorrhage has occurred in patients who were also receiving warfarin, presumably due to displacement of the anticoagulant from its protein binding sites by the nalidixic acid. Hemolytic anemia has been described several times in infants with or without glucose-6-phosphate dehydrogenase deficiency; in adults, death has occurred from autoimmune hemolytic anemia. Arthralgia and severe metabolic acidosis have rarely been reported.

CLINICAL USE

Urinary tract infection
Prophylaxis in patients undergoing transurethral surgery
Treatment of acute shigellosis

Preparations and dosage

Proprietary names: Mictral, Negram, Uriben.

Preparations: Tablets, suspension.

Dosage: Adults, oral, 900 mg–1 g every 6 h for 7 days; for chronic infections, 500–600 mg every 6 h. Children >3 months, oral, 50 mg/kg per day in four divided doses; reduced in prolonged therapy to 30 mg/kg per day.

Widely available.

Schaad UB, Wedgwood-Krucko J. Nalidixic acid in children: retrospective matched controlled study for cartilage toxicity. *Infection*. 1987;15:165–168.

OTHER GROUP 1 QUINOLONES

ROSOXACIN (ACROSOXACIN)

The antibacterial spectrum and potency are similar to those of other members of this group, but it is particularly active against *N. gonorrhoeae* (MIC 0.06–0.1 mg/L).

A single oral dose of 300 mg produces a mean peak plasma concentration of 4–5 mg/L at about 2–4 h, with an apparent elimination half-life of about 6 h. Elimination in the urine is partly as the *N*-oxide metabolite and the glucuronide of this metabolite.

Side effects are those common to quinolones, notably gastrointestinal tract and CNS disturbances. About 50% of patients treated with single oral doses of 100–400 mg developed dizziness, drowsiness, altered visual perception and other CNS effects.

It is effective as single-dose treatment of patients with urethral and anorectal gonorrhea, but coexistent *C. trachomatis* infection is not eliminated from most patients and postgonococcal urethritis develops in up to 30%.

Preparations and dosage

Proprietary name: Eradicil.

Preparation: Capsules.

Dosage: Adult, oral, 300 mg as a single dose.

Limited availability.

Romanowski B, Austin TW, Pattison FLM, et al. Rosoxacin in the therapy of uncomplicated gonorrhea. *Antimicrob Agents Chemother.* 1984;25:445–457.

CINOXACIN

A cinnoline derivative formulated for oral administration. It is active against most Enterobacteriaceae, but *Ps. aeruginosa*, Gram-positive bacteria and anaerobes are resistant (Table 26.1, p. 307).

It is well-absorbed when given orally. Administration with food reduces the peak concentration by about one-third, but the area under the concentration–time curve (AUC) remains unchanged. Concentrations in prostatic and bladder tissues reach 60% and 80%, respectively, of the simultaneous serum concentrations.

It is almost entirely eliminated in the urine, about 40–60% as unchanged drug and the rest as metabolites, most of which have no antibacterial activity. Urinary concentrations of active drug in the first 2 h after administration of a dose is 100–500 mg/L. Elimination is reduced by probenecid and by renal impairment, the half-life rising to about 12 h in end-stage renal failure.

Adverse reactions that are common to the group are reported in 4–5% of patients; these are primarily gastrointestinal tract disturbances, but rashes occur in up to 3% and CNS disturbances in less than 1%. Use is restricted to uncomplicated urinary tract infection.

Preparations and dosage

Proprietary name: Cinobac.

Preparation: Capsules.

Dosage: 500 mg every 12 h or 250 mg every 6 h; prophylaxis 250–500 mg per day for 7–14 days.

No longer widely available.

Further information

- Anonymous. Cinoxacin. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C224–C226.
Sica TS, Heel RC, Romakiewicz JA. Cinoxacin. A review of its pharmacological properties and therapeutic efficacy in the treatment of urinary tract infections. *Drugs.* 1983;25:544–569.

PIPEMIDIC ACID

An orally administered pyridopyrimidine derivative with a 7-piperazinyl moiety. The piperazinyl moiety at C-7

increases in-vitro activity against *Ps. aeruginosa*. Pipemidic acid is inactive against Gram-positive bacteria or anaerobes (Table 26.1, p. 307).

It is well absorbed orally. The drug is rapidly metabolized, primarily to acetyl, formyl and oxo derivatives, which exhibit much reduced antibacterial activity. It is eliminated in the urine, 50–85% of a dose appearing over the first 24 h, less than 2% as inactive metabolites. Non-renal clearance accounts for 10–40% of a dose in the young, rising to 40–70% in elderly subjects, thereby compensating for possible renal insufficiency. No dosage adjustment is necessary in patients with mild renal insufficiency. Some of the drug is eliminated in the bile and a significant portion appears in the feces.

Nausea and vomiting are common; dizziness, weakness and grand mal seizures have been observed, principally in the elderly. A number of reactions have been sufficiently severe to require discontinuation of therapy. Clinical use is restricted to urinary tract infections.

Preparations and dosage

Proprietary name: Pipram.

Preparation: Tablets.

Dosage: Adults, oral, 400 mg every 12 h.

Available in Europe (not UK) and Japan.

Further information

Klinge E, Mannisto PT, Mantyla R, Mattila J, Hanninen U. Single- and multiple-dose pharmacokinetics of pipemidic acid in normal human volunteers. *Antimicrob Agents Chemother.* 1984;26:69–73.

FLUMEQUINE

A tricyclic fluorinated 4-quinolone, with activity similar to that of nalidixic acid in vitro, although it is somewhat more active against some Enterobacteriaceae.

Following escalating oral doses of 400, 800 or 1200 mg, mean peak plasma levels reached at 2 h are 13.5, 23.8 and 31.9 mg/L, respectively. The apparent elimination half-life is about 7 h. The main metabolite, hydroxyflumequine, is much more rapidly eliminated. About 60% of a dose appears in the urine, mostly in the form of conjugates. Urinary concentrations following an 800 mg dose are 10–35 mg/L, with a peak of 105 mg/L. It has no effect on the pharmacokinetics of theophylline.

Flumequine is generally well tolerated, side effects being mainly mild gastrointestinal tract disturbances, rashes, dizziness and confusion.

It is principally used in uncomplicated urinary tract infections.

Preparations and dosage

Proprietary name: Apurone.

Preparation: Tablets.

Dosage: Adult, oral, 400 mg every 8–12 h.

Limited availability in Europe.

Further information

Schuppan D, Harrison LI, Rohlffing SR, et al. Plasma and urine levels of flumequine and 7-hydroxyflumequine following single and multiple oral dosing. *J Antimicrob Chemother.* 1985;15:337–343.

OXOLINIC ACID

An oral 4-quinolone with a tricyclic structure. Its antibacterial spectrum is very similar to that of nalidixic acid, but it is more active against Enterobacteriaceae (MIC 0.25–2 mg/L). Gram-positive bacteria, *Ps. aeruginosa* and anaerobes are resistant.

After repeated doses of 750 mg twice daily, mean plasma concentrations are initially very low, but steady state is reached at the third day and C_{\max} is around 3.5 mg/L. Administration with food delays absorption. Binding to plasma protein is about 80%. It undergoes complex biotransformation, and an enterohepatic cycle may account for the increase in the apparent elimination half-life from 4 to 15 h over 7 days of treatment as well as for the 20% of dose which can be recovered from the feces. About 50% of the dose appears in the urine in the first 24 h, partly in the form of metabolites, some of which display antibacterial activity.

Side effects common to the quinolones occur frequently. About one-quarter of patients treated with 750 mg every 12 h suffer nausea and vomiting or restlessness and insomnia. Its only use is in the treatment of lower urinary tract infections.

Preparations and dosage

Proprietary name: Urotrate.

Preparation: Tablets.

Dosage: Adults, oral, 750 mg every 12 h. Children, 50–600 mg every 12 h (age dependent).

Available in some European countries.

Further information

Gleckman R, Alvarez S, Joubert DW, Matthews SJ. Drug therapy reviews: oxolinic acid. *Am J Hosp Pharm.* 1979;36:1077–11010.

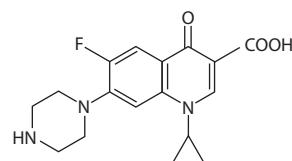

PIROMIDIC ACID

A pyrimidopyrimidine derivative with a C7-pyrrolidinyl ring, allowing a slight increase in activities against Gram-positive cocci. Its main antibacterial activity is close to that of nalidixic acid and there have been reports of renal toxicity. It is available in only a few countries.

GROUP 2 QUINOLONES

CIPROFLOXACIN

Molecular weight (free base): 331.4.

A 6-fluoro, 7-piperazinyl quinolone formulated as the hydrochloride for oral administration and as the lactate for intravenous use.

ANTIBACTERIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 26.2 (p. 307). It exhibits potent activity against most Enterobacteriaceae, as well as against *Acinetobacter* spp. (MIC 0.25–1 mg/L), fastidious Gram-negative bacilli such as *Mor. catarrhalis* (MIC 0.06–0.25 mg/L) and *Campylobacter jejuni* (MIC 0.12 mg/L). In common with other quinolones, it is active against *Bacillus anthracis*. Ciprofloxacin is the most active quinolone against *Ps. aeruginosa* and exhibits good activity in vitro against other non-fermenting Gram-negative bacilli. In-vitro activity against *Staph. aureus* coagulase-negative staphylococci, *Str. pyogenes*, *Str. pneumoniae* and *Enterococcus* spp. (MIC c. 0.5–2 mg/L) is moderate. Most methicillin-resistant strains of staphylococci are resistant. It has poor activity against anaerobes, but is active against *M. tuberculosis*, *Mycoplasma* spp. and intracellular pathogens such as *Chlamydia*, *Chlamydophila* and *Legionella*.

PHARMACOKINETICS

Oral absorption	50–80%
C_{\max} 500 mg oral	1.5–2 mg/L after 1–2 h
200 mg intravenous (15-min infusion)	3.5 mg/L end infusion
Plasma half-life	3–4 h
Volume of distribution	3–4 L/kg
Plasma protein binding	20–40%

Absorption

After escalating oral doses, mean peak plasma levels increase proportionately with dose. However, accumulation occurs after repeated doses of 500 mg orally or 200 mg intravenously every 12 h; the apparent elimination half-life has been reported to rise to about 6 h after a regimen of 250 mg every 12 h for 6 days. Absorption is delayed, but seems unaffected by food and, in common with other quinolones, is reduced by certain antacids. Co-administration of sucralfate reduces the peak plasma concentrations to undetectable levels in many subjects (mean value from 2 to 0.2 mg/L) and the AUC is reduced to 12% of the value obtained when ciprofloxacin is administered alone. Ferrous sulfate and multivitamin preparations containing zinc significantly reduce absorption, which is also impaired in patients receiving cytotoxic chemotherapy for hematological malignancies. Calculated total bioavailability is 60–70%.

Distribution

It is widely distributed in body fluids, concentrations in most tissues and in phagocytic cells approximating those in plasma. Concentrations in the CSF, even in the presence of meningitis, are about half the simultaneous plasma levels.

Metabolism and excretion

It is partly metabolized to four metabolites, all but one of which (desethylciprofloxacin) display antibacterial activity. About 95% of a dose can be recovered from feces and urine. Around 40% of an oral and 75% of an intravenous dose appear in the urine over 24 h. Elimination is by both glomerular filtration and tubular secretion (60–70%) and is reduced by concurrently administered probenecid and by renal insufficiency. It is poorly removed by hemodialysis. Part of the administered drug is eliminated in the bile. An enterohepatic cycle results in prolongation of the half-life. The four metabolites are eliminated in the urine and feces at low concentration in comparison to the parent compound.

TOXICITY AND SIDE EFFECTS

Untoward reactions are uncommon, those encountered being typical of the group (p. 309). Reactions severe enough to require withdrawal of treatment have occurred in <2% of patients. The most common reactions, gastrointestinal tract disturbances, have been seen in 5% of patients and rashes in about 1%. CNS disturbances typical of quinolones have been reported in 1–2% of patients. Tendinitis and tendon rupture (especially of the Achilles tendon) may occur in a small number of patients and ciprofloxacin should be avoided in patients at risk for these conditions. Potentiation of the action of theophylline and other drugs metabolized by microsomal enzymes may occur. Crystalluria and transient arthralgia have been reported.

In volunteers, dosages of up to 750 mg produced no change in the numbers of fecal streptococci and anaerobes, but did produce a $2.5 \times \log_{10}$ decline in the numbers of enterobacteria, which lasted 1 week. There was no change in the susceptibility of the affected organisms and no overgrowth by resistant strains. As with other quinolones, ciprofloxacin is not recommended for use in children or in pregnant or lactating women.

Urinary tract infections (especially pathogens resistant to standard agents)

Prostatitis

Uncomplicated urogenital and rectal gonorrhea (single dose)

Purulent bronchitis, bronchopneumonia, acute exacerbations of chronic obstructive airways disease, pneumonia (other than pneumococcal pneumonia) and bronchiectasis; pulmonary exacerbations in cystic fibrosis; legionellosis; atypical pneumonia (*Mycoplasma, Chlamydophila*)

Osteomyelitis caused by Gram-negative bacteria

Enteric fever (including chronic carriage), severe bacterial gastroenteritis, cholera

Mycobacterial infections caused by multidrug-resistant *M. tuberculosis*

Eradication of nasopharyngeal carriage of *N. meningitidis*

Anthrax (skin and inhalation)

The drug should be avoided in suspected or confirmed infections caused by *Str. pneumoniae*. It is inferior to conventional agents and some other fluoroquinolones in the treatment of genital tract infections caused by *C. trachomatis*.

Ciprofloxacin has also been shown to be effective in the treatment of patients with malignant otitis externa, cat-scratch disease, prevention of infection in patients undergoing biliary tract surgery, and treatment of biliary tract infections. A topical preparation for use in the treatment of ocular infections is available, but is neither more effective nor safer than established topical agents; it may be indicated for superficial eye infections caused by pathogens resistant to conventional drugs or in patients unable to tolerate standard therapeutic agents.

Preparations and dosage

Proprietary names: Ciproxin, Ciflox, Cipro, Ciloxan (ophthalmic)

Preparations: Tablets (including extended-release tablets), oral suspension, infusion, ophthalmic solution.

Dosage: Adults, oral, 250–750 mg every 12 h; i.v. infusion, 100–400 mg every 12 h. Children, where the benefits outweigh the risks, oral, 7.5–15 mg/kg per day in two divided doses; i.v., 5–10 mg/kg per day in two divided doses. Higher doses (400 mg every 12 h) needed in pseudomonal lower respiratory tract infection in cystic fibrosis.

Widely available.

NORFLOXACIN

Molecular weight: 319.3.

A 6-fluoro, 7-piperazinyl quinoline available for oral administration and as an ophthalmic ointment.

ANTIBACTERIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 26.2 (p. 307). It is active against a wide range of Gram-negative bacteria, including Enterobacteriaceae and *Campylobacter* spp. *Ps. aeruginosa*, *Acinetobacter*, *Serratia* and *Providencia* spp. are weakly susceptible (and often resistant). It has no useful activity against anaerobes, *Chlamydia*, *Mycoplasma* and *Mycobacterium* spp.

PHARMACOKINETICS

Oral absorption	50–70%
C_{max} 400 mg oral	1.5 mg/L after 1–1.5 h
Plasma half-life	3–4 h
Volume of distribution	2.5–3.1 L/kg
Plasma protein binding	15%

Absorption and distribution

Norfloxacin displays linear kinetics. There is no significant accumulation with the recommended dosage of 400 mg every 12 h. Food slightly delays but does not otherwise impair absorption. Antacids reduce absorption. It is widely distributed, but concentrations in tissues other than those of the urinary tract are low; levels in the prostate are around 2.5 mg/g.

Metabolism and excretion

Six or more inactive metabolites are produced. Around 30% of a dose appears as unchanged drug in the urine and <10% as metabolites, producing peak concentrations of microbiologically active drug of around 100–400 mg/L. Urinary recovery is halved by probenecid, with little effect on the plasma concentration. The apparent plasma elimination half-life increases with renal impairment, rising to around 8 h in the anuric patient. Some of the drug appears in the bile where concentrations three- to seven-fold greater than the simultaneous plasma levels are achieved, but this is not a significant route of elimination and hepatic impairment is without effect. Very variable quantities, averaging 30% of a dose, appear in the feces, producing concentrations of active agent of around 200–2000 mg/kg.

TOXICITY AND SIDE EFFECTS

Untoward reactions are those common to the fluoroquinolones (p. 309). Gastrointestinal tract disturbances, which are generally mild, have been reported in 2–4% of patients. CNS disturbances have largely been limited to headache, drowsiness and dizziness. Co-administration with theophylline results in increased plasma theophylline levels.

CLINICAL USE

Complicated and uncomplicated urinary tract infections (including prophylaxis in recurrent infections), prostatitis
Uncomplicated gonorrhea
Gastroenteritis caused by <i>Salmonella</i> , <i>Shigella</i> and <i>Campylobacter</i> spp., <i>Vibrio cholerae</i>
Conjunctivitis (ophthalmic preparation)

Preparations and dosage

Proprietary names: Utinor, Noroxin, Chibroxin (ophthalmic).

Preparations: Tablets, ophthalmic solution.

Dosage: Adults, oral, 400 mg every 12 h for 7–10 days; uncomplicated lower urinary tract infections, 400 mg every 12 h for 3 days; chronic relapsing urinary tract infections, 400 mg every 12 h for 12 weeks, reduced to 400 mg per day if adequate suppression within the first 4 weeks. Widely available.

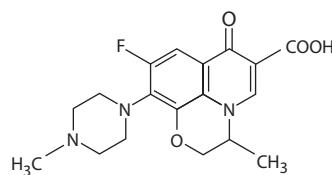

Further information

Anonymous. Norfloxacin. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:N137–N141.
 Holmes B, Brogden RN, Richards DM. Norfloxacin. A review of its antibacterial activity, pharmacokinetic properties and therapeutic use. *Drugs*. 1985;30:482–513.
 Symposium. Norfloxacin: a fluoroquinolone carboxylic acid antimicrobial agent. *Am J Med*. 1987;82(suppl 6B):1–92.

OFLOXACIN

Molecular weight: 361.38.

A tricyclic 6-fluoro, 7-piperazinyl quinoline with a methyl substituted oxazine ring substituted. It is a racemic mixture of L- (levofloxacin, see p. 319) and D-isomers.

ANTIBACTERIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 26.2 (p. 307). It exhibits good activity against a wide range of enterobacteria, including strains resistant to nalidixic acid, as well as against *Aeromonas*, *Campylobacter*, *Vibrio* and *Moraxella* spp. Activity against methicillin-sensitive *Staph. aureus* is good, but streptococci, including *Str. pneumoniae* and enterococci, are less susceptible. Most anaerobes are moderately or completely resistant. It is active against *L. pneumophila*, *Ch. pneumoniae*, *C. trachomatis*, mycoplasmas, ureaplasmas and *M. tuberculosis*. Other mycobacteria such as *M. fortuitum*, *M. kansasii*, *M. chelonei* and the *M. avium* complex are moderately susceptible.

PHARMACOKINETICS

Oral absorption	c. 95%
C_{\max} 400 mg oral 200 mg intravenous (30-min infusion)	3–5 mg/L after 1–1.5 h 1.8 mg/L 1 h after end infusion
Plasma half-life	5–7 h
Volume of distribution	1–2.5 L/kg
Plasma protein binding	c. 25%

Absorption and distribution

There is no significant interference with absorption by magnesium-aluminum hydroxide or calcium carbonate compounds,

providing administration is separated by at least 2 h. In patients receiving repeated 200 mg doses, the mean peak plasma concentration rose from 2.7 mg/L after the first dose to 3.4 mg/L after the seventh.

It is widely distributed, achieving levels $\geq 50\%$ of simultaneous plasma concentrations in many tissues, including lung and bronchial secretions. In cantharides and suction blisters, peak concentrations exceed those in plasma, while the elimination half-life is similar. In patients with non-inflamed meninges, 200 mg administered orally or by intravenous infusion over 30 min produced CSF concentrations of around 0.4–1 mg/L at 2–4 h while the plasma concentration was 1.7–4 mg/L; a 400 mg intravenous infusion yielded a CSF concentration of 2 mg/L, which is adequate for some Gram-negative bacteria, but not for Gram-positive bacteria or *Ps. aeruginosa*.

Metabolism and excretion

It is poorly metabolized into desmethyl and N-oxide derivatives (<5% of the administered dose), only about 20% of a dose being eliminated by non-renal routes. There is a very slight effect on cytochrome P₄₅₀-related isoenzymes and no significant effect on the metabolism of theophylline in dosages of up to 800 mg.

About 60% of a dose appears in the urine over 12 h and 80–90% over 48 h. The apparent elimination half-life is prolonged in renal failure, reaching 30–50 h in anuria, necessitating a dosage reduction. The desmethyl metabolite accumulates in all patients and the N-oxide in 50%. Absorption and distribution are not affected by renal failure. Significant amounts of the drug appear in the feces, producing very variable concentrations up to 100 mg/kg.

TOXICITY AND SIDE EFFECTS

Untoward reactions have been described in 2.5–7.5% of patients, and are those common to the group: gastrointestinal tract disturbances, rashes, tendon rupture and insomnia. CNS effects rarely occur.

CLINICAL USE

Complicated and uncomplicated infections of the urinary tract, chronic prostatitis
Uncomplicated urogenital and anorectal gonorrhea (single-dose), chancroid (3-day course), genital chlamydial infections (7-day course)
Lower respiratory tract infections, including bronchopneumonia, community-acquired pneumonia (except pneumococcal pneumonia), acute bacterial exacerbations of chronic bronchitis (unless pneumococci are involved) and bronchiectasis
Enteric fever, including the chronic carrier state; gastroenteritis caused by enterotoxigenic <i>Escherichia coli</i> , <i>Salmonella</i> , <i>Shigella</i> and <i>Campylobacter</i> spp.
Ocular infections (ophthalmic preparation)

Preparations and dosage

Proprietary names: Floxin, Oflocet, Tarivid, Exocin (ophthalmic).

Preparations: Tablets, injection, ophthalmic.

Dosage: Adults, oral, 200–400 mg per day, increased to 400 mg every 12 h in severe infections; i.v., 200–400 mg every 12 or 24 h depending on severity of infection.

Widely available.

OTHER GROUP 2 QUINOLONES

BALOFLOXACIN

A 6-fluoro-8-methoxy quinolone derivative. It has good antistaphylococcal activity (MIC 0.4–4 mg/L), but is inactive against methicillin-resistant *Staph. aureus* (MRSA) and quinolone-resistant *Staph. aureus*; *Str. pneumoniae* is inhibited by 0.4 mg/L. It has good activity against Enterobacteriaceae, but is inactive against *Ps. aeruginosa* (MIC 8–16 mg/L). After a 200 mg oral dose a peak level of 1.7 mg/L is reached in 1 h. The apparent elimination half-life is about 8 h, rising to 13 h in elderly subjects. Plasma protein binding is about 16%. It was withdrawn from the market in Japan because of adverse events, but is available in China.

ENOXACIN

A 1,8 naphthyridone derivative available as an oral drug. It exhibits good activity in vitro against many species of Enterobacteriaceae. It is inactive against *Ps. aeruginosa*, *Serratia*, *Citrobacter*, *Acinetobacter* and *Mycobacterium* spp., as well as anaerobes, chlamydiae and ureaplasmas.

It is well absorbed and widely distributed when given orally. Absorption is not significantly affected by food, but ranitidine, sucralfate and some antacids or mineral supplements may interfere with absorption. After repeated doses of 400 mg every 12 h for 14 days, mean peak plasma levels reach 3.5–4.5 mg/L, a steady state being achieved in 3–4 days.

About 40–60% of the administered dose is eliminated unchanged in the urine with <10% as the 3-oxo metabolite, which is 10–20 times less active than the parent compound. In renal failure, the apparent elimination half-life rises to >20 h, with marked reduction in the elimination of the oxo metabolite. Hemodialysis removes insignificant amounts of both compounds. Part is eliminated in bile, where concentrations of 4.5–25 mg/L have been noted when the corresponding serum levels were 0.5–2 mg/L.

About 6% of patients experience mild and transient effects typical of the quinolones: gastrointestinal tract disturbances, rashes, headaches and dizziness. Epileptiform and asthmatic attacks have occurred, but serious effects have been rare. Enoxacin interferes with theophylline metabolism.

It is no longer widely used, but is available in some countries for the treatment of urinary tract infection.

Preparations and dosage

Proprietary name: Enoxor.

Preparation: Tablets.

Dosage: Adults, oral, 200–400 mg every 12 h.

Available in Japan and parts of Europe.

Further information

Henwood JM, Monk JP. Enoxacin. A review of its antibacterial activity, pharmacokinetic properties and therapeutic use. *Drugs*. 1988;36:32–66.

FLEROXACIN

A trifluorinated quinolone formulated as the hydrochloride for oral use. The antibacterial spectrum and activity are similar to those of norfloxacin and ofloxacin (p. 307).

It is well absorbed, achieving a mean plasma concentration of 6 mg/L 1–2 h after a 400 mg dose. The apparent elimination half-life is 9–12 h. Absorption is unaffected by food. Bioavailability is absolute and binding to plasma protein is around 30%. It is widely distributed with tissue or fluid: plasma ratios of 0.6 in saliva, 0.3–2 in prostate and 1.7 in seminal fluid. About 50% of a dose appears in the urine as unchanged drug, giving urinary concentrations of the active compound of around 150–300 mg/L. The dosage interval (normally 24 h) should be increased in patients with renal failure.

Fleroxacin has been withdrawn from clinical use in many countries and is no longer recommended for the systemic treatment of infections.

Further information

Balfour JA, Todd PA, Peters DH. Fleroxacin. A review of its pharmacology and therapeutic efficacy in various infections. *Drugs*. 1995;49:794–850.

LOMEFLOXACIN

A difluoropiperazinyl quinolone formulated as the hydrochloride salt for oral administration. The in-vitro activity is very similar to that of norfloxacin (p. 307). It is active against Enterobacteriaceae and fastidious Gram-negative bacilli, including *L. pneumophila*. Activity against *Campylobacter* spp., *Ps. aeruginosa*, *Acinetobacter* and *Chlamydia* spp. is poor. It has reduced activity against staphylococci and poor activity against streptococci, *L. monocytogenes*, anaerobes and *Mycobacterium* spp.

A 400 mg oral dose achieves a concentration of 3–5 mg/L after 1–1.5 h. In escalating oral doses of 100, 400 and 800 mg to volunteers, the AUC was essentially proportional to the dosage, the mean plasma concentrations following 100, 400 and 800 mg doses being approximately 1.1, 4.7 and 7.5 mg/L, respectively.

Several metabolites have been described, accounting for <5% of the oral dose. Elimination occurs principally via the kidneys and 50–70% of a dose appears in the urine over 24 h. In patients with impaired renal function given 400 mg orally, the apparent elimination half-life ranged from 8 to 44 h, depending on the degree of renal failure. Non-renal clearance was also impaired, but there was no significant change in other pharmacokinetic parameters. The daily dosage (400 mg) should be reduced to 280 mg when the creatinine clearance falls below 30 mL/min. Hemodialysis has no effect on the plasma concentration. The effect of lomefloxacin on the plasma concentration of theophylline is clinically insignificant and no dosage adjustment is required.

The main adverse event is phototoxicity; other adverse events (mainly diarrhea, abdominal pain, skin reactions, dizziness, headache and insomnia) occur in about 10% of patients.

It is chiefly used in urinary tract infection, but is no longer widely available.

Preparations and dosage

Proprietary names: Maxaqin, Okacin.

Preparations: Tablets, ophthalmic.

Dosage: Adults, oral, 400 mg once daily.

Available in Japan, Russia and some European countries.

PAZUFLOXACIN

A tricyclic fluoroquinolone, formulated as mesylate and hydrochloride salts for oral or parenteral use or as a methane sulfonate (eye ointment).

It displays good activity in vitro against methicillin-susceptible *Staph. aureus* (MIC 0.2 mg/L), but is inactive against *Str. pyogenes*, *Str. pneumoniae* (MIC ≥4 mg/L) and enterococci. *L. pneumophila* is inhibited by 0.03 mg/L. Activity against Enterobacteriaceae, fastidious Gram-negative bacilli, *Ps. aeruginosa* and *Acinetobacter* spp. is similar to that of ofloxacin. It is weakly active against *Sten. maltophilia* and *Burkholderia cepacia* (MIC c. 2 mg/L). Against *M. tuberculosis*, MICs range from 0.8 to 4 mg/L. It is inactive against anaerobes.

After oral doses of 100 or 400 mg, peak plasma concentrations range from 0.94 mg/L (100 mg) to 4.5 mg/L (400 mg) after <1 h. The apparent elimination half-life is around 2 h. Most of the administered dose is eliminated in urine, about 70% within 24 h. Four metabolites have been reported. In elderly patients, according to the renal function, the peak plasma concentration may be elevated (up to 5.6 mg/L) and significantly delayed (2–6 h). The plasma protein binding ranges from 17% to 28%.

Preparations and dosage

Proprietary names: Pasil, Pazucross.

Preparations: Tablets, injection, eye ointment.

Dosage: 600 mg per day.

Available in China and Japan.

Further information

- Fukuoka Y, Ikeda Y, Yamashiro Y, Takahata M, Todo Y, Narita H. in vitro and in vivo antibacterial activities of T-3761, a new fluoroquinolone. *Antimicrob Agents Chemother*. 1993;37:384–392.
- Yamaki K-I, Hasegawa T, Matsuda I, Nadai M, Aoki H, Takagi K. Pharmacokinetic characteristics of a new fluoroquinolone, pazufloxacin in elderly patients. *J Infect Chemother*. 1997;3:97–102.

PEFLOXACIN

A 6-fluoro, 7-piperazinyl quinoline available for oral and intravenous administration. The in-vitro activity is very similar to that of norfloxacin (p. 307). It is active against *H. ducreyi*, *V. cholerae* and *Legionella* spp., but *Campylobacter* and *Acinetobacter* spp. and pseudomonads are not susceptible. It has poor activity against pneumococci, chlamydiae, mycoplasmas and ureaplasmas. *L. monocytogenes*, *Nocardia* spp. and anaerobes are resistant.

A plasma concentration of *c.* 5 mg/L is achieved 1–1.5 h after a 400 mg oral dose. The plasma elimination half-life is 8.5–15 h. It is widely distributed, concentrations in bone, brain, blister fluid, CSF, saliva, sputum and prostate all approximating, and in some cases exceeding, the simultaneous plasma concentration. It is extensively metabolized to the desmethyl (= norfloxacin) and *N*-oxide derivatives. Some 60–70% of a dose, only about 10% of which is unchanged, appears in the urine; 25% of a dose appears in the feces, a small part contributed by elimination in the bile.

The half-life increases with hepatic impairment, but is virtually unaffected by renal failure. In patients on continuous ambulatory peritoneal dialysis (CAPD) given 800 mg followed by 400 mg every 12 h for 10–12 days, there was no significant accumulation of pefloxacin or its metabolite, norfloxacin, but concentrations of pefloxacin *N*-oxide rose continuously in plasma and dialysate; all concentrations fell rapidly when treatment was discontinued.

Adverse reactions are those common to the group (p. 309). Most common are gastrointestinal tract disturbances, although some typical CNS reactions have been encountered. Skin eruptions (some photosensitive) occur and rashes appeared in about one-third of a group of patients who were given long-term therapy. Clinical uses are similar to those of ofloxacin.

Preparations and dosage

Proprietary name: Peflacine.

Preparations: Tablets, injection.

Dosage: Adults, oral, i.v., 400 mg every 12 h.

Available in Europe, Africa and Asia.

Further information

Gonzalez JP, Henwood JM. Pefloxacin: a review of its antibacterial activity, pharmacokinetic properties and therapeutic use. *Drugs*. 1989;37:628–668.
Symposium. Pefloxacin in clinical practice. *J Antimicrob Chemother*. 1990;26(suppl B):1–229.

PRULIFLOXACIN

A lipophilic prodrug which is very rapidly metabolized by esterase into ulifloxacin, a 6-fluoro, 7-piperazinyl thiazetoquinoline.

Ulifloxacin is moderately active against *Staph. aureus* (MIC 0.4–0.8 mg/L) and inactive against *Str. pneumoniae* (MIC 2–8 mg/L) as well as against *Enterococcus* spp. Against Enterobacteriaceae (MIC 0.05–0.8 mg/L) and *Ps. aeruginosa* (MIC 0.2–0.8 mg/L) activity is similar to that of ciprofloxacin. It is active against fastidious Gram-negative bacilli, but not against anaerobes and non-fermentative Gram-negative bacilli. Activity against *Acinetobacter* spp. is modest.

Prulifloxacin is rapidly converted into ulifloxacin and after 3 h is no longer detected in blood. In volunteers receiving a single oral dose, peak plasma concentrations of 0.68 mg/L (300 mg dose) to 1.88 mg/L (for 400 mg dose) were attained between 0.67 and 1.25 h. The mean apparent elimination half-life was 8 h and the mean cumulative elimination rate in urine within 48 h was 31–46%. Other inactive metabolites account for 7% of the dose. Half the administered dose is eliminated in feces within 72 h as ulifloxacin and 4% as prulifloxacin. Protein binding is 45%.

Preparations and dosage

Proprietary names: Glimbax, Keraflox, Primax, Pruquin, Unidrox.

Preparations: Tablets.

Dosage: Adults, oral, 600 mg per day.

Available in Italy and in Asia; under development in North America for treatment of traveler's diarrhea.

Yoshida T, Mitshuashi S. Antibacterial activity of NM-394, the active form of prodrug NM 441, a new quinolone. *Antimicrob Agents Chemother*. 1993;37:793–800.

RUFLOXACIN

A tricyclic fluoroquinolone formulated as the hydrochloride salt. It is inactive against Gram-positive cocci with MICs >2 mg/L. It displays weak activity in vitro against Enterobacteriaceae with the MIC for most species >1 mg/L. Activity against *Ps. aeruginosa* is poor (MIC 16–32 mg/L). After loading doses of 400 and 600 mg followed with 9 days of either 200 or 300 mg, mean peak plasma levels were around 4.5–7 mg/L, respectively. The mean apparent elimination half-life was 44 h. Approximately 50% is eliminated in the urine.

It has been used in urinary tract infection and chronic prostatitis, but clinical experience is limited.

Preparations and dosage

Proprietary name: Monos, Qari, Ruflox, Tebraxin, Uroclar, Uroflox.

Preparation: Tablets.

Dosage: Adults, oral, 400 mg on day 1, followed by 200 mg per day.

Available in some countries such as Italy, Mexico and Thailand.

GROUP 3 QUINOLONES

LEVOFLOXACIN

For molecular weight and structure, see ofloxacin (p. 315). Levofloxacin is the L-isomer of ofloxacin.

ANTIBACTERIAL ACTIVITY

Levofloxacin is the active component of ofloxacin; D-ofloxacin is without significant antibacterial activity. The activity against common bacterial pathogens is shown in Table 26.3. It exhibits good activity in vitro against Gram-positive cocci (including *Str. pneumoniae*), Enterobacteriaceae, some fastidious Gram-negative bacilli and *Ps. aeruginosa* as well as

chlamydiae, *Mycoplasma pneumoniae*, *L. pneumophila* and *M. tuberculosis*. MICs for *Acinetobacter* spp. and *Sten. maltophilia* are 0.06–0.25 and 0.5–2.0 mg/L, respectively. Activity against anaerobes is moderate to low.

PHARMACOKINETICS

Oral absorption	>95%
C_{max} 500 mg oral	c. 5 mg/L after 1.5–2 h
750 mg oral	c. 8 mg/L after 1.5–2 h
500 mg intravenous (90-min infusion)	c. 6 mg/L end infusion
750 mg intravenous (90-min infusion)	c. 12 mg/L end infusion
Plasma half-life	6–8 h
Volume of distribution	0.6–0.8 L/kg
Plasma protein binding	<25%

Co-administration with antacids, calcium, sucralfate and heavy metals decreases bioavailability and AUC. No interactions with warfarin or theophylline have been observed. Co-administration of a non-steroidal anti-inflammatory drug may increase the risk of convulsions. It undergoes limited metabolism and is primarily eliminated unchanged in urine by both glomerular filtration and tubular secretion. The free AUC:MIC ratio for *Str. pneumoniae* increases from about 55 to 70 when the daily dosage is raised from 500 mg to 750 mg.

It is stable in plasma and does not revert to D-ofloxacin. It undergoes limited metabolism and is primarily eliminated

Table 26.3 Activity of group 3 and group 4 fluoroquinolones against common pathogenic bacteria: MIC (mg/L)

	Garenoxacin	Gatifloxacin	Gemifloxacin	Levofloxacin	Moxifloxacin	Sparfloxacin	Tosufloxacin	Trovafloxacin

unchanged in the urine. Renal clearance in excess of the glomerular filtration rate suggests that tubular secretion also occurs. Concomitant administration of either cimetidine or probenecid reduces renal clearance by approximately one-third. Clearance is reduced and half-life is prolonged in patients with impaired renal function (creatinine clearance <50 mL/min) requiring dosage adjustment in such patients.

TOXICITY AND SIDE EFFECTS

Side effects have been reported in 6–7% of patients and include fever, rash and other events common to the group. Elderly patients are at increased risk of developing severe tendon disorders including rupture, a risk increased by concomitant corticosteroid therapy.

CLINICAL USE

- Acute bacterial sinusitis
- Acute bacterial exacerbations of chronic bronchitis, community-acquired pneumonia
- Uncomplicated and complicated skin and skin structure infections
- Uncomplicated and complicated urinary infections including acute pyelonephritis
- Chronic bacterial prostatitis

Preparations and dosage

- Proprietary names:** Cravit, Levaquin, Oftaquix, Quixin, Tavanic.
Preparations: Tablets, injection, ophthalmic solution.
Dosage: Adults, oral, 250–750 mg per day; i.v., 250–750 mg per day. Community-acquired pneumonia, acute bacterial sinusitis, 750 mg once daily. Ophthalmic solution 0.5% (Oftaquix, Quixin).
 Widely available.

OTHER GROUP 3 QUINOLONES

GATIFLOXACIN

Activity against common bacterial pathogens is shown in Table 26.3 (p. 319). The spectrum includes *Acinetobacter* spp. and *Aeromonas* spp. but it is not very active against *Ps. aeruginosa* and other non-fermentative Gram-negative rods. It is more active against methicillin-susceptible strains of staphylococci than methicillin-resistant strains. It is also active against *Chlamydia*, *Mycoplasma* and *Legionella* spp. and has some activity against anaerobes.

It is almost completely absorbed when given orally and is widely distributed throughout the body into many body tissues and fluids. The plasma half-life is 6–8 h. More than 70% of the drug is excreted unchanged in the urine. Renal clearance is reduced by 57% in moderate renal insufficiency and by 77% in severe renal insufficiency.

Prolongation of the QTc interval in some patients and interference with diabetes mellitus have resulted in withdrawal of the drug in most countries for systemic usage. Gatifloxacin remains in use in North America only as an ophthalmic solution.

SPARFLOXACIN

Activity against common bacterial pathogens is shown in Table 26.3 (p. 319). It is highly active against most aerobic Gram-positive cocci and Gram-negative bacilli, including fastidious Gram-negative bacilli, *Acinetobacter* spp., *Campylobacter* spp. and *Legionella* spp. *Ps. aeruginosa* is weakly susceptible. Activity also extends to the genital mycoplasmas, *M. tuberculosis* and *M. avium* complex isolates. It is moderately active against some anaerobes (including the *B. fragilis* group); *L. monocytogenes* is resistant.

It is well absorbed, achieving a plasma concentration of 1–1.5 mg/L 4.5 h after a 400 mg oral dose. Absorption is decreased in the presence of antacids owing to the formation of chelates with metallic ions. Concentrations in many tissues, including lung, exceed those in plasma. The plasma half-life is 15–20 h. CSF penetration is limited. Around 5–10% of a dose is eliminated unchanged in the urine, with about 30% appearing as the glucuronide. Total clearance is 10–15 L/h. The plasma half-life increases only modestly in renal failure to 30–40 h. About 50–60% of the dose appears as unchanged drug in the feces, mainly as the glucuronide, accounting for 10–20% of the administered dose.

Adverse events are those common to fluoroquinolones (p. 309), in particular gastrointestinal tract disturbances, CNS effects (mainly headache and insomnia) and rashes. Photosensitivity reactions have been observed in 2–11% of patients. It can prolong the QTc interval and cases of torsade de pointes have been reported. It does not potentiate the toxicity of theophylline.

It has been used for respiratory and other infections caused by susceptible bacteria, but use has been restricted in the USA and Europe because of phototoxicity and cardiotoxicity.

Preparations and dosage

Proprietary name: Zagam.
Preparation: Tablets.
Dosage: Adult, oral, loading dose of 400 mg on day 1; maintenance doses of 200 mg per day thereafter.
 Restricted use in the USA and the European Union but available in Asia.

TOSUFLOXACIN

Activity against common bacterial pathogens is shown in Table 26.3 (p. 319). It is active against a wide range of Gram-positive and Gram-negative bacteria, including *Acinetobacter* spp., *L. pneumophila* and *Campylobacter* spp. Unlike many quinolones it is moderately active against *L. monocytogenes*. *C. trachomatis* is also moderately susceptible. It is active against some anaerobes, including the *B. fragilis* group. Activity against *Mycobacterium* spp. is limited. It is well absorbed by the oral route, achieving a plasma concentration of c. 1 mg/L 4 h after a 300 mg dose. Around 30–35% of the dose is eliminated in the urine, with an apparent elimination half-life of 6–7 h.

Clinical experience is limited, but high clinical and bacteriological cure rates have been obtained in patients with skin and soft-tissue infections.

Preparations and dosage

Proprietary names: Ozex, Tosuxacin.
Preparation: Tablets.
Dosage: Adult, oral, 150 mg every 8 h.
 Available in Japan; not available in the USA or the European Union.

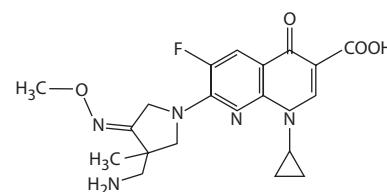

Further information

GROUP 4 QUINOLONES

GEMIFLOXACIN

Molecular weight: 389.4.

A fluoronaphthyridone derivative with a dual substituted pyrrolidine moiety at the C-7 position. It is formulated as the mesylate.

ANTIBACTERIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 26.3 (p. 319). The broad antibacterial spectrum embraces most Gram-positive cocci (including high potency against *Str. pneumoniae*) and Gram-negative bacilli. It possesses a high affinity for pneumococcal topoisomerase IV. Activity against Gram-negative respiratory tract pathogens such as *H. influenzae*, *Mor. catarrhalis*, *Ch. pneumoniae*, *L. pneumophila* and *Mycoplasma pneumonia* is good. It is relatively inactive against *Ps. aeruginosa* and *Enterococcus* spp. Activity against Enterobacteriaceae is similar to that of moxifloxacin but it is less potent against anaerobes. Gemifloxacin is inactive against *M. tuberculosis*. Activity against *Nocardia asteroides* (MIC 0.5–1 mg/L) is better than that of other quinolones other than the investigational compound nemonoxacin (see below).

Multistep resistance studies suggest that it is less likely than other quinolones to select for quinolone-resistant *Str. pneumoniae* strains. Because it inhibits both DNA gyrase and DNA topoisomerase IV enzyme systems at therapeutically relevant drug levels in *Str. pneumoniae*, single mutations in *parC* or *gyrA* result in only a small increase in the MIC. In *Str. pneumoniae* *gyrA* mutations arise at a lower rate (1.6×10^{-11}) than mutations in *parC*. It seems to be unaffected clinically by quinolone efflux mechanisms in *Str. pneumoniae*. Low rates of resistance selection have also been reported in *H. influenzae*.

PHARMACOKINETICS

Oral absorption	71%
C_{\max} 320 mg oral	1.6 mg/L after 0.5–2 h
Plasma half-life	c. 7 h
Volume of distribution	4.97 L/kg
Plasma protein binding	60–70%

Absorption and distribution

In oral escalating dose studies (single doses of 20–800 mg), C_{\max} ranged from 0.12 to 4.33 mg/L after an average of 1 h.

Antacids significantly reduce the systemic availability and protein binding is relatively high. Excellent concentrations are achieved in serum as well as various tissues such as bronchial mucosa, epithelial lining fluid and alveolar macrophages. Absolute bioavailability of the 320 mg oral tablet is around 71%. Pharmacokinetics are not significantly altered when administered with a high fat meal.

Metabolism and excretion

The apparent elimination half-life ranges from 6 to 9 h, and 26–40% of administered doses are eliminated in urine. It is metabolized to a limited extent in the liver. Cytochrome P₄₅₀ enzymes do not play an important role in metabolism, and the metabolic activity of these enzymes is unaffected. Around 65% of the parent compound and its metabolites are eliminated in the feces and the remainder in the urine. The mean renal clearance after repeated doses of 320 mg is about 11.6 L/h, indicating active renal secretion. The mean apparent elimination half-life at steady state following administration of 320 mg to healthy subjects was approximately 7 h. No dosage adjustment is recommended in patients with mild, moderate or severe hepatic impairment. Clearance is reduced and plasma elimination is prolonged in patients with renal insufficiency, leading to an average increase in AUC values of c. 70%. Hemodialysis removes approximately 20–30% of an oral dose from plasma.

TOXICITY AND SIDE EFFECTS

The most commonly reported side effects are diarrhea (3.6%), rash (2.8%) and nausea (2.7%). No evidence has emerged of a clinically significant prolongation in QTc interval. The phototoxicity potential is low and similar to that seen with ciprofloxacin. The overall incidence of drug-related rash is 2.8%. The rash is most commonly mild, macropapular (occasionally urticarial), predominantly self-limiting, and mainly occurs in women under 40 years and in postmenopausal women on hormone replacement therapy after ≥10 days.

CLINICAL USE

Community-acquired pneumonia in adults
Acute exacerbations of chronic bronchitis in adults

Preparations and dosage

Proprietary name: Factive.

Preparation: Tablets.

Dosage: Adults, 320 mg once daily for 5–7 days.

Available in the USA; not available in Europe.

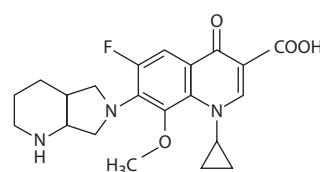

Further information

Allen A, Bygate E, Oliver S, et al. Pharmacokinetics and tolerability of gemifloxacin (SB-265805) after administration of single oral doses to healthy volunteers. *Antimicrob Agents Chemother*. 2000;44:1604–1608.

MOXIFLOXACIN

Molecular weight: 401.4.

A fluoroquinolone substituted with an 8-methoxy group and a 7-diazabicyclononyl moiety, formulated as the hydrochloride for oral or intravenous use.

ANTIBACTERIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 26.3 (p. 319). It displays good activity in vitro against Enterobacteriaceae and fastidious Gram-negative bacilli such as *H. influenzae* and *Mor. catarrhalis*, as well as against Gram-positive cocci including *Str. pneumoniae*, but is poorly active against *Enterococcus* spp. Activity against non-fermentative Gram-negative bacilli is species dependent: *Acinetobacter* spp. (MIC 0.006–2.0 mg/L) and *Sten. maltophilia* (MIC 0.5–2.0 mg/L) are partially susceptible in vitro, but it has poor activity against *Ps. aeruginosa* and other non-fermenting Gram-negative rods. It

displays good in-vitro activity against *Ch. pneumoniae*, *C. trachomatis*, mycoplasmas (including *M. pneumoniae*), *L. pneumophila* and *B. fragilis*. Although highly active against *M. tuberculosis*, it is less active against the *M. avium* complex, *M. intracellulare*, *M. chelonei* and *M. fortuitum*.

PHARMACOKINETICS

Oral absorption	86%
C_{\max} 400 mg oral	1.62–3.8 mg/L after 1–2 h
400 mg i.v. infusion (1 h, single dose)	3.6 mg/L end infusion
Plasma half-life	12–15 h
Volume of distribution	11.6 L/kg
Plasma protein binding	40%

Absorption and distribution

By the oral route, drug uptake is rapid, with moderate variability. As with all quinolones iron and antacids significantly reduce the bioavailability. No significant drug interactions with theophylline, itraconazole, probenecid or oral contraceptives have been found. In escalating dose studies (50–80 mg doses), C_{\max} and AUC values increased proportionally to the dose.

It is widely distributed throughout the body and into many tissues in concentrations exceeding those in plasma. Around 50–80% of plasma concentrations penetrate into CSF if the meninges are inflamed. The apparent plasma half-life is 15.6 h.

Metabolism and excretion

Biliary elimination and metabolism are the main elimination pathways. About 19.3% of the administered dose is eliminated in the urine, with a bioavailability of 86.2%. Urinary excretion is via glomerular filtration and tubular reabsorption. Two main metabolites are recovered: M1 (a sulfocompound) and M2 (a glucuronide). M1 is mainly eliminated in feces (34.4%) and only 2.5% in urine; M2 is eliminated in urine (13.8%).

TOXICITY AND SIDE EFFECTS

Adverse events are similar to those for other fluoroquinolones. Phototoxicity rates are not significantly above placebo levels. Gastrointestinal side effects are the most common, particularly nausea, diarrhea, abdominal pain and vomiting. Dizziness and headache may occur as well as allergic reactions. Attention has been drawn to a potential to cause life-threatening hepatotoxicity. Moxifloxacin has the potential to prolong the QTc interval in some patients but the clinical significance of this phenomenon is unclear.

CLINICAL USE

Acute bacterial exacerbations of chronic bronchitis and community-acquired pneumonia

Acute bacterial sinusitis

Treatment of complicated skin and soft-tissue infections caused by methicillin-susceptible *Staph. aureus* and Gram-negative rods (i.v. formulation)

Treatment of complicated intra-abdominal infections (i.v. formulation)

Preparations and dosage

Proprietary name: Avelox.

Preparations: Tablets, ophthalmic drops, i.v. infusion.

Dosage: Adults, oral, 400 mg tablets once daily; i.v. infusion 400 mg per day for 5–14 days.

Widely available.

OTHER GROUP 4 QUINOLONES

GARENOXACIN

An oral and parenteral des-fluoro(6) quinolone formulated as the mesylate. Activity against common bacterial pathogens is shown in Table 26.3 (p. 319). Activity in vitro against Enterobacteriaceae is similar to that of moxifloxacin. It is extremely active against *L. pneumophila* and is one of the most active quinolones against *Ch. pneumoniae* and *C. trachomatis*, as well as *M. pneumoniae* and *Ureaplasma urealyticum* (MIC 0.12–0.25 mg/L). It is poorly active or inactive against non-fermentative Gram-negative bacilli including *Ps. aeruginosa* but exhibits very good activity against Gram-positive cocci including methicillin-susceptible *Staph. aureus* and *Str. pneumoniae*. It is one of the most active quinolones against Gram-positive and Gram-negative anaerobes: 93% of isolates are inhibited by a concentration of 2 mg/L. Activity in vitro against *M. tuberculosis* is weak and it has no useful activity against *M. leprae* in mouse footpad tests.

After a single dose peak plasma levels vary between 1.2 mg/L (100 mg dose) and 16.3 mg/L (1200 mg dose). The apparent terminal half-life is around 11 h and protein binding is c. 80%. Main metabolites found in plasma, urine and feces include sulfate conjugates and glucuronides. Urinary elimination rates of approximately 31% and 43% at 24 h and 72 h, respectively, are found. Maximum plasma concentrations decrease by 20–52% in patients with severely impaired renal function and activity is slightly reduced in patients with moderately or severely impaired hepatic function. About 1.5–11% is removed by CAPD and hemodialysis.

Drugs containing aluminum, magnesium, calcium, iron and zinc decrease the activity. The incidence of hypotension tends to increase when it is co-administered parenterally with nitroglycerine or isosorbide nitrate. It is hardly metabolized by cytochrome P₄₅₀.

Clinically significant adverse effects include: shock or anaphylactoid reactions; hypotension; Stevens–Johnson syndrome; bradycardia; sinus arrest or atrioventricular block; hepatic function disorder with raised liver enzymes; hypoglycemia; pseudomembranous colitis; agranulocytosis; and rhabdomyolysis.

Preparations and dosage

Proprietary name: Geninax.

Preparation: Tablets.

Dosage: 400 mg once daily.

Available in Japan.

Further information

Fung-Tomc JC, Minassian B, Kolek B, et al. Antibacterial spectrum of a novel des-fluoro(6) quinolone, BMS-284756. *Antimicrob Agents Chemother*. 2000;44:3351–3356.
Liebtrau A, Rodloff AC, Behra-Miellet J, Dubreuil L. In vitro activities of a new des-fluoro(6) quinolone, garenoxacin, against clinical anaerobic bacteria. *Antimicrob Agents Chemother*. 2003;47:3667–3671.

SITAFLOXACIN

A group 4 quinolone formulated for oral or intravenous use. In-vitro activity is similar to or better than that of moxifloxacin. The antibacterial spectrum covers Gram-positive and Gram-negative bacteria including anaerobes. It has a chlorine atom at the C-8 position, and therefore has potential for phototoxicity. Early interest in this compound has not been maintained, but it is available in Japan.

Preparations and dosage

Proprietary name: Gracevit.

Preparations: Tablets, i.v. infusion.

Dosage: 400 mg once daily.

Available in Japan.

TROVAFLOXACIN

A trifluoroquinolone, formulated as the mesylate for oral administration and as a prodrug formulation (alatrofloxacin mesylate) for parenteral use. Activity against common bacterial pathogens is shown in Table 26.3 (p. 319). It is active against a wide range of Gram-positive and Gram-negative micro-organisms, including *L. pneumophila* and *L. monocytogenes*. It is inactive against *Ps. aeruginosa* and against non-fermentative Gram-negative bacilli such as *Sten. maltophilia* and *Burkholderia cepacia*. Most anaerobes other than *Clostridium difficile* are susceptible.

The mesylate is very well absorbed, achieving a plasma concentration of c. 2.5 mg/L 1 h after an oral dose. The apparent plasma half-life is 11 h.

Hepatotoxicity, sometimes with clinical jaundice and life-threatening acute liver failure, has been reported, resulting in withdrawal of the oral and intravenous formulations of the drug. It is no longer recommended for clinical use except as noted below.

Preparations and dosage

Proprietary name: Trovan.

Dosage: Adult, 200–300 mg i.v. infusion once daily. Oral, 100–200 mg once daily.

Available in the USA only as a compliance pack with azithromycin (see p. 287) for single-dose treatment of gonococcal and non-gonococcal urethritis. Limited availability elsewhere.

QUINOLONES USED SOLELY FOR TOPICAL INFECTIONS

BESIFLOXACIN

An amino-azepinyl quinolone formulated as a suspension for ophthalmic usage. It exhibits good antistaphylococcal activity, as well as activity against *Str. pneumoniae*, Enterobacteriaceae, *H. influenzae* and *Mor. catarrhalis*. It is weakly active against *Corynebacterium* spp. and has no useful activity against *Ps. aeruginosa*. After instillation into the eye, less than 0.1% of the drug reaches the plasma. It is used for bacterial conjunctivitis.

Preparations and dosage

Proprietary name: Besivance.

Preparation: 0.6% suspension.

Available in the USA.

Further information

Tepedino ME, Heller WH, Usner DW, et al. Phase II efficacy and safety study of besifloxacin ophthalmic suspension 0.6% in the treatment of bacterial conjunctivitis. *Curr Med Res Opin.* 2009;25:1159–1169.

NADIFLOXACIN

A lipophilic tricyclic fluorobenzoquinoline with a 4-hydroxylpiperinyl moiety at the C-8 position, formulated as a cream for topical use. It is active against many Gram-positive bacteria involved in skin infections, including *Propionibacterium acnes* (MIC 0.25–2.0 mg/L), and *Staph. aureus* (MIC 0.015–2 mg/L). It appears to inhibit the generation of reactive oxygen species by neutrophils. The sodium salt is used as a 1% cream for use in acne vulgaris and cutaneous staphylococcal infections.

Preparations and dosage

Proprietary name: Acutim, Nadiflox, Nadixa, Nadoxin.

Preparation: 1% cream.

Available in Japan and some European countries (e.g. Spain, Germany, Russia).

INVESTIGATIONAL QUINOLONES

Current research is mainly focused on derivatives able to overcome quinolone resistance or with activity against mycobacteria. Compounds in development at the time of writing include the following:

- Delafloxacin** (WQ 3034, ABT 492). It exhibits a broad antibacterial spectrum with expanded activity against Gram-positive organisms, including *Enterococcus* spp., and quinolone-resistant *Str. pneumoniae* and *Staph. aureus* that owe their resistance to efflux. Activity against *Ps. aeruginosa* is similar to that of ciprofloxacin (MIC 0.06–0.25 mg/L), but it is not active against ciprofloxacin-resistant Enterobacteriaceae. It has good in-vitro activity against *Helicobacter pylori*, *M. tuberculosis* and anaerobes. It is active against *Ch. pneumoniae* (MIC 0.125 mg/L) and *M. pneumoniae* (MIC 0.25–8 mg/L). In oral dosing studies peak plasma concentrations of 1.4 mg/L (100 mg dose) to 11.5 mg/L (1200 mg dose) were reached in around 1 h. The apparent elimination half-life is about 4 h.

- Levonadifloxacin** (WCK 771). A derivative of nadifloxacin formulated for parenteral use; an oral prodrug (WCK 2349) has also been synthesized. The *S* (–) isomer is 64–256 times more active than the *R* (+) isomer and twice as active as the racemate (nadifloxacin). It is more active than levofloxacin against *Str. pneumoniae* (MIC 0.5 mg/L) and displays potent antistaphylococcal activity (MIC 0.03 mg/L); strains resistant to methicillin and quinolones are inhibited by 0.5–1 mg/L. It has good overall activity in vitro against Gram-positive and Gram-negative anaerobic bacteria. At the end of a 1 h infusion, plasma concentrations ranged from 2 mg/L (50 mg dose) to 28 mg/L (800 mg dose). The apparent elimination half-life was around 5–6 h. Less than 5% of the parent compound is eliminated in urine, and 20% as glucuronate and sulfate metabolites.

- Nemonoxacin**. A 6(des)-fluoro quinolone. It displays good activity in vitro against *Staph. aureus* (MIC 0.03–0.06 mg/L) including strains resistant to other quinolones (MIC 1–2 mg/L) and is highly active against *Str. pneumoniae* (MIC ≤0.03–0.06 mg/L). It is inactive against *M. tuberculosis*. Absorption after oral administration is rapid; the peak plasma concentration ranges from 0.37 mg/L (50 mg dose) to 12.1 mg/L (1500 mg dose) with a long apparent elimination half-life (*c.* 10–13 h). It is mainly eliminated in urine (around 50%). The protein binding is 16%. Food affects the pharmacokinetics by delaying absorption. After repeated doses, the half-life increases significantly and steady state is reached after 3–5 days.

- Zabofloxacin** (DW 224a). An analog of gemifloxacin anticipated to have better tolerability. It exhibits good in-vitro activity against Gram-positive cocci including *Str. pneumoniae* and *Staph. aureus*. It displays a bimodal distribution of activity against *Ps. aeruginosa* and *Sten. maltophilia*. Activity against Enterobacteriaceae is similar to that of ofloxacin. It is inactive against *Enterococcus* spp. but is very active against *H. influenzae*. After single oral ascending doses, peak plasma concentrations ranged from 0.7 mg/L (200 mg dose) to 3.6 mg/L (800 mg dose) after an average of 2 h. The mean apparent elimination half-life was 6 h. Protein binding was 77%.

CHAPTER

27 Rifamycins

Francesco Parenti and Giancarlo Lancini

The rifamycins are a family of antibiotics produced by an actinomycete now classified as *Amycolatopsis mediterranei*. All the therapeutically useful rifamycins are semisynthetic derivatives of rifamycin B, a fermentation product that is poorly active, but easily produced and readily converted chemically into rifamycin S, from which most active derivatives are prepared. They all share the general structure:

Natural products like rifamycins, which are characterized by an aromatic ring spanned by an aliphatic bridge (ansa) are called 'ansamycins'. To this class belong the streptovaricins and the tolypomycins (chemically and biologically similar to rifamycins) and geldanamycin and the maytansines, which have quite different, antineoplastic, biological activities. Among the vast number of rifamycin derivatives investigated, rifampicin (rifampin) is by far the most important and most widely used. Various others, notably rifabutin, rifapentine and rifaximin, are also in use in various parts of the world. Rifamycin SV and rifamide are much less widely available.

Interest in these antibiotics centers on their potent activity against pathogenic Gram-positive cocci and mycobacteria. Knowledge of the general properties of the group is largely based on extensive study and use of rifampicin but, insofar as they have been investigated, the main features are exhibited also by the other congeners:

- Bactericidal action through inactivation of bacterial DNA-dependent RNA polymerase
- Mechanism of resistance consisting of mutation of specific amino acids in the β -chain of RNA polymerase

- Relatively high frequency of resistant mutants; resistance is not horizontally transferable
- Significant biliary excretion and stimulation of hepatic metabolism.

The structure of RNA polymerase is highly conserved among bacteria and when tested in cell-free systems all rifamycins present similar intrinsic activity. Differences in the minimum inhibitory concentration (MIC) values among the various congeners are caused by different abilities to penetrate into cells. Rifamycins also inhibit the RNA polymerase of eukaryotic organelles, such as mitochondria, since these are of a prokaryotic type. Some rifamycins carrying a large lipophilic chain inhibit eukaryotic RNA and DNA polymerases and viral reverse transcriptases. These effects have no clinical significance.

The different congeners differ substantially in their pharmacokinetic behavior and in their therapeutic efficacy. The principal use of rifampicin and rifapentine is in the treatment of tuberculosis and leprosy. Rifabutin is approved for the prevention of mycobacterial infections in AIDS patients. Rifampicin proved so important in the treatment of tuberculosis that in many countries its use was restricted to that indication for fear that more widespread use would encourage the emergence of resistant *Mycobacterium tuberculosis* strains. Those fears have proven to be exaggerated and interest has been increasingly refocused on what was originally anticipated to be an important use: treatment of severe Gram-positive infections. To prevent emergence of resistance, co-administration of another effective agent is required.

Rifaximin does not encourage emergence of resistance in mycobacteria and is used in the treatment of gastrointestinal infections. Rifamycin SV and rifamide were originally released for the treatment of infections with susceptible Gram-positive organisms and infections of the biliary tract.

RIFABUTIN

Rifabutine; ansamycin. Molecular weight: 847.02.

A semisynthetic spirocyclic derivative of rifamycin S, available for oral administration. It is slightly soluble in water and soluble in organic solvents.

ANTIMICROBIAL ACTIVITY

The activity is similar to that of rifampicin, but it is more active against the *Mycobacterium avium* complex (MIC 0.01–2 mg/L) (Table 27.1) and several other atypical mycobacteria.

It inhibits the replication of human immunodeficiency virus 1 (HIV-1) in concentrations (10 mg/L) that are not toxic to lymphoid cells, but no efficacy on HIV infections has been demonstrated.

ACQUIRED RESISTANCE

The frequency of spontaneously resistant mutants in several bacterial species, including *M. tuberculosis*, *M. leprae*, *Staphylococcus aureus* and *Chlamydia trachomatis*, is somewhat lower than with rifampicin.

Table 27.1 Activity of rifabutin and rifampicin on clinical isolates of *M. avium* complex strains (MIC for 90% of strains)

Organism	Rifampicin	Rifabutin
<i>Mycobacterium avium</i>	4	0.4
<i>M. intracellulare</i>	2	0.5
<i>M. avium</i> complex (AIDS patients) (non-AIDS patients)	2 4	1 2

PHARMACOKINETICS

Oral absorption	12–20%
C_{max} 300 mg oral	0.38 mg/L after 3.3 h
Plasma half-life	16 h
Volume of distribution	9.3 L/kg
Plasma protein binding	85%

Absorption and distribution

Oral absorption is rapid but incomplete, with considerable inter-patient variation. It is well distributed, concentrations in many organs being higher than that in plasma. The average concentration in lungs is 6.5 times the simultaneous plasma concentration.

Metabolism and excretion

Rifabutin is mainly metabolized to the active desacetyl derivative, although several other oxidation products have been detected in urine, where some 10% of the dose is eliminated. About 30–50% of the dose can be recovered from the feces. Elimination from plasma is biphasic, with a terminal half-life of 45 h. The drug is a weak inducer of hepatic enzymes. The rate of metabolism increases, and the plasma area under the concentration–time curve (AUC) declines as the treatment continues.

INTERACTIONS

Clarithromycin and ritonavir both inhibit cytochrome P₄₅₀, resulting in decreased metabolism and increased plasma levels of rifabutin when the drugs are used together. Association with delavirdine should be avoided.

TOXICITY AND SIDE EFFECTS

Rash (4% of patients), gastrointestinal intolerance (3%) and neutropenia (2%) are fairly common and may require discontinuation of treatment. Uveitis and general arthralgia are rare with a 300 mg dosage, but frequent with higher dosages, especially with concomitant use of fluconazole or macrolide antibiotics.

CLINICAL USE

Prevention of infections with <i>M. avium</i> complex in AIDS patients
Treatment of non-tuberculous mycobacterial disease (in combination with other agents)

Rifabutin in combination with other agents has been proposed as a rescue therapy after *Helicobacter pylori* treatment failures.

Although some efficacy has been observed in the treatment of tuberculosis, its use for this condition is not recommended.

Preparations and dosage

Proprietary name: Mycobutin.

Preparation: Capsules.

Dosage: Adults, oral, prophylaxis of *M. avium* complex infections in immunocompromised patients with low CD4 count, 300 mg per day as a single dose. Treatment of non-tuberculous mycobacterial disease, in combination with other drugs, 450–600 mg per day as a single dose for up to 6 months after cultures become negative. Treatment of pulmonary tuberculosis, in combination with other drugs, 150–450 mg per day as a single dose for at least 6 months.

Widely available, including the UK and the USA.

RIFAMPICIN

Rifampin (USAN). Molecular weight: 822.95.

A semisynthetic derivative of rifamycin SV, available for oral administration or intravenous infusion and in several combined formulations with other antimycobacterial drugs. It is poorly soluble in water, but soluble in organic solvents.

ANTIMICROBIAL ACTIVITY

The activity against common bacterial pathogens is shown in Table 27.2. It exhibits potent activity in vitro against Gram-positive cocci, including methicillin-resistant staphylococci (MIC <0.025–0.5 mg/L) and penicillin-resistant pneumococci. Enterococci are less susceptible. Gram-positive bacilli, including *Bacillus* spp., *Clostridium difficile*, *Corynebacterium* spp. and *Listeria monocytogenes*, are highly susceptible (MIC 0.025–0.5 mg/L). The pathogenic *Neisseria* and *Moraxella* spp. are also highly susceptible.

Enteric Gram-negative bacteria are generally less sensitive (MIC 1–32 mg/L), but *Bacteroides fragilis* is highly susceptible. Among other Gram-negative bacilli, *Haemophilus influenzae*, *H. ducreyi*, *Flavobacterium meningosepticum* and *Legionella* spp. are highly susceptible (MIC <0.025–2 mg/L). *Chlamydia trachomatis* and *Chlamydophila psittaci* are inhibited by low concentrations (0.025–0.5 mg/L).

Most strains of *M. tuberculosis*, *M. kansasii* and *M. marinum* are inhibited by <0.01–0.1 mg/L, but *M. fortuitum* and members of the *M. avium* complex are resistant. *M. leprae* is highly sensitive.

Rifampicin is active against some eukaryotic parasites through inhibition of the prokaryote-like polymerase of kinetoplasts or mitochondria. Maturation of *Plasmodium falciparum* is inhibited by 2–10 mg/L; at higher concentrations *Leishmania* spp. are also inhibited.

High concentrations inhibit growth of a variety of poxviruses by interference with viral particle maturation; viral reverse transcriptase is unaffected.

Table 27.2 Activity of rifampicin against common pathogenic bacteria

Organism	MIC (mg/L)
<i>Staphylococcus aureus</i>	0.008–0.06
<i>Streptococcus pyogenes</i>	0.03–0.1
<i>Str. pneumoniae</i>	0.06–4
<i>Enterococcus faecalis</i>	1–4
<i>Mycobacterium tuberculosis</i>	0.1–1
<i>Neisseria gonorrhoeae</i>	0.06–0.5
<i>N. meningitidis</i>	0.01–0.5
<i>Haemophilus influenzae</i>	0.5–1
<i>Escherichia coli</i>	8–16
<i>Klebsiella pneumoniae</i>	16–32
<i>Pseudomonas aeruginosa</i>	32–64

ANTIMICROBIAL INTERACTIONS

Because of the relative ease with which resistant mutants emerge, rifampicin is normally used in combination with unrelated antibiotics. Combination with β -lactam agents or glycopeptides (vancomycin and teicoplanin) in vitro usually results in antagonism or indifference, but synergy with penicillins is found in some strains of *Staph. aureus* and the combination has proved effective in some cases in vivo. Rifampicin antagonizes the bactericidal effect of ciprofloxacin against *Staph. aureus*. Synergy with aminoglycosides occurs in vitro against *Escherichia coli* and with polymyxin B against multiresistant *Serratia marcescens*. Synergy with trimethoprim against enterobacteria, streptococci and staphylococci has been reported, but others have found indifference, or sometimes antagonism, and there appears to be substantial individual strain variation. Synergy with erythromycin, clindamycin and other antistaphylococcal agents has been demonstrated against some strains of *Staph. aureus*.

In-vitro activity against *M. tuberculosis* is increased in the presence of streptomycin and isoniazid, but not ethambutol. Synergy with amphotericin B against *Candida albicans* and against the mycelial phase of *Coccidioides immitis* is seen in vitro. However, this is not a clinically useful interaction.

ACQUIRED RESISTANCE

Most large bacterial populations contain resistant mutants, which readily emerge in the presence of the drug and can emerge during treatment. The mutation rate to resistance in *Staph. aureus*, *Str. pyogenes*, *Str. pneumoniae*, *Esch. coli* and *Proteus mirabilis* is about 10^{-7} and that to *M. tuberculosis* and *M. marinum* 10^{-9} – 10^{-10} . Primary resistance in *M. tuberculosis* remained low for many years, but is increasing.

Resistance is of the one-step type, and several classes of mutants exhibiting different degrees of resistance can be selected by exposing a large population to a relatively low concentration of the drug. Some of these mutants may be susceptible to other rifamycin derivatives.

Resistance is due to a change in a single amino acid of the β subunit of DNA-dependent RNA polymerase, which no longer forms a stable complex with rifampicin. It is not transferable and there is no cross-resistance with any other antibiotic class. The susceptible strains of the gastrointestinal flora become rapidly resistant during rifampicin treatment without alteration in the flora composition, and revert to susceptibility within a few weeks of cessation of treatment.

PHARMACOKINETICS

Oral absorption	>90%
C_{max} 300 mg oral	4 mg/L after 2 h
600 mg oral	10 mg/L after 2 h
Plasma half-life	2.5 h
Volume of distribution	1.5 L/kg
Plasma protein binding	80%

Absorption

Rifampicin is virtually completely absorbed when administered orally, but substantial differences in blood levels have been reported in comparisons of capsules or tablets from different manufacturers. Peak plasma levels differ noticeably between individuals. Food affects absorption, the peak plasma levels being delayed and about 2 mg/L lower after a meal. Although the AUC and the length of time for which effective antibacterial levels are maintained are little affected, it is preferable that patients take the drug before meals.

Intravenous administration produces AUCs and elimination half-lives similar to those obtained after oral doses.

Distribution

The lipid solubility of the drug facilitates its distribution. It is widely distributed in the internal organs, bones and fluids, including tears, saliva, ascitic fluid and abscesses. It penetrates into cells and is active against intracellular bacteria. Low concentrations are found in the cerebrospinal fluid (CSF), but these are substantially higher when the meninges are inflamed. Concentrations around 60% of the simultaneous plasma value were found in the heart valves of patients receiving a 600 mg dose before surgery.

Metabolism

Rifampicin is metabolized principally to its desacetyl derivative, which is also antimicrobially active, and this process is accelerated by its stimulatory effect on hepatic microsomal enzymes. As a consequence, hepatic clearance increases on continuous administration and, especially with high doses, the serum half-life becomes shorter after a few days of treatment.

Excretion

The main route of elimination is secretion into the bile, a process that is dose dependent, being efficient at low dosage but limited at high dosage. As a result, the dose determines the proportion excreted via the bile or passing the liver to be excreted in the urine. Because there is a limit to the rate at

which the liver can deliver the drug to the bile, the elimination half-life after a 600 mg dose rises to 3 h and may be as long as 5 h with a 900 mg dose.

The desacetyl compound is mainly found in the bile, where the parent compound accounts for only 15% of the total. Plasma levels are increased by hepatic insufficiency and biliary obstruction, and by probenecid, which depresses hepatic uptake. The drug escaping biliary excretion appears in the urine, to which it imparts an orange-red color, the parent compound and the desacetyl metabolites being present in about equal proportions. The plasma concentration and half-life are not significantly affected by renal failure. The drug is not removed by hemodialysis.

DRUG INTERACTIONS

The antibiotic is a potent inducer of hepatic cytochrome P₄₅₀ microsomal enzymes, which leads not only to more rapid self-elimination but also to enhanced metabolism of other agents handled by the same process. The effect is selective and it is not possible to predict which drugs may be affected. The most important are warfarin, the anticoagulant effect of which is thereby diminished, and oral contraceptives, with possible breakthrough bleeding and unwanted pregnancy. Addisonian crises have been described, and adjustments to steroid dosage in patients with Addison's disease may be necessary. Plasma concentrations of a number of other drugs may be affected, including digoxin, quinidine, methadone, hypoglycemic agents and barbiturates, with corresponding pharmacological effects.

Among antiretroviral drugs, use in combination with indinavir and its congeners is not recommended, but it can be used with ritonavir or nevirapine.

TOXICITY AND SIDE EFFECTS

Rifampicin is relatively non-toxic, even when administered for a long period (as in the treatment of tuberculosis). However, several unwanted effects, including pink staining of soft contact lenses, are associated with its use. Other reactions can be divided into those associated with daily or intermittent administration, and those found only with intermittent therapy.

Adverse events associated with daily or intermittent therapy

Most common are skin reactions (mostly flushing with or without rash, and often transient even when therapy is continued), gastrointestinal disturbances (usually mild and most

common in the early weeks of treatment) and disturbance of hepatic function. Transient abnormalities of liver function, especially a rise in serum transaminases (and, less often, a raised bilirubin level), are common, and clinical hepatitis, usually of mild degree, also occurs. Hepatitis was commonly recorded in some early studies, but the incidence in short-course regimens appears to be low. Early suggestions that hepatic damage was more common in rapid acetylators when given in combination with isoniazid have not been confirmed.

Thrombocytopenia, associated with complement-fixing serum antibodies, is uncommon. The platelet count falls within a few hours, returning to normal within a day or two. Rifampicin administration should be discontinued at once. Thrombocytopenia is more common with intermittent schemes, but is also encountered in patients receiving daily treatment.

Adverse events confined to patients receiving intermittent therapy

The most important is the 'flu' syndrome, with fever, chills and malaise usually developing after 3–6 months of treatment. Its incidence is less with frequent than infrequent dosage; less with lower than higher doses; and less when intermittent therapy is preceded by an initial phase of daily treatment. It was not, however, prevented by a daily supplement of 25 mg in an intermittent regimen. Circulating immunoglobulin M (IgM) antibodies to rifampicin are found in serum, and the 'flu' syndrome may be caused by resulting complement activation.

Other rare syndromes associated with intermittent administration are acute renal failure, sometimes associated with acute hemolysis. Shortness of breath, wheezing and fall of blood pressure have occasionally been recorded. Immunosuppressive properties are demonstrable in a number of experimental systems, but no resultant adverse effect has been described in humans.

CLINICAL USE

Tuberculosis (in combination with other antituberculosis agents; see Ch. 58)

Leprosy (in combination with other antileprotic agents; see Ch. 57)

Serious infection with multiresistant staphylococci and pneumococci (in combination with a glycopeptide)

Elimination of nasopharyngeal carriage of *Neisseria meningitidis* and *H. influenzae*.

Reference is made to its use in legionellosis (Ch. 45), meningitis (Ch. 50) and brucellosis (Ch. 61).

Preparations and dosage

Proprietary names: Rifadin, Rimactane. In combination with isoniazid: Rifinah, Rimactazid. In combination with isoniazid and with pyrazinamide: Rifater.

Preparations: Capsules, syrup, i.v. infusion.

Dosage: Adults, oral, 450–600 mg per day as a single dose, based on approx. 10 mg/kg per day. Children, up to 20 mg/kg per day as a single dose (maximum dose, 600 mg per day). Premature and newborn infants, 5–10 mg/kg once daily; treat only in cases of emergency and with extreme caution because their liver enzyme system may not be fully developed. Adults, i.v. infusion, 450–600 mg per day as a single dose, based on approx. 10 mg/kg per day. Lower doses are recommended for small or frail patients. Children, 20 mg/kg per day (maximum dose, 600 mg per day). Premature and newborn infants, 10 mg/kg per day with caution, as for oral dose. Chemoprophylaxis of meningococcal meningitis: adults, oral, 600 mg every 12 h for 2 days; children 1–12 years, 10 mg/kg every 12 h for 2 days; infants up to 1 year, 5 mg/kg every 12 h for 2 days.

Widely available.

An analog of rifampicin in which a cyclopentyl group is substituted for a methyl group on the piperazine ring. It is available for oral administration.

ANTIMICROBIAL ACTIVITY

Activity is similar to that of rifampicin, but it is more active against atypical mycobacteria, especially the *M. avium* complex (MIC <0.06–0.5 mg/L). It has good activity on staphylococci and streptococci (MIC 0.01–0.5 mg/L), *L. monocytogenes* and *Brucella* spp.; less against *Enterococcus faecalis* (MIC 1–4 mg/L). *Bacteroides* spp. are inhibited by 0.5–2 mg/L. Gram-negative cocci are susceptible and, although some Gram-negative bacilli are inhibited by 4–32 mg/L, most are resistant.

PHARMACOKINETICS

Oral absorption	c. 70%
C_{max} 600 mg oral	12 mg/L after 5 h
Plasma half-life	13 h
Volume of distribution	1.5 L/kg
Plasma protein binding	97%

RIFAPENTINE

Molecular weight: 877.04.

Absorption

The absolute oral bioavailability of rifapentine has not been determined. The relative bioavailability of capsules (with an oral solution as reference) is 70%. Food increases absorption: a 600 mg dose taken after a meal gives C_{max} and AUC values 44% higher than under fasting conditions. The extended half-life provides therapeutic concentrations for at least 72 h after administration, allowing less frequent dosing.

Distribution

Animal data suggest that it is well distributed in the body, with tissue concentrations exceeding the plasma concentration, except in bone, testes and brain. The ratio of intracellular:extracellular concentration in macrophages was estimated as 24:1.

Metabolism

The main metabolite is an antimicrobially active 25-desacetyl derivative. Although it induces liver cytochromes it is not an inducer of its own metabolism, which is mediated by an esterase. The peak concentration of 25-desacetyl rifapentine is about one-third of that of the unchanged drug, and is attained after about 11 h.

Excretion

The main route of elimination is through the bile. In healthy volunteers about 70% of a 600 mg dose of ¹⁴C rifapentine was recovered in the feces, and less than 17% in the urine. There is evidence of enterohepatic recycling in humans.

DRUG INTERACTIONS

The metabolism of several drugs concurrently administered can be substantially accelerated and adjustment of their dosage may be necessary. In particular, treatment of AIDS patients with rifapentine resulted in a 70% reduction in the AUC of indinavir. It should be used with extreme caution, if at all, in patients who are also taking protease inhibitors.

TOXICITY AND SIDE EFFECTS

Signs of teratogenic effects and fetal toxicity have been observed when administered during pregnancy to rats and rabbits. Rifapentine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

The most common adverse effect observed in combinations with other antimycobacterial agents was hyperuricemia, most probably due to pyrazinamide. Effects likely to be due to rifapentine were neutropenia (3.7% of patients) and hepatitis (increased transaminases in 1.6% of patients).

CLINICAL USE

Tuberculosis (in combination with other antituberculosis drugs)

Preparations and dosage

Proprietary name: Priftin.

Preparation: 150 mg tablets.

Dosage: Adults, oral, 600 mg (4 tablets) twice a week during the 2-month intensive phase treatment; 600 mg once a week in the 4-month continuation phase.

Available in the USA.

RIFAXIMIN

Molecular weight: 785.879.

A semisynthetic derivative of rifamycin S formulated for oral administration. It is poorly absorbed from the gastrointestinal tract, where its high concentrations are effective against a variety of gastrointestinal pathogens.

ANTIMICROBIAL ACTIVITY

The in-vitro activity is slightly inferior to that of rifampicin. The MIC₉₀ for Gram-positive cocci is well below 1 mg/L, with the exception of enterococci (MIC 2–8 mg/L). Among intestinal pathogens *C. difficile* is sensitive (MIC₉₀ 0.8 mg/L), *Esch. coli*, *Salmonella* spp. and *Shigella* spp. are inhibited by 4–8 mg/L. *Campylobacter jejuni* is mostly insensitive.

PHARMACOKINETICS

Oral absorption is very low. However, a fraction of the dose may be absorbed and rapidly eliminated through the bile. A 400 mg oral dose produces a maximum plasma concentration of 3.8 µg/L after 1.2 h. The plasma half-life is 5.8 h. Up to 90% of the administered dose is concentrated in the gut, less than 0.2% in the liver and kidney, and less than 0.01% in other tissues.

TOXICITY AND SIDE EFFECTS

Oral doses up to 100 mg/kg for 6 months produced no significant signs of toxicity to rats. Teratogenic effects in rats and rabbits have been reported (pregnancy category C).

Very few adverse effects were reported during human treatment, mostly gastrointestinal discomfort. Prolonged therapy was associated with infrequent urticarial skin reactions.

CLINICAL USE

It is used for a variety of gastrointestinal diseases, including the treatment of traveler's diarrhea. Preliminary results suggest clinical efficacy in the therapy of hepatic encephalopathy and of *C. difficile* infections.

Preparations and dosage

Proprietary names: Normix, Rifacol, Xifaxan, Rifaximina, Rifaximine and others.

Preparations: Tablets, granules, topical.

Dosage: Adults, oral, 10–15 mg/kg per day. Children, oral, 20–30 mg/kg per day.

Widely available.

of tuberculosis because of insufficient distribution to the tissues.

Preparations and dosage

Preparations: Parenteral injection, i.m., i.v., topical.

Dosage: i.m., 250 mg every 8 h; i.v. infusion (slow), up to 750 mg every 12 h.

Limited availability.

OTHER RIFAMYCINS

RIFAMIDE

The diethyl amide of rifamycin B, formulated as the sodium salt for parenteral administration. It exhibits high activity against Gram-positive organisms and *M. tuberculosis* typical of the group. MICs for Gram-negative bacilli are of the order of 20–50 mg/L.

It is absorbed orally and is rapidly eliminated through the bile, achieving concentrations sufficient to inhibit Gram-negative bacilli. In contrast to rifampicin, it can be administered as the sodium salt by intramuscular injection. A dose of 150 mg produces mean plasma levels of about 1 mg/L. The plasma half-life is about 2 h. The same dosage produces concentrations over 1 g/L in bile and c. 40 mg/L in the gallbladder wall.

Toxicity and side effects are similar to those of other rifamycins. It has been used in staphylococcal infections and infections of the biliary tract. It is unsuitable for the treatment

RIFAMYCIN SV

The simplest rifamycin in clinical use, obtained by elimination of a glycolic moiety from rifamycin B. Formulated as sodium salt for parenteral administration. Also available for topical use. Its activity, general properties and pharmacokinetics are very similar to those of rifamide. It is orally absorbed and excreted mainly in the bile. Intramuscular doses of 250 mg produce mean plasma levels of about 2 mg/L. The plasma half-life is around 2 h.

In addition to uses similar to those of rifamide, it is administered topically in surgery and has been proposed for the treatment of synovitis by intra-articular injections. A topical preparation is used for application to wounds and bedsores. Cases of anaphylactic reactions have been reported after local administration of the drug.

Preparations and dosage

Proprietary names: Chibro-Rifamycin, Otofa, Rifocene.

Preparations: Parenteral injection, i.m., i.v., topical.

Dosage: i.m., 250 mg every 8 h; i.v. infusion (slow), up to 750 mg every 12 h.

Available in Italy, Switzerland and Germany.

28 Streptogramins

Francisco Soriano

Streptogramins are natural mixtures of cyclic peptides produced by *Streptomyces* spp., which display a synergistic inhibitory effect on some bacteria. They are macrocyclic lactone peptolides, having two basic chemical structures classified as either group A or group B. Compounds of group A are polyunsaturated cyclic peptolides, the best known being virginiamycin M₁, pristinamycin II_A, pristinamycin II_B and dalfopristin (a pristinamycin II_B derivative). Compounds of group B are cyclic hexadepsipeptides, with virginiamycin S and pristinamycins I_A, I_B and I_C as the principal compounds. Quinupristin is a pristinamycin I_A derivative.

Streptogramins behave as bacteriostatic drugs, but a mixture of group A and group B antibiotics causes a 10–100-fold greater inhibition of bacterial growth than the individual components. Useful activity is mainly restricted to Gram-positive organisms (Table 28.1). Naturally occurring group A and group B components are both highly water insoluble and have to be administered by mouth. Quinupristin and dalfopristin are water soluble and can be administered parenterally in a fixed 30:70 ratio marketed as Synercid.

Table 28.1 In-vitro activity of three streptogramins against Gram-positive organisms: MIC (mg/L)

	Quinupristin-dalfopristin	Pristinamycin	NXL 103
<i>Staphylococcus aureus</i>			
methicillin-susceptible	0.12–0.5	≤0.06–1	0.06–0.25
methicillin-resistant	0.12–1	0.25–2	0.06–0.5
<i>Staph. epidermidis</i>	≤0.06–0.5	≤0.06–2	0.06–1
<i>Streptococcus pneumoniae</i>	0.12–1	0.12–1	0.06–1
<i>Str. pyogenes</i>	0.25–1	≤0.06–0.12	≤0.06
<i>Str. agalactiae</i>	0.5–2	0.12–0.25	≤0.03–0.06
Viridans group streptococci	0.12–4	0.25–1	0.06–0.25
<i>Enterococcus faecium</i>	0.5–2	0.12–2	≤0.06–1
<i>E. faecalis</i>	1–32	0.5–16	0.12–2

QUINUPRISTIN-DALFOPRISTIN

Molecular weight quinupristin: 1022; dalfopristin: 690

A fixed combination of two purified water-soluble compounds derived from natural pristinamycin I_A and II_B, respectively. Both compounds are formulated as the mesylate for intravenous infusion. It is the only streptogramin combination presently available for parenteral use.

ANTIMICROBIAL ACTIVITY

Quinupristin–dalfopristin is mainly active against Gram-positive organisms, with modest activity against selected Gram-negative and anaerobic pathogens. It inhibits vancomycin-sensitive and -resistant *Enterococcus faecium*, including multidrug-resistant strains with a minimum inhibitory concentration required to inhibit the growth of 90% of organisms (MIC₉₀) of ≤4 mg/L, but has little activity against *E. faecalis* (MIC₉₀ 16 mg/L). It is active against *Staphylococcus aureus*, including methicillin-resistant *Staph. aureus* (MRSA), coagulase-negative staphylococci, *Streptococcus pneumoniae* and *Str. pyogenes*. The drug is also active against *Moraxella catarrhalis*, *Chlamydophila* (formerly *Chlamydia*) *pneumoniae*, *Legionella pneumophila*, *Mycoplasma hominis* and *Ureaplasma urealyticum*. The use of this drug should be governed by susceptibility testing.

Quinupristin–dalfopristin exhibits a significant post-antibiotic effect estimated at 5–7.5 h for staphylococci and 4 h for enterococci.

ACQUIRED RESISTANCE

Resistance can be chromosomal or plasmid mediated and is mainly due to methylation of the drug target, resulting in resistance to all macrolides, lincosamides and group B streptogramins, but not to group A streptogramins. Resistance can also occur by drug-modifying enzymes or active efflux. Other mechanisms of resistance to macrolides and lincosamides, including those of target modification and active efflux, do not affect streptogramins.

PHARMACOKINETICS

	Quinupristin and metabolites	Dalfopristin and metabolites
C _{max} 7.5 mg/kg i.v. infusion (1 h)	2.5–3.2 mg/L	6.5–7.96 mg/L
Plasma half-life	1 h	0.75 h
Volume of distribution	c. 1.0 L/kg	c. 1.0 L/kg
Plasma protein binding	55–78%	11–26%

Quinupristin–dalfopristin is usually administered by 1 h intravenous infusion at a dose of 7.5 mg/kg in 5% glucose–dextrose every 8–12 h. Reported values for protein binding vary considerably. The compound does not cross the non-inflamed blood–brain barrier or placenta to any significant degree and is rapidly converted in the liver to several active metabolites. In experimental endocarditis quinupristin is homogeneously distributed in cardiac vegetations whereas dalfopristin shows a gradient concentration. Biliary excretion into feces is the main route of elimination for both compounds and their metabolites with only 15–19% eliminated in the urine. Dosage adjustments may be needed in patients with hepatic dysfunction but it seems unnecessary in patients with renal impairment, those undergoing peritoneal dialysis, the obese or the elderly.

INTERACTIONS

The metabolism is not affected by the cytochrome P₄₅₀ 3A4 system but may alter the metabolism of other drugs metabolized by this pathway, such as ciclosporin (cyclosporine). Quinupristin–dalfopristin can also interfere with the metabolism of drugs associated with QTc prolongation and co-administration of these compounds should be avoided.

TOXICITY AND SIDE EFFECTS

The drug has significant toxicity problems, including arthralgia–myalgia syndrome (7.3–9.5%), venous intolerance experienced as pain at the infusion site (14.8%) and inflammation (6.2–11.1%). Hyperbilirubinemia and liver toxicity can also occur.

CLINICAL USE

Serious, refractory infections caused by multiresistant Gram-positive organisms, including *Staph. aureus* and *E. faecium*

If mixed infection is documented or suspected, the drug should be used in combination with an agent active against Gram-negative organisms.

Preparations and dosage

Proprietary name: Synercid.

Preparation: Intravenous infusion. Vials of 500 and 600 mg containing quinupristin–dalopristin in a 30:70 ratio (mesylate salts).

Dosage: Adults, i.v., 7.5 mg/kg every 8 h.

Widely available.

OTHER STREPTOGRAMINS

PRISTINAMYCIN

The two major components are pristinamycin I_A and pristinamycin I_B. It is available in some countries for the oral treatment of upper respiratory, bronchopulmonary, dental, skin, genital and bone infections caused by susceptible organisms. In-vitro activity is summarized in Table 28.1. The drug

is usually well tolerated, although minor gastrointestinal disturbances and rash may occur.

Preparations and dosage

Proprietary name: Pyostacine.

Preparation: Tablets (250 and 500 mg).

Dosage: Adults, oral, 2–4 g per day, in three equal doses, with meals. Children, 50–100 mg/kg per day in three equal doses, with meals.

Available in Belgium and France.

VIRGINIAMYCIN

A natural product of *Streptomyces virginiae* with antimicrobial activity similar to that of other streptogramins. It has chiefly been used as an animal feed additive, but is available in some countries for oral administration and in topical preparations.

NXL103

NXL103 (formerly XRP 2868) is one of several new oral streptogramins under development. It is a 30:70 mixture of streptogramins B and A (RPR 202868 and RPR 132552) and is in clinical trial as a treatment for mild to moderate community-acquired pneumonia. It is somewhat more active than quinupristin–dalopristin in vitro (Table 28.1). Clinical efficacy and safety appear to be good, with the most frequent adverse events related to gastrointestinal intolerance. Available information suggests that the relationship between its pharmacokinetics and efficacy is similar to that of quinupristin–dalopristin.

CHAPTER

29 Sulfonamides

David Greenwood

The original sulphonamide, sulphamamide, is the active principle of Prontosil, which holds a special place in medicine as the first agent to exhibit broad-spectrum activity against systemic bacterial disease (see Ch. 1). Within a few years of the introduction of Prontosil, numerous sulfonamide derivatives were synthesized. Advances included increased antibacterial potency, decreased toxicity, and the introduction of compounds with special properties such as high or low solubility and prolonged duration of action. Most have since been discarded, as safer and more active antibacterial agents have overtaken them, but a few are still in use for particular purposes, often in combination with diaminopyrimidines (see Ch. 17). Some survive in topical preparations, often in multi-ingredient formulations. Discussion here is limited to the most important sulfonamides that are still widely available; a short description is included of some of the many other compounds that are of more restricted availability.

ANTIBACTERIAL ACTIVITY

Sulfonamides exhibit broad-spectrum activity against common Gram-positive and Gram-negative pathogens, although the potency against many bacteria within the spectrum is modest by present standards. Meningococci are generally much more susceptible than gonococci. Other organisms commonly susceptible include *Bordetella pertussis*, *Yersinia pestis*, *Actinomyces* spp., *Nocardia* spp., *Bacillus anthracis*, *Corynebacterium diphtheriae*, *Legionella pneumophila*, *Brucella* spp. and several important causes of sexually transmitted diseases (*Chlamydia trachomatis*, *Haemophilus ducreyi* and *Calymmatobacterium granulomatis*). Activity against anaerobes is generally poor. *Pseudomonas aeruginosa* is usually resistant, as are *Leptospira*, *Treponema* and *Borrelia* spp., *rickettsiae*, *Coxiella burnetii* and mycoplasmas. Mycobacteria are resistant, although the related sulfone, dapsone, exhibits good activity against *M. leprae* (see p. 387) and *para*-aminosalicylic acid, which is structurally similar, was formerly widely used in tuberculosis (p. 392). Sulfonamides act synergistically with certain diaminopyrimidines against many bacteria and some protozoa, including plasmodia and *Toxoplasma gondii* (see Ch. 17).

In-vitro tests are markedly influenced by the composition of the culture medium and the size of the inoculum. The different derivatives vary somewhat in antibacterial activity (Table 29.1). Among those that are still fairly widely available as antibacterial agents, sulfadimidine shows comparatively low activity, whereas sulfadiazine, sulfisoxazole (sulphafurazole) and sulfamethoxazole, the sulfonamide commonly combined with trimethoprim (p. 256), are relatively more active.

ACQUIRED BACTERIAL RESISTANCE

Resistance is now widespread and there is complete cross-resistance among sulfonamides. Plasmid-mediated resistance in all enterobacteria is common. Resistance is found in 25–40% of strains of *Escherichia coli* and other enterobacteria infecting the urinary tract. Many strains of meningococci and *H. ducreyi* are now resistant.

PHARMACOKINETICS

Most sulfonamides are well absorbed after oral administration, reaching a peak concentration in the blood of 50–100 mg/L 2–4 h after a dose of 2 g. After absorption, the behavior of the individual compounds varies widely, depending on the extent of protein-binding and metabolism. The main metabolic pathway is conjugation by acetylation in the liver, although glucuronidation and oxidation also occur. Sulfonamide acetylation shows a bimodal distribution in the population, rapid and slow inactivators corresponding with rapid and slow inactivators of isoniazid (p. 390). The conjugates are inactive antibacterially and the low solubility of the acetyl conjugates of some of the earlier compounds may give rise to renal toxicity.

A proportion, varying considerably with different compounds, is contained in the red cells, some is free in the plasma and some is bound to plasma albumin. Protein binding varies widely, the highest levels being seen with long-acting

Table 29.1 Activity of selected sulfonamides against common pathogenic bacteria: MIC (mg/L)

	Sulfadiazine	Sulfadimidine	Sulfamethoxazole	Sulfisoxazole
<i>Staphylococcus aureus</i>	16–32	32–R	4–32	4–16
<i>Streptococcus pyogenes</i>	0.5–64	1–64	0.25–16	0.25–4
<i>Str. pneumoniae</i>	8–64	4–64	4–64	2–16
<i>Enterococcus faecalis</i>	R	R	R	R
<i>Haemophilus influenzae</i>	2–4	8–16	2–4	0.5–2
<i>Neisseria gonorrhoeae</i>	1–32	16–R	1–32	1–64
<i>N. meningitidis</i>	0.12–1	0.5–8	0.12–1	0.12–0.5
<i>Escherichia coli</i>	4–16	16–64	4–8	8–16
<i>Klebsiella pneumoniae</i>	8–16	64–R	4–16	8–16
<i>Pseudomonas aeruginosa</i>	64	R	R	R

R, resistant (MIC >64 mg/L).

sulfonamides such as sulfadoxine. Sulfonamides can be displaced from their protein binding sites by a variety of compounds, the most important clinically being oral anticoagulant drugs. Administration of these compounds with sulfonamides potentiates the anticoagulant effect and produces higher concentrations of diffusible sulfonamide. Competition for plasma albumin binding sites causes sulfonamides to displace albumin-bound bilirubin.

Sulfonamides are distributed throughout the body tissues. Access to the cerebrospinal fluid (CSF) is normally limited to the unbound drug, but with increasing capillary permeability and the passage of protein into the CSF in inflammation, protein-bound sulfonamide enters and the total concentration of drug in the CSF rises. The concentration of short-acting sulfonamides in CSF varies between 30% and 80% of the corresponding plasma concentration. Sulfonamides also enter other body fluids, including the eye. They pass readily through the placenta into the fetal circulation and also reach the infant via the breast milk.

Sulfonamides are excreted mainly in the urine, the free drug and its conjugates being frequently excreted at different rates and by different mechanisms. Excretion is partly by glomerular filtration and partly by tubular secretion, during which some of the drug is reabsorbed. Substances with high clearances (e.g. sulfisoxazole) are rapidly eliminated from the plasma and achieve high concentrations in the urine. Substances with low clearances are slowly excreted, plasma levels are maintained for long periods, and low concentrations appear in the urine. If renal function is impaired, excretion may be delayed still further and therapeutic levels may persist for considerably longer; if the drugs are given repeatedly, high and possibly toxic levels may develop. Less than 1% of the dose of most sulfonamides is excreted in the bile, but the proportion is 2.4–6.3% for the long-acting compounds.

TOXICITY AND SIDE EFFECTS

With proper attention to dosage, side effects are relatively uncommon, but some are serious. Crystals of less soluble compounds, such as sulfadiazine, or of less soluble conjugates may deposit in the urine and block the renal tubules or the upper orifice of the ureter. Hematuria is a common early sign. However, renal damage during sulfonamide therapy is often due to a hypersensitivity reaction, rather than to tubular blockage, with changes of tubular necrosis or vasculitis. Renal failure has been recorded in several patients after treatment with sulfamethoxazole, as a component of co-trimoxazole.

Hypersensitivity reactions usually occur as moderate fever with a rash on about the ninth day of a course of treatment. Repetition after an interval elicits the reaction immediately. Rashes are commonly erythematous, maculopapular or urticarial, and recur if the drug is given again. Well documented, but uncommon, is a severe serum-sickness-like reaction with fever, urticarial rash, polyarthropathy and eosinophilia. Eosinophilia may occur without other allergic manifestations.

Stevens–Johnson syndrome is a rare but potentially fatal complication (one estimate puts the risk at 1–2 cases per 10 million doses). The relative risks of different sulfonamides are not known accurately, but there are many reports of this complication following the use of long-acting sulfonamides. The time of onset varies from 2 to 24 days, and sometimes as long as 6 weeks after discontinuing the drug. Toxic epidermal necrolysis (Lyell's syndrome) has also been recorded after administration of long-acting sulfonamides.

Drug fever without other features may occur. A special problem of hypersensitivity to the sulfonamide component of co-trimoxazole is its frequency in the treatment of AIDS.

Sulfonamides are among the compounds reported to provoke systemic lupus erythematosus. An intractable type of sensitization may result from local applications.

In patients with inherited glucose-6-phosphate dehydrogenase deficiency, intravascular hemolysis and hemoglobinuria may occur. Hemolysis may also occur as part of a generalized sensitivity reaction. Agranulocytosis, aplastic anemia and thrombocytopenia have been occasionally reported, especially with earlier sulfonamides. Liver injury is rare.

Interference with bilirubin transport in the fetus by sulfonamide administered to the mother may increase the free plasma bilirubin level and result in kernicterus. Many other interactions arise as a result of competition for plasma albumin binding sites. Those of greatest potential clinical importance are increases in the actions of oral anticoagulants and sulfonylureas (but not biguanides) and increased toxicity of methotrexate.

CLINICAL USE

Sulfonamides were formerly much used, alone or in combination with trimethoprim, for the treatment of urinary tract infection, but are no longer recommended because of potential adverse reactions. Use in the treatment of respiratory infections is now confined to a few special problems, notably nocardiosis (and also for cerebral nocardiosis) and, in combination with trimethoprim, in the prevention and treatment of *Pneumocystis jirovecii* pneumonia. The value of sulfonamides in the prophylaxis and treatment of meningo-coccal infection is now greatly reduced by bacterial resistance. Sulfonamides are sometimes used for chlamydial infections and chancroid but are unreliable. Some formulations are used topically in eye infections and bacterial vaginosis. Combined preparations with pyrimethamine are used in the treatment of drug-resistant malaria and for toxoplasmosis (see Chs 62 and 63).

SULFADIAZINE

2-Sulfanilamidopyrimidine. Molecular weight: 250.3.

Sulfadiazine is almost insoluble in water and unstable on exposure to light. It is administered orally or, as the sodium salt, by intravenous injection. It is a component of several multi-ingredient preparations. Its low solubility in urine led to its general replacement by other compounds. The intravenous solution is highly alkaline and should not be given by any other route.

ANTIMICROBIAL ACTIVITY

Sulfadiazine is somewhat more active than other sulphonamides (Table 29.1).

PHARMACOKINETICS

Oral absorption	Very good
C_{\max} 3 g oral	c. 50 mg/L after 3–4 h
Plasma half-life	7–12 h
Volume of distribution	0.36 L/kg
Plasma protein binding	c. 40%

Absorption and distribution

Adequate blood concentrations are easily achieved and maintained after oral administration. It is well distributed and penetrates in therapeutic concentrations into the CSF, but because of resistance it is no longer the drug of choice in meningitis. It crosses the placenta and enters breast milk to achieve concentrations around 20% of plasma levels.

Metabolism and excretion

Sulfadiazine is subject to acetylation in the liver. The acetyl derivative lacks antibacterial activity and is excreted more slowly (half-life 8–18 h). Parent compound and metabolite are both excreted mainly by glomerular filtration.

TOXICITY AND SIDE EFFECTS

In addition to side effects common to the group, sulfadiazine inhibits the metabolism of phenytoin. The risk of crystalluria can be reduced by high fluid intake and alkalization of the urine.

CLINICAL USE

Urinary tract infection
Nocardiosis
Chancroid
Toxoplasmosis (in combination with pyrimethamine)
Meningococcal infections
Prophylaxis of rheumatic fever

See also silver sulfadiazine (p. 343).

Preparations and dosage

Preparations: 4 mL ampoules, each containing 1 g for i.v. injection; tablets.

Dosage: Adult, i.v., 1–1.5 g every 4 h for 2 days, then oral.

Available in the UK, the USA, Canada, Belgium and Australia. Widely available in multi-ingredient preparations.

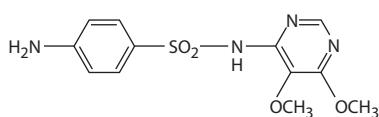

Further information

Anonymous. Sulfadiazine. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:S126–S129.
Dusseault BN, Croce KJ, Pais VM. Radiographic characteristics of sulfadiazine urolithiasis. *Urology*. 2009;73:928.

SULFADOXINE

4-Sulfanilamido-5,6-dimethoxypyrimidine. Molecular weight: 310.3.

An ultra-long-acting sulfonamide. It is no longer prescribed alone, but is used in combination with pyrimethamine as the antimalarial agent Fansidar (see Ch. 62). It is poorly soluble in water.

ANTIMICROBIAL ACTIVITY

Its antibacterial activity is relatively poor. Used alone it has a slow and uncertain effect against malaria parasites. Resistance of malaria parasites to the combination with pyrimethamine is common in many endemic areas.

PHARMACOKINETICS

Oral absorption	Extensive
C_{\max} 500 mg oral	c. 60 mg/L after 3–4 h
Plasma half-life	c. 6 days
Volume of distribution	0.13 L/kg
Plasma protein binding	94%

The extremely long half-life allows administration at weekly intervals. The acetyl metabolite has a similarly long half-life, but sulfadoxine is less extensively metabolized than many other sulfonamides.

TOXICITY AND SIDE EFFECTS

Side effects are those common to the group. There have been many reports of Stevens–Johnson syndrome following its use and the combination with pyrimethamine is no longer recommended for the prophylaxis of malaria.

CLINICAL USE

Sulfadoxine is used only in combination with pyrimethamine.

Preparations and dosage

Proprietary names: Fansidar, Fansasil, in combination with pyrimethamine.

Preparation: Tablets containing 500 mg sulfadoxine and 25 mg pyrimethamine.

Dosage: Adults, oral, three tablets as a single dose. Children 10–14 years, two tablets; 7–9 years, 1½ tablets; 4–6 years, one tablet; under 4 years, half a tablet.

Limited availability. No longer available in UK and Europe.

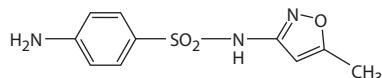

Further information

Anonymous. Sulfadoxine. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:S132–S135.
Barnes KL, Little F, Smith PJ, Evans A, Watkins WM, White NJ. Sulfadoxine–pyrimethamine pharmacokinetics in malaria: pediatric dosing implications. *Clin Pharmacol Ther*. 2006;80:582–596.

SULFAMETHOXAZOLE

5-Methyl-3-sulfanilamidoisoxazole. Molecular weight: 253.2.

This is the sulfonamide component of co-trimoxazole (p. 256). It is slightly soluble in water.

ANTIMICROBIAL ACTIVITY

The intrinsic activity is similar to that of sulfadiazine (Table 29.1).

PHARMACOKINETICS

Oral absorption	85%
C_{\max} 800 mg oral	c. 50 mg/L after 3–6 h
Plasma half-life	6–20 h
Volume of distribution	12–18 L
Plasma protein binding	65%

Penetration of extravascular sites, including the CSF, is good. It crosses the placenta and achieves levels in breast milk of about 10% of the simultaneous plasma concentration. It is extensively metabolized, but about 30% of the dose is excreted unchanged in urine so that high concentrations are achieved.

TOXICITY AND SIDE EFFECTS

Unwanted effects are those common to sulfonamides. In addition, benign intracranial hypertension has been reported in children. Most side effects of co-trimoxazole are thought to be attributable to the sulfonamide component.

CLINICAL USE

Sulfamethoxazole is used only in combination with the diaminopyrimidine trimethoprim (see p. 256).

Preparations

Very limited availability as a single agent.

Further information

Anonymous. Sulfamethoxazole and trimethoprim combination. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:S136–S140.

OTHER SULFONAMIDES

SULFACETAMIDE

N-acetylsulfanilamide. It is very soluble in water and was formerly used in urinary tract infection. It is available in some countries in ophthalmic preparations and as a component (with sulfathiazole and sulfabenzamide) of a triple sulfonamide cream for the topical treatment of bacterial vaginosis.

Sulfacetamide is one of the least active sulfonamides. It is well absorbed when given orally and is excreted in the urine with a half-life of around 9 h. About 70% is excreted unchanged, the remainder being present as the acetyl metabolite. Adverse reactions are those common to the group. Stevens–Johnson syndrome has been reported several times after topical use in conjunctivitis.

SULFADIMETHOXINE

2,4-Dimethoxy-6-sulfanilamido-1,3-diazine. A rapidly absorbed compound with a long half-life (38–40 h) and a high degree of protein binding (98%). Renal clearance is very slow, and daily dosage maintains adequate plasma levels.

SULFADIMIDINE

2-Sulfanilamido-4,6-methylpyrimidine (*syn*: sulphamethazine, sulfamezathine). A water-soluble compound, unstable on exposure to light. It is usually administered by mouth and is a component of some triple sulfonamide combinations.

The spectrum is typical of the group, but sulfadimidine exhibits relatively low potency (Table 29.1). It is well absorbed after oral administration. It is extensively metabolized, predominantly by acetylation. The mean plasma half-life (1.5–5 h) varies with acetylator status.

In addition to side effects common to the group, a serious interaction between ciclosporin (cyclosporin A) and sulfadimidine, leading to reduced ciclosporin levels, has been reported.

SULFAFURAZOLE (SULFISOXAZOLE)

3,4-Dimethyl-5-sulfanilamidoisoxazole. It is highly soluble, even in acid urine. The spectrum and potency are typical of the group. It is well absorbed, achieving a concentration of around 20 mg/L 3–4 h after a 2 g oral dose.

Side effects are those common to other sulfonamides. It is less prone than some other members of the group to cause renal problems. Its principal use is in urinary tract infection, and is present in some ophthalmic preparations.

SULFAGUANIDINE

1-Sulfanilylguanidine. A poorly absorbed compound, less potent than succinylsulfathiazole but with similar uses. Blood concentrations of 15–40 mg/L have been found after single doses of 1–7 g. Excretion in the urine is rapid.

SULFALENE (SULFAMETOPYRAZINE)

2-Sulfanilamido-3-methoxypyrazine. A very long-acting compound (plasma half-life 60 h). Adequate blood levels can be maintained by giving a dose of 2 g once weekly. The protein binding is c. 70%. It has been successfully used in the single-dose treatment of urinary tract infection. As with other long-acting compounds, sulfametopyrazine has been associated with an increased incidence of erythema multiforme.

SULFALOXATE

A poorly absorbed compound formulated as the calcium salt. About 5% is absorbed from the gastrointestinal tract. Formerly used to treat intestinal infections.

SULFAMERAZINE

2-Sulfonamido-4-methylpyrimidine. A component of some triple sulfa combinations. Plasma half-life is c. 24 h and protein binding c. 75%. It is less active than sulfadiazine.

SULFAMETHIZOLE

2-Sulfanilamido-5-methyl-1,3,4-thiodiazole. A short-acting sulfonamide (plasma half-life 2.5 h). Protein binding is c. 85%. About 60% is excreted in the urine within 5 h. It was formerly widely used in the treatment of urinary tract infection.

SULFAMETHOXYDIAZINE

2-Sulfanilamido-5-methoxypyrimidine. A long-acting compound with activity similar to that of sulfadiazine. Binding to plasma proteins is about 75%.

SULFAMETHOXPYRIDAZINE

3-Sulfanilamido-6-methoxypyridazine. Properties are similar to those of sulfadimethoxine. A rapidly absorbed, long-acting compound (half-life 38 h) with a high degree of protein binding (96%). A 1 g oral dose achieves a peak plasma concentration of around 100 mg/L after 5 h. Its use has been largely discontinued because of frequent adverse effects, but there are reports of benefit in dermatitis herpetiformis. It has been used in combination with trimethoprim.

SULFATHIAZOLE

2-Sulfanilamidothiazole. A short-acting compound (half-life c. 4 h) with relatively high activity. Protein binding is c. 75%. Its use has declined because of a high incidence of side effects. It is one of the constituents of triple sulfonamide mixtures, of which local preparations are still available.

Two compounds, phthalylsulfathiazole (sulfathalidine) and succinylsulfathiazole (sulfasuxidine) owe their activity to the slow liberation of sulfathiazole in the bowel. They are poorly soluble and very little is absorbed after oral administration. They were formerly used in the treatment of intestinal infections and in bowel preparation before surgery. They are available in multi-ingredient preparations in some countries.

SULFISOMIDINE

6-Sulfanilamido-2,4-dimethylpyrimidine (*syn*: sulphasomidine). A highly soluble sulfonamide with a plasma half-life of 6–8 h. Protein binding is about 90%. Activity is similar to that of sulfadiazine. It is less extensively metabolized than most other sulfonamides and is largely excreted unchanged in the urine.

SULFONAMIDES FOR SPECIAL PURPOSES

MAFENIDE

p-Aminomethylbenzene sulfonamide; Sulfamylon.

A topical agent formerly used extensively in burns, especially for its action in suppressing *Ps. aeruginosa*. It is rapidly absorbed through burned skin and is unusual in that it is

not neutralized by *p*-aminobenzoic acid or by tissue exudates. Disadvantages of its use are local pain and burning, a variety of allergic reactions including erythema multiforme and its capacity to inhibit carbonic anhydrase, necessitating careful observation to detect the development of metabolic acidosis. Its metabolite, *p*-carboxybenzene sulfonamide, also inhibits carbonic anhydrase but has no antibacterial activity. Mafenide propionate was formerly used in ophthalmic preparations.

SILVER SULFADIAZINE

Silver sulfadiazine is extremely insoluble. In addition to the usual activity of sulfonamides it exhibits activity – almost certainly attributable to the silver component – against *Ps. aeruginosa* and some fungi.

It is variably absorbed after topical application depending on the integrity of the skin. Toxic concentrations may be achieved in patients with extensive burns. It is used topically, mainly for burns, pressure sores and leg ulcers. Central venous catheters impregnated with chlorhexidine and silver sulfadiazine have been developed to reduce bacterial colonization. Other suggested uses include the prevention of infection in skin graft donor sites and cord care in newborn infants.

Preparations

Proprietary name: Flamazine.

Preparation: Topical cream containing 1% w/w silver sulfadiazine.

Widely available.

SULFASALAZINE

One of the earliest and most successful sulfonamides to be developed was sulfapyridine, which fell into disuse because of unwanted effects such as crystalluria. Later, a number of salicylazosulfonamides, developed because of their increased water solubility, showed anti-inflammatory properties; one of them, sulfasalazine (salicylazosulfapyridine), has come into general use for ulcerative colitis.

After oral administration, some intact compound is absorbed from the upper gastrointestinal tract, appearing in the blood in 1–2 h, but most is cleaved by colonic bacteria to yield sulfapyridine and 5-aminosalicylic acid (mesalamine, mesalazine). Controlled trials have confirmed the efficacy of 5-aminosalicylic acid alone in ulcerative colitis, the sulfonamide component merely acting as a carrier. Thus, in remarkable extension of the good fortune that attended the discovery of sulfanilamide as the unexpected active principle of Prontosil (see Ch. 1), a cleavage product appears to be responsible for the beneficial effect of sulfasalazine. Since most of the side effects associated with sulfasalazine are attributable to sulfapyridine, there seems little reason, other than cost, to use it in preference to mesalamine.

Sulfasalazine is also of benefit in Crohn's disease and rheumatoid arthritis, but the role, if any, of sulfapyridine in the overall effect is unclear.

Preparations

Proprietary name: Salazopyrin.

Preparations: Tablets, enema, suppositories, suspension.

Widely available.

CHAPTER

30 Tetracyclines

Ian Chopra

A group of natural products derived from *Streptomyces* spp. and their semisynthetic derivatives. The minimum pharmacophore is a linear fused tetracyclic molecule, 6-deoxy-6-demethyltetracycline:

The various members of the class contain a variety of functional groups attached to the rings designated A, B, C and D. Natural products include chlortetracycline, oxytetracycline, tetracycline and demeclocycline (demethylchlortetracycline). Semisynthetic derivatives include doxycycline, minocycline, methacycline, lymecycline, rolitetracycline and tigecycline, a glycycline that has been specifically developed to overcome problems of bacterial resistance to earlier tetracyclines.

ANTIMICROBIAL SPECTRUM

Tetracyclines are broad-spectrum, essentially bacteriostatic agents. They share a similar spectrum of activity, though that of tigecycline is somewhat different from that of earlier tetracyclines.

In general, tetracyclines are active against many Gram-positive and Gram-negative bacteria, chlamydiae, mycoplasmas, rickettsiae, coxiellae, spirochetes and some mycobacteria. Most streptococci are sensitive, except *Streptococcus agalactiae*, and enterococci. Susceptible Gram-positive bacilli include *Actinomyces israelii*, *Arachnia propionica*, *Listeria monocytogenes*, most clostridia and *Bacillus anthracis*. *Nocardia* spp. are much less susceptible, minocycline demonstrating the greatest activity against them.

Among Gram-negative bacteria most enterobacteria and most strains of *Moraxella catarrhalis*, *Neisseria meningitidis* and *Haemophilus influenzae* are sensitive. Legionellae,

brucellae, *Francisella tularensis*, *Vibrio cholerae*, *Campylobacter* spp., *Helicobacter pylori*, *Plesiomonas shigelloides* and *Aeromonas hydrophila* are all susceptible. Many anaerobic bacteria are susceptible, doxycycline and minocycline being the most active. Rickettsiae are generally sensitive, especially to doxycycline, minocycline and tetracycline. None is active against *Pseudomonas aeruginosa*, *Proteus* spp. or *Providencia* spp., but *Burkholderia pseudomallei* and *Stenotrophomonas maltophilia* are usually susceptible.

ACQUIRED RESISTANCE

Resistance to tetracyclines has emerged in an ever-increasing number of bacterial species and is geographically widespread. Resistance arises primarily from acquisition of genes that either encode transporters of the major facilitator superfamily (MFS), which remove the antibiotics from the cell (e.g. TetB, TetK), or encode proteins that protect the ribosome from inhibition (e.g. TetM, TetO). Tigecycline is not affected by these resistance mechanisms and consequently is active against many species resistant to earlier tetracyclines. In some Gram-negative bacteria resistance can also be due to the activity of innate (endogenous) bacterial efflux proteins such as the chromosomally encoded resistance–nodulation–cell division efflux pumps that confer resistance to several structurally unrelated biocides and antibiotics, as well as all classes of tetracyclines. The presence of these pumps explains the inherent resistance of most *Ps. aeruginosa* and *Proteus* spp. to all tetracyclines.

PHARMACOKINETICS

ABSORPTION

Tetracyclines are usually administered by mouth. However, tigecycline is available only for intravenous infusion.

Absorption of oral tetracyclines occurs largely in the proximal small bowel, but may be diminished by the simultaneous presence of food, milk or cations, which form non-absorbable tetracycline chelates. Cimetidine and presumably other H₂-receptor antagonists also impair absorption of tetracyclines by interfering with their dissolution, which is pH dependent.

The absorption problems of earlier compounds have been essentially overcome in the later tetracyclines. Improved absorption is claimed for lymecycline, demeclocycline and methacycline, but is best established for doxycycline and minocycline, which may be administered with food and for which the proportion of administered dose absorbed is more than 90%.

DISTRIBUTION

For orally administered tetracyclines, peak serum concentrations follow 1–4 h after ingestion. Serum levels achieved after normal dosage of orally bioavailable tetracyclines are of the order of 1.5–4.0 mg/L. Most tetracyclines must be given four times daily to maintain therapeutic concentrations in the blood, but demeclocycline and minocycline can be administered twice daily and doxycycline once daily.

Tetracyclines penetrate moderately well into body fluids and tissues, reflected in relatively large volumes of distribution. Concentrations of most tetracyclines in the cerebrospinal fluid (CSF) are usually about 10–25% of those in the blood, although penetration of tigecycline into the CSF is poor. A unique feature of tetracyclines is deposition and persistence in areas where bone is being laid down. Radioactive tracer studies in animals suggest that tigecycline also concentrates in the bone but concentration at this site in humans remains unproven owing to technical difficulties with assay methods.

Older tetracyclines are known to penetrate into the sebum and are excreted in perspiration, properties which contribute to their usefulness in the management of acne. The older tetracyclines are also known to be concentrated in the eye.

EXCRETION

Excretory routes are the kidney and feces. Fecal excretion occurs even after parenteral administration as a result of passage of the drug into the bile. The concentrations obtained in bile are 5–25 times those in the blood, doxycycline attaining especially high levels. These concentrations are lowered in the presence of biliary obstruction. The proportion of administered dose found in the urine is, for most tetracyclines, in the range 20–60%, but is less for chlortetracycline and doxycycline and least for minocycline and tigecycline.

TOXICITY AND SIDE EFFECTS

Known adverse effects are primarily based on studies with older tetracyclines and it is not yet clear whether they also apply to tigecycline. However, it might be expected that tigecycline will share at least some of the unwanted side effects associated with all members of the class.

The most important adverse effect is gastrointestinal intolerance, reported for all tetracyclines including tigecycline. Photosensitivity is a class phenomenon; it is most marked for demeclocycline but is not yet reported for tigecycline. Deposition in developing bones and teeth precludes the use of older tetracyclines in young children and during late pregnancy; tigecycline may also exhibit these properties and is contraindicated in these situations. Most compounds accumulate in renal failure, with the exception of doxycycline and tigecycline. Nausea and vomiting are presumed to be due to a direct irritant effect of the drug on the gastric mucosa, but diarrhea is probably the result of disturbance of the normal flora. The frequency and nature of superinfection with resistant organisms depends much on local ecology. Pseudomembranous colitis has been associated with the use of older tetracyclines, but they do not appear to be a common precursor of that complication. Other organisms that often become dominant in the fecal flora after administration of tetracyclines are *Candida*, *Proteus* or *Pseudomonas* spp. *Staph. aureus* enterocolitis, which was described in hospital patients when tetracyclines were widely prescribed, now seems to be rare.

Glossitis and pruritus ani, vulvitis and vaginitis are well-recognized side effects associated with the use of older tetracyclines; less common side effects include esophageal ulceration and acute pancreatitis. Changes occur in the surface lipids of the skin, notably a decrease in fatty acids and reciprocal increase in triglycerides that probably results from inhibition of extracellular bacterial lipase production by *Propionibacterium acnes*.

Deaths have been reported in pregnant women given large intravenous doses (>1 g per day), usually for the treatment of pyelonephritis. The main lesion found at autopsy was diffuse fatty degeneration of the liver, which may also involve the pancreas, kidneys and brain. Mild derangements of liver enzyme function are not uncommon.

A number of infants have developed bulging of the anterior fontanelle; benign intracranial hypertension has also been described in older children and even in adults, with headache, photophobia and papilledema. Symptoms disappear quickly after the drug is withdrawn, but papilledema may persist in some patients for many months or reappear when tetracyclines are given again. The mechanism is unknown.

Hypersensitivity rashes, including exfoliation, occasionally occur, but skin reactions are more often manifestations of photosensitivity. A reaction may occur after administration of any tetracycline, but is especially associated with demeclocycline and may be less common with doxycycline and minocycline. Fixed drug eruptions, onycholysis and nail and

Table 30.1 Current applications of tetracyclines (excluding tigecycline)

Type of infection	First choice	Acceptable alternative to other agents
Respiratory	Atypical pneumonia due to <i>Mycoplasma pneumoniae</i> , <i>Chlamydophila</i> (formerly <i>Chlamydia</i>) <i>pneumoniae</i> , <i>Ch. psittaci</i>	Community-acquired pneumonia ^a Infective exacerbations of chronic bronchitis ^a Legionellosis (doxycycline)

^aExcept in situations where there is a high rate of resistance among pneumococci and/or *H. influenzae*.

^bIn combination with other agents.

thyroid pigmentation have also been reported. Angiodema and anaphylaxis are rare. Hypersensitivity reactions to one tetracycline generally infer cross-hypersensitivity to the other agents. Reported inhibitory effects on several human polymorphonuclear leukocyte and lymphocyte functions in vitro have yet to be shown to have any therapeutic significance.

Drug interactions include complexes with divalent and trivalent cations together with chelation by iron-containing preparations. The anticonvulsants carbamazepine, phenytoin and barbiturates decrease the half-life of doxycycline through enzyme induction. The anesthetic methoxyflurane has been reported to cause nephrotoxicity when co-administered with older tetracyclines. Tigecycline is reported to affect the pharmacokinetic profile of warfarin such that anticoagulation tests should be performed if it is administered with warfarin. The efficiency of oral contraceptives is reduced by tetracyclines, as with many other broad-spectrum antibiotics.

CLINICAL USE

The use of tetracyclines has significantly declined in most countries as the incidence of bacterial resistance has increased and more active and better tolerated antimicrobial agents have been introduced. However, some new applications have emerged, such as their use as part of multidrug regimens for the management of gastritis and peptic ulcer disease associated with *H. pylori*. Their activity against malaria has become important for prophylaxis following the rapid increase of chloroquine- and mefloquine-resistant *Plasmodium falciparum*.

Current applications of the older tetracyclines are summarized in Table 30.1. Tigecycline is currently approved only for use in complicated skin and skin structure infections (including those caused by methicillin-resistant *Staph. aureus*), complicated intra-abdominal infections and community-acquired bacterial pneumonia, but use for other indications, including those listed in Table 30.1, may emerge if there is suitable clinical evidence.

CHLORTETRACYCLINE

Molecular weight (free base): 478.9; (hydrochloride): 515.3.

7-Chlortetracycline. A fermentation product of certain strains of *Streptomyces aureofaciens*. Formulated as the hydrochloride or the free base for oral or topical application.

ANTIMICROBIAL ACTIVITY

The activity against a range of pathogenic bacteria is shown in Table 30.2. It is slightly less active than tetracycline against many bacteria, with the exception of Gram-positive organisms.

PHARMACOKINETICS

Oral absorption	30–60%
C_{\max} 500 mg oral	2.5–7 mg/L
Plasma half-life	5–6 h
Volume of distribution	c. 2 L/kg
Plasma protein binding	47–65%

Absorption is relatively poor compared with other tetracyclines. It undergoes rapid metabolism and is largely eliminated by biliary excretion, with only a small proportion eliminated via the kidney. Despite this, chlortetracycline is not recommended for patients in renal failure, since accumulation occurs as a consequence of the half-life increase to approximately 7–11 h.

TOXICITY AND SIDE EFFECTS

Side effects are typical of the group (p. 345). Contact hypersensitivity has been reported with topical application to abraded skin and varicose ulcers.

CLINICAL USE

Its uses are those common to the group (Table 30.1, p. 346). It has also been used topically in the management of recurrent aphthous ulcers of the mouth, but experience is limited and the mechanism of action is unknown.

Preparations and dosage

Proprietary name: Aureomycin.

Preparations: Topical, ophthalmic, capsules.

Dosage: Adults, oral, 250–500 mg, every 6 h.

Widely available; oral preparation not available in the UK.

Table 30.2 Activity of the most important tetracyclines against common pathogenic bacteria: MIC (mg/L). Data compiled from a variety of sources

Further information

Anonymous. Chlortetracycline (hydrochloride). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:C199–C201.

DEMECLOCYCLINE

Molecular weight (free base): 464.9; (hydrochloride): 501.3.

6-Demethyl-7-chlortetracycline. A fermentation product of a mutant strain of *Streptomyces aureofaciens* formulated as the hydrochloride for oral administration.

ANTIMICROBIAL ACTIVITY

Activity against a range of pathogenic bacteria is shown in Table 30.2. Occasional strains of viridans streptococci, *N. gonorrhoeae* and *H. influenzae* are more susceptible than to tetracycline. It is the most active tetracycline against *Brucella* spp.

PHARMACOKINETICS

Oral absorption	60–70%
C_{\max} 300 mg oral	2 mg/L after 3–6 h
Plasma half-life	c. 12 h
Volume of distribution	c. 1.7 L/kg
Plasma protein binding	90%

Absorption

It is promptly yet incompletely absorbed by mouth, giving mean peak plasma levels after a single dose that are slightly higher than those produced by oxytetracycline and chlortetracycline, but lower than those achieved by tetracycline. However, with repeat dosing, steady-state concentrations exceed those for tetracycline. Simultaneous administration of antacids markedly depresses blood levels.

Distribution and excretion

It is widely distributed, achieving concentrations in pleural exudates similar to those of blood. CSF penetration is poor, especially in the absence of inflammation. Biliary concentrations are 20–30 times higher than those of plasma,

and 40–50% of the drug can be recovered from feces. The other route of elimination is via glomerular filtration without reabsorption and accumulation occurs in renal failure.

TOXICITY AND SIDE EFFECTS

Untoward reactions, notably gastrointestinal intolerance, are generally those typical of the group (p. 345). Occasional patients develop transient steatorrhoea.

Of particular note is the occurrence of nephrogenic diabetes insipidus with development of vasopressin-resistant polyuria. The effect is dose dependent and occurs with daily doses in excess of 1.2 g. The drug inhibits activation of adenylate cyclase and protein kinase, which are both important in the interaction of antidiuretic hormone (ADH) with receptors within the renal tubule, thus decreasing the effect of ADH on the kidney. As a result, it has found a place in the treatment of inappropriate ADH secretion.

Renal failure may occur, particularly if prescribed for those with advanced liver cirrhosis. The mechanism is uncertain but may in part be related to the antianabolic effect of the tetracyclines as well as a direct toxic effect.

Photosensitivity may be severe and accompanied by vesication, edema and onycholysis. It is largely restricted to exposed skin; patients should avoid prolonged exposure to sunlight.

CLINICAL USE

Its uses are those common to the group (Table 30.1, p. 346). It has been extensively used in the management of the syndrome of inappropriate ADH secretion in a dose of at least 1.2 g per day; therapeutic response may take several days, but is superior to that of lithium. It has also found occasional use in patients with water retention as a result of congestive cardiac failure and in those with alcoholic cirrhosis and water and electrolyte retention.

Preparations and dosage

Proprietary names: Declomycin, Ledermycin.

Preparations: Capsules, tablets.

Dosage: Adults, oral, 150 mg every 6 h, or 300 mg every 12 h.

Widely available.

Further information

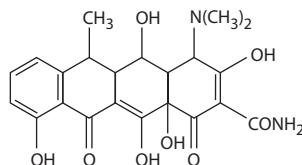

Anonymous. Demeclocycline (hydrochloride). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:D29–D31.

Geheb M, Cox M. Renal effects of demeclocycline. *J Am Med Assoc*. 1980;243:2519–2520.

Miller PD, Linas SL, Schrier RW. Plasma demeclocycline levels and nephrotoxicity. Correlation in hyponatremic cirrhotic patients. *J Am Med Assoc*. 1980;243:2513–2515.

DOXYCYCLINE

Molecular weight (free base): 444.5; (hydyclate): 512.9.

6-Deoxy-5 β -hydroxytetracycline. A semisynthetic product supplied as the hydyclate, calcium salt or the hydrochloride for oral and intravenous administration.

ANTIMICROBIAL ACTIVITY

Its activity and spectrum are typical of the group (Table 30.2). It is active against some tetracycline-resistant *Staph. aureus* and is more active than other tetracyclines against *Str. pyogenes*, enterococci and *Nocardia* spp. *Mor. catarrhalis* (MIC 0.5 mg/L), *Legionella pneumophila* and most strains of *Ureaplasma urealyticum* (MIC 0.5 mg/L) are susceptible.

PHARMACOKINETICS

Oral absorption	90%
C_{max} 100–200 mg oral	1.7–5.7 mg/L after 2–3.5 h
100 mg intravenous infusion (1 h)	2.5 mg/L end infusion
Plasma half-life	18 h
Volume of distribution	0.9–1.8 L/kg
Plasma protein binding	90%

Absorption

Doxycycline is rapidly absorbed from the upper gastrointestinal tract and absorption appears to be linearly related to the administered dose. Food, especially dairy products, reduces peak serum concentrations by 20%. Alcohol also delays absorption. As with other tetracyclines, divalent and trivalent cations, as in antacids and ferrous sulfate, form chelates which reduce absorption.

Distribution

The greater lipophilicity of doxycycline is responsible for its widespread tissue distribution. Concentrations in liver, biliary system, kidneys and the digestive tract are approximately twice those in plasma. Within the respiratory tract, it achieves concentrations of 2.3–6.7 mg/kg in tonsils and 2.3–7.5 mg/kg in maxillary sinus mucosa. In bronchial secretions concentrations are

about 20% of plasma levels, increasing to 25–35% in the presence of pleurisy. Gallbladder concentrations are approximately 75% those of plasma, and prostate concentrations are 60–100%. It penetrates well into the aqueous humor. CSF concentrations range from 11% to 56% of plasma levels and are not affected by inflammation. In the elderly, tissue concentrations are 50–100% higher than in young adults. The half-life remains unaltered and one explanation is reduced fecal elimination.

Metabolism and excretion

Doxycycline is largely excreted unchanged. Around 35% is eliminated through the kidneys and the remainder through the digestive tract. Renal clearance ranges from 1.8 to 2.1 L/h, and is largely via glomerular filtration, with approximately 70% tubular reabsorption. Alkalization enhances renal clearance. Fecal elimination partly reflects biliary excretion but also includes diffusion across the intestinal wall. Provided the drug is not chelated, reabsorption occurs with enterohepatic recycling. The elimination half-life is long (15–25 h).

The half-life and the area under the concentration–time curve (AUC) are little altered in renal insufficiency, with no evidence of accumulation after repeat dosing, even in anuric patients, evidently as a result of increased clearance through the liver or gastrointestinal tract, since biliary and fecal concentrations increase in renal failure. Although the plasma elimination half-life is unchanged, the drug appears to accumulate in tissues with increasing renal failure, and it has been suggested that less drug is bound to plasma protein and red cells through competition with other metabolites, which in turn increases hepatic elimination. Pharmacokinetics are unaltered by hemodialysis or peritoneal dialysis. Clearance is decreased by about half in patients with type IIa and type IV hyperlipidemia.

The plasma elimination half-life is shortened by various antiepileptic agents including phenytoin, barbiturates and carbamazepine, presumably as a result of liver enzyme induction, although there is also evidence for some interference with the protein binding of doxycycline.

TOXICITY AND SIDE EFFECTS

Untoward reactions are generally those typical of the group but gastrointestinal side effects are less common than with other tetracyclines due to the lower total dosage and the ability to administer the drug with meals. Esophageal ulceration as a result of capsule impaction has been reported. Dental and bone deposition appear to be less common than with other tetracycline derivatives. Other adverse phenomena include occasional vestibular toxicity.

Hypersensitivity reactions include photosensitivity and eosinophilia, but rarely anaphylaxis. In common with demeclocycline and chlortetracycline it may be a more powerful sensitizer than other tetracyclines. It is contraindicated in patients with acute porphyria because it has been demonstrated to be porphyrinogenic in animals.

CLINICAL USE

Uses are those common to the group (Table 30.1, p. 346). Its once-daily administration and safety in renal insufficiency make it one of the most widely used tetracyclines. It is used in the prophylaxis and treatment of malaria in areas in which resistance to conventional antimalarial agents is common.

Preparations and dosage

Proprietary name: Vibramycin.

Preparations: Capsules, tablets, suspension.

Dosage: Adults, oral, 200 mg on day 1 then 100 mg per day; severe infections, 200 mg per day; acne, 50 mg per day for 6 weeks or longer. Widely available.

resistant to other tetracyclines are susceptible. *Sten. maltophilia* is susceptible, as are most strains of *Acinetobacter* spp. and *L. pneumophila*.

It is notable for its activity against *Bacteroides* and *Fusobacterium* spp., and is more active than other tetracyclines against *C. trachomatis*, brucellae and nocardiae. It inhibits *Mycobacterium tuberculosis*, *M. bovis*, *M. kansasii* and *M. intracellulare* at 5–6 mg/L. *Candida albicans* and *C. tropicalis* are also slightly susceptible.

PHARMACOKINETICS

Oral absorption	95–100%
C_{\max} 150 mg oral	2 mg/L after 2 h
300 mg oral	4 mg/L after 2h
Plasma half-life	12–24 h
Volume of distribution	80–115 L
Plasma protein binding	76%

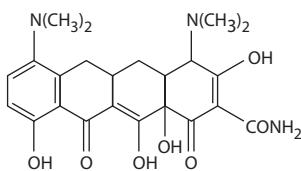

Further information

Anonymous. Doxycycline hydiate. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:D229–D232.
Cunha BA. Doxycycline re-visited. *Arch Intern Med*. 1999;159:1006–1007.

MINOCYCLINE

7-Dimethylamino-6-demethyl-6-deoxy-tetracycline. Molecular weight (free base): 457.5; (hydrochloride): 493.9.

A semisynthetic tetracycline derivative supplied as the hydrochloride for oral administration.

ANTIMICROBIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 30.2 (p. 347). It exhibits the broad-spectrum activity typical of the group, but retains activity against some strains of *Staph. aureus* resistant to older tetracyclines. It is active against β -hemolytic streptococci and some tetracycline-resistant pneumococci. It is also active against some enterobacteria resistant to other tetracyclines, probably because some Gram-negative efflux pumps remove minocycline less effectively than other tetracyclines. Some strains of *H. influenzae*

Absorption

Food does not significantly affect absorption, which is depressed by co-administration with milk. It is chelated by metals and suffers the effects of antacids and ferrous sulfate common to tetracyclines. On a regimen of 100 mg every 12 h, steady-state concentrations ranged between 2.3 and 3.5 mg/L.

Distribution

The high lipophilicity of minocycline provides wide distribution and tissue concentrations that often exceed those of the plasma. The tissue:plasma ratio in maxillary sinus and tonsillar tissue is 1.6; that in lung is 3–4. Sputum concentrations may reach 37–60% of simultaneous plasma levels. In bile, liver and gallbladder the ratios are 38, 12 and 6.5, respectively.

Prostatic and seminal fluid concentrations range from 40% to 100% of those of serum. CSF penetration is poor, especially in the non-inflamed state. Concentrations in tears and saliva are high, and may explain its beneficial effect in the treatment of meningococcal carriage.

Metabolism

Biotransformation to three microbiologically inactive metabolites occurs in the liver; the most abundant is 9-hydroxyminocycline.

Excretion

Only 4–9% of administered drug is excreted in the urine, and in renal failure elimination is little affected. Neither hemodialysis nor peritoneal dialysis affects drug elimination. Fecal

excretion is relatively low and evidence for enterohepatic recirculation remains uncertain. Despite high hepatic excretion, dose accumulation does not occur in liver disease, such as cirrhosis. Type IIa and type IV hyperlipidemic patients show a decreased minocycline clearance of 50%, suggesting that dose modification may be necessary.

TOXICITY AND SIDE EFFECTS

Minocycline shares the untoward reactions common to the group with gastrointestinal side effects being most common, and more prevalent in women. Diarrhoea is relatively uncommon, presumably as a result of its lower fecal concentrations. Hypersensitivity reactions, including rashes, interstitial nephritis and pulmonary eosinophilia, are occasionally seen.

Staining of the permanent dentition occurs with all tetracyclines; a side effect that appears to be unique to minocycline is that of tissue discolouration and skin pigmentation. Tissues that may become pigmented include the skin, skull and other bones and the thyroid gland, which at autopsy appears blackened. The pigmentation tends to resolve slowly with discontinuation of the drug and is related to the length of therapy. Three types of pigmentation have been identified:

- A brown macular discolouration ('muddy skin syndrome'), which occurs in sun-exposed parts and is histologically associated with melanin deposition.
- Blue-black macular pigmentation occurring within inflamed areas and scars associated with hemosiderin deposition.
- Circumscribed macular blue-gray pigmented areas occurring in sun-exposed and unexposed skin, which appears to be linked to a breakdown product of minocycline.

CNS toxicity has been prominent, notably benign intracranial hypertension, which resolves on discontinuation of the drug, and, more commonly, dizziness, ataxia, vertigo, tinnitus, nausea and vomiting, which appear to be more frequent in women. These primarily vestibular side effects have ranged in frequency from 4.5% to 86%. They partly coincide with plasma concentration peaks, but their exact pathogenesis has yet to be determined.

CLINICAL USE

There appear to be few situations in which it has a unique therapeutic advantage over other tetracyclines. Its use has been tempered by the high incidence of vestibular side effects.

Although used in the long-term management of acne, the potential for skin pigmentation must be considered. Because of its high tissue concentrations, it may occasionally provide a useful alternative to other agents for the treatment of chronic prostatitis. It has a role in the treatment of sexually transmitted chlamydial infections.

Preparations and dosage

Proprietary name: Minocin.

Preparations: Tablets, capsules.

Dosage: Adults, oral, 100 mg every 12 h; acne, 100 mg per day as a single dose or two divided doses.

Widely available.

Further information

OXYTETRACYCLINE

5-Hydroxytetracycline. Molecular weight (free base): 460.4; (dihydrate): 496.5.

A fermentation product of certain strains of *Streptomyces rimosus*, supplied as the dihydrate or hydrochloride for oral or parenteral administration.

ANTIMICROBIAL ACTIVITY

Its spectrum and activity are typical of the group (Table 30.2, p. 347). It is slightly less active than other tetracyclines against most common pathogenic bacteria.

PHARMACOKINETICS

Oral absorption	c. 60%
C_{max} 500 mg oral	3–4 mg/L after 2–4 h
Plasma half-life	c. 9 h
Volume of distribution	c. 1.8 L/kg
Plasma protein binding	20–35%

Oxytetracycline is moderately well absorbed from the upper gastrointestinal tract. Food decreases plasma levels by approximately 50%. Although widely distributed in the tissues, it

achieves lower concentrations than related agents such as minocycline. Sputum concentrations of 1 mg/L have been recorded on a daily dosage of 2 g. Approximately 60% is excreted in the urine and the half-life is prolonged in renal insufficiency.

TOXICITY AND SIDE EFFECTS

Gastrointestinal intolerance is responsible for most side effects, and tends to be more severe than with other tetracyclines. Esophageal irritation may result from the local effects of the swallowed drug. Potentially serious adverse reactions have included neuromuscular paralysis following intravenous administration to patients with myasthenia gravis. Thrombocytopenic purpura and lupus erythematosus syndrome have been reported, although a direct role for the drug in the latter remains uncertain. Apart from the effect on nitrogen balance common to many tetracyclines, a metabolic effect on glucose homeostasis has been noted in type 1 diabetes mellitus. Allergic contact sensitivity reactions have also been reported.

CLINICAL USE

Its uses are those common to the group (Table 30.1, p. 346). It offers no unique therapeutic advantages, although it is one of the cheaper preparations.

Preparations and dosage

Proprietary name: Terramycin.

Preparations: Tablets, capsules.

Dosage: Adults, oral, 250–500 mg every 6 h; acne, 250 mg–1 g per day as a single dose or two divided doses.

Widely available.

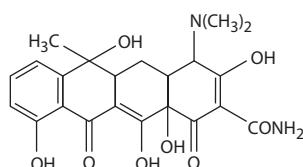

Further information

Anonymous. Oxytetracycline (dihydrate). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:O55–O58.

TETRACYCLINE

Molecular weight (free base): 444.4; (hydrochloride): 480.9.

A fermentation product of *Streptomyces aureofaciens*, also produced from chlortetracycline. Available as the hydrochloride for oral and topical use.

ANTIMICROBIAL ACTIVITY

Its activity against common pathogenic bacteria is shown in Table 30.2 (p. 347). It is also active against *V cholerae*, chlamydiae, rickettsiae and spirochetes.

PHARMACOKINETICS

Oral absorption	c. 75%
C_{max} 500 mg oral	2–4 g/L
Plasma half-life	8.5 h
Volume of distribution	c. 1.3 L/kg
Plasma protein binding	c. 50–60%

Absorption

When taken with food, absorption is reduced by approximately 50%. Steady-state plasma concentrations of 4–5 mg/L occur after oral doses of 500 mg every 6 h. Women appear to produce higher concentrations than men. Divalent and trivalent cations such as calcium and aluminum present in antacids and milk interfere with absorption through chelation, as does ferrous sulfate. H₂-receptor antagonists, by raising gastric pH, also interfere with absorption through impaired drug dissolution. Despite the effect of gastric pH, oral absorption is not affected in elderly patients with achlorhydria.

Distribution

Tetracycline is widely distributed in the body tissues. In particular, it penetrates well into the prostate, uterus, ovary and bladder, and also appears to be preferentially taken up by the gastrointestinal tract. It is also detectable within reticuloendothelial cells of the liver, spleen and bone marrow.

Protein binding is reduced in states of malnutrition. It is also bound to bone, dentine and tooth enamel of unerupted teeth. Sputum concentrations of 0.4–2.6 mg/L have been detected after 250 mg oral dosage every 8 h. Maxillary sinus secretions and bronchial mucosal tissue have concentrations comparable to those of serum.

CSF penetration is poor, but increases with meningeal inflammation. It crosses the placenta readily to enter the fetal circulation, where it achieves 25–75% of the maternal plasma concentration. It is also present in breast milk.

Metabolism

A small amount is metabolized to 4-epitetracycline.

Excretion

Tetracycline is largely eliminated unchanged by glomerular filtration, with more than 50% excreted within 24 h after oral administration. This rises to approximately 70% following parenteral administration. Urinary concentrations of 300 mg/L occur within the first 2 h and persist for up to 12 h. Urinary excretion is enhanced in alkaline urine. Renal clearance is reduced in severe protein calorie malnutrition, possibly through reduced glomerular filtration. It accumulates in the presence of renal failure and is only slowly removed by hemodialysis and minimally by peritoneal dialysis.

The bile is an important route of excretion, accounting for about one-third of the dose. Biliary concentrations may be 10–25 times those found in serum. Impaired hepatic function or biliary obstruction leads to an increase in blood levels.

TOXICITY AND SIDE EFFECTS

The gastrointestinal side effects common to the group are the most frequent cause of intolerance. Metallic taste and glossitis are less burdensome than diarrhea. Antibiotic-associated enterocolitis caused by *Clostridium difficile* toxin and staphylococcal enterocolitis have been reported. Steatorrhea and acute pancreatitis has also been described. Irritation and ulceration of the esophagus has occurred with local impaction of the drug. *C. albicans* overgrowth is common and may result in symptomatic oral or vaginal candidiasis and occasionally candida diarrhea.

Hypersensitivity reactions include contact dermatitis, urticaria, facial edema and asthma. Anaphylaxis is rare. A lupus syndrome has been reported, but its cause is uncertain. Photosensitivity can be severe and cause vesication, desquamation and onycholysis. The Jarisch–Herxheimer reaction has been observed in the treatment of syphilis, louse-borne relapsing fever, leptospirosis, brucellosis and tularemia. Deposition in deciduous teeth and bone (where it may temporarily inhibit growth) is of continuing concern. Between 3% and 44% of administered tetracycline is incorporated in the inorganic phase of bone, which may become visibly discolored and fluoresce. Concentrations as high as 290 mg/g have been recorded in bone in those on long-term tetracycline treatment for acne.

Existing renal insufficiency may be aggravated and is probably related to the antianabolic effect of this class of drugs; interference with protein synthesis places an additional burden on the kidney from amino acid metabolism. Acute renal failure may occur and can be aggravated by drug-induced diarrhea. Dehydration and salt loss from diuretic therapy may aggravate nephrotoxicity. Methoxyflurane and tetracycline in combination may be synergistically nephrotoxic.

An uncommon but serious adverse reaction is acute fatty liver, which may be complicated by renal insufficiency and electrolyte abnormalities. This is most likely to occur with high-dose intravenous administration, especially during pregnancy.

Hematological toxicity is uncommon. Leukopenia, thrombocytopenia and hemolytic anemia have been reported. Altered coagulation may also occur with high intravenous dosage. Phagocyte function may be impaired as a result of the increased excretion of vitamin C.

Neurological toxicity is uncommon but includes benign intracranial hypertension (p. 345). A transient myopathy has complicated long-term oral use for the treatment of acne, while intravenous administration has caused increased muscle weakness in those with myasthenia gravis and has also potentiated curare-induced neuromuscular blockade.

Metabolic effects include: precipitation of lactic acidosis in diabetic patients receiving phenformin; a reduction in vitamins B₁₂, B₆ and pantothenic acid with long-term therapy; interference with laboratory tests of urinary catecholamines and urinary tests for glucose (Clinitest and Benedict's); and elevation of serum lithium concentrations. In addition, warfarin is potentiated and failure of oral contraception occurs.

CLINICAL USE

Uses are those listed in Table 30.1 (p. 346). Along with doxycycline it is one of the most commonly used tetracyclines.

Preparations and dosage

Proprietary names: Achromycin, Sustamycin, Tetrabid-Organon, Tetrachel, Deteclo (in combination with chlortetracycline and demeclocycline), Mysteclin (in combination with nystatin).

Preparations: Tablets, capsules.

Dosage: Adults, oral, 250–500 mg every 6–8 h, depending on severity of infection; acne, 500 mg–1 g per day as a single dose or two divided doses. Widely available as oral formulation.

TIGECYCLINE

Molecular weight: 585.6

9-T-butylglycylamido-minocycline. A compound of the glycylcycline class available as a powder for intravenous infusion.

ANTIMICROBIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 30.2 (p. 347). It is as potent as, or more potent than, earlier tetracyclines and activity is retained against strains expressing acquired tetracycline resistance determinants. It displays better activity than tetracycline, doxycycline or minocycline against *Streptococcus* spp. and against *Enterococcus faecalis* and *E. faecium*. Among Gram-negative organisms it displays improved activity against *Citrobacter freundii*, *Escherichia coli*, *Enterobacter cloacae*, *Klebsiella pneumoniae*, *Salmonella* spp., *Serratia marcescens* and *Shigella* spp. The spectrum includes rapidly growing mycobacteria. *Ps. aeruginosa*, *Pr. mirabilis*, other *Proteus* spp. and some strains of *Corynebacterium jeikeium* are resistant. Activity against strains expressing acquired resistance to earlier tetracyclines is attributed to failure of the MFS efflux pumps to recognize tigecycline, and to a novel mechanism of ribosome binding that permits tigecycline to overcome ribosomal protection mechanisms.

Comparative susceptibility data for some atypical pathogens are not available. However, in common with earlier tetracyclines, it is active against *Chlamydophila* and *Mycoplasma* spp. and rapidly growing *Mycobacteria* spp. It is less active than minocycline or tetracycline against *U. urealyticum*.

PHARMACOKINETICS

C_{\max} 100 mg intravenous infusion (1 h)	0.85–1 mg/L
Plasma half-life	37–67 h
Volume of distribution	7–10 L/kg
Plasma protein binding	68%

Distribution and excretion

It is widely distributed and is concentrated in the gallbladder, colon and lung. The volume of distribution is dose related and variable, but is generally greater than that of older tetracyclines. CSF penetration is poor. Tigecycline is excreted in the feces and urine predominantly as the unchanged molecule. The elimination half-life is long (37–67 h). Tigecycline clearance is decreased by 20% in patients with renal failure. No dosage adjustments are apparently necessary for tigecycline in patients with renal impairment.

TOXICITY AND SIDE EFFECTS

Side effects typical of the group, including nausea, vomiting, diarrhea and headache, occur. Occasional cases of pancreatitis, hypoproteinemia, antibiotic-associated colitis and thrombocytopenia have also been reported.

CLINICAL USE

Complicated skin and skin structure infections
 Complicated intra-abdominal infections
 Community-acquired bacterial pneumonia

Recommended principally for the treatment of infections with multiresistant organisms.

Preparations and dosage

Proprietary name: Tygacil.

Preparation: Powder.

Dosage: Adults, i.v. infusion of 100 mg followed by 50 mg every 12 h for 5–14 days.

Available in the USA, Europe and Japan.

OTHER TETRACYCLINES

LYMECTYLINE

2-N-lysinomethyl-tetracycline. A water-soluble prodrug of tetracycline available for oral administration.

Its antimicrobial activity is due to the tetracycline content. It is lipophilic, rapidly absorbed from the gastrointestinal tract and widely distributed. Concentrations around 1 mg/kg have been found in maxillary sinus tissue some 3 h after administration of a conventional dose. The half-life is 7–14 h. Approximately 30% of an orally administered dose is excreted as active drug in the urine, where it achieves concentrations of 300 mg/L.

Its untoward effects and clinical uses are those of tetracycline, although it is claimed to be better tolerated.

lower dosages used. There are no unique adverse drug reactions, although skin and conjunctival pigmentation have been reported.

Preparations and dosage

Proprietary name: Rondomycin.

Preparation: Capsules.

Dosage: Adults, oral, 600 mg per day in two or four divided doses.

Widely available in continental Europe.

Preparations and dosage

Proprietary name: Tetralysal 300.

Preparation: Capsules.

Dosage: Adults, oral, 408 mg every 12 h.

Available in the UK and continental Europe.

ROLITETRACYCLINE

2-N-pyrrolidinomethyl-tetracycline. A semisynthetic derivative of tetracycline supplied as the nitrate sesquihydrate for parenteral use.

It is not absorbed from the gastrointestinal tract. It is highly soluble and therefore can be administered parenterally. Peak plasma concentrations of 4–6 mg/L occur at 0.5–1 h after 350 mg intravenously. The plasma elimination half-life is 5–8 h. About 50% of the dose is excreted in the urine, producing high concentrations.

Intravenous administration is occasionally accompanied by abnormal taste, shivering and rigors, hot flushes, facial redening, dizziness and, rarely, circulatory collapse. Symptoms of myasthenia gravis have occasionally been exacerbated.

METHACYCLINE

6-Methylene-5-hydroxy-tetracycline. A semisynthetic derivative supplied as the hydrochloride for oral administration.

Mean peak plasma concentrations of 2–6 mg/L are found about 4 h after a 300 mg oral dose. Both food and milk reduce uptake by half. Protein binding is 80–90%. The plasma elimination half-life varies between 7 and 15 h and increases to 44 h in severe renal impairment. It is widely distributed, producing lung concentrations similar to, or greater than, the simultaneous plasma concentration. About one-third is excreted in the urine.

Gastrointestinal intolerance is reported to be less frequent than with other tetracyclines, largely because of the

Preparations and dosage

Proprietary name: Reverin.

Preparation: Injection.

Dosage: Adults, i.m., 350 mg per day; i.v., 275 mg per day.

Limited availability in continental Europe.

CHAPTER

31

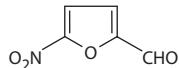

Miscellaneous antibacterial agents

David Greenwood

This chapter is concerned with various antimicrobial compounds that are structurally different from the major antimicrobial drug families and from each other. Most are of limited use in human medicine, except in specific diseases or as topical agents.

NITROFURANS

Antimicrobial nitrofurans are based on the 5-nitro-2-furaldehyde molecule:

Antimicrobial activity requires the 5-nitro group. Substitutions on the aldehyde at the 2 position produce compounds with varying activities and pharmacokinetic properties. They are yellow or orange compounds and are relatively easy to synthesize. They are poorly soluble in water, but often dissolve well in solvents such as dimethyl sulfoxide or dimethylformamide.

Many nitrofurans have been developed since their antibacterial activity was discovered in the early 1940s, but few have survived into medical and veterinary practice. Nitrofurantoin is the most important, but furazolidone is also widely used in some countries for non-specific treatment of gastrointestinal infections.

Nitrofurans are active in vitro against a wide range of bacteria, including staphylococci, streptococci, enterococci, corynebacteria, clostridia and many species of enterobacteria (Table 31.1). *Serratia marcescens*, *Pseudomonas aeruginosa* and members of the Proteae tribe are resistant. They are less active under alkaline conditions.

They are active against strains of *Helicobacter pylori* that have acquired resistance to metronidazole, but it is not clear whether this reflects therapeutic efficacy. Nifurtimox is one of the few antimicrobial agents with activity against trypanosomes.

Many nitrofurans are mutagenic, and some are said to be co-carcinogenic. However, therapeutic use of nitrofurans over many years has shown no evidence of long-term harmful effects. Nitrofurans share a class side effect of causing nausea. They may also bring about hemolysis in patients with a deficiency of glucose-6-phosphate dehydrogenase.

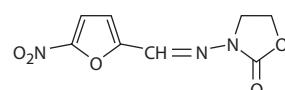

Further information

Raether W, Hänel H. Nitroheterocyclic drugs with broad spectrum activity. *Parasitological Research.* 2003;90(supp 1):S19–S39.

FURAZOLIDONE

Molecular weight: 225.2.

A non-ionic synthetic compound, available for oral use only. It is poorly soluble in water (40 mg/L) and ethanol (90 mg/L), but dissolves well in dimethylformamide (10 g/L). It decomposes in the presence of alkali.

ANTIMICROBIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 31.1. It is active against a wide range of enteric pathogens, including *Salmonella enterica*, *Shigella* spp., enterotoxigenic *Escherichia coli*, *Campylobacter jejuni*, *Aeromonas hydrophila*, *Plesiomonas shigelloides*, *Vibrio cholerae* and *V. parahaemolyticus*. *Yersinia enterocolitica* is intrinsically resistant. Furazolidone is also active against the protozoa *Giardia lamblia* and *Trichomonas vaginalis*.

Table 31.1 Activity of nitrofurans against common pathogenic bacteria: MIC (mg/L)

	Furazolidone	Nitrofurantoin	Nitrofurazone
<i>Staphylococcus aureus</i>	2–8	4–32	8–16
<i>Streptococcus pyogenes</i>	4–8	4–16	8–64
<i>Enterococcus faecalis</i>	8–32	4–128	32–128
<i>Neisseria gonorrhoeae</i>	No data	0.25–2	0.1–8
<i>Escherichia coli</i>	<0.5–4	0.5–16	4–16
<i>Proteus</i> spp.	32–128	8–R	8–128
<i>Klebsiella pneumoniae</i>	2–8	32–R	8–128
<i>Salmonella enterica</i>	0.25–2	4–128	4–16
<i>Shigella</i> spp.	0.25–4	4–128	4–32
<i>Pseudomonas aeruginosa</i>	R	R	R
<i>Bacteroides fragilis</i>	8–16	8–16	4–32
<i>Helicobacter pylori</i>	0.06–0.25	8–32	No data

R, resistant (MIC >128 mg/L).

ACQUIRED RESISTANCE

Acquired resistance has been observed in *V. cholerae* O1 and O139, *S. enterica* serotypes Typhi and Enteritidis, *A. hydrophila* and *Shigella* spp. Such resistance may be transferable, and there is cross-resistance with nitrofurantoin. Many of these reports come from the Indian sub-continent, where furazolidone is used widely for treating diarrhoeal diseases.

PHARMACOKINETICS

There is substantial absorption (65–70%) after oral administration, but the drug is heavily metabolized, so that only about 5% of the material excreted is microbiologically active. A dose of 5 mg/kg achieves a maximum plasma concentration of around 1 mg/L. Protein binding is about 30%. Intact drug can be found in various body fluids in concentrations approximating to the minimum inhibitory concentration (MIC) for various intestinal pathogens. Less than 1% of the drug is excreted into urine.

TOXICITY AND SIDE EFFECTS

Most reported side effects are mild and only rarely cause discontinuation of treatment. Nausea and vomiting are experienced by around 8% of patients. Other adverse events include neurological reactions (mainly headache; 1.3% of patients), ‘systemic’ reactions such as fever and malaise (0.6%) and skin

rashes (0.54%). Administration of furazolidone may give rise to inhibition of monoamine oxidase, and disulfiram-like reactions have been reported.

CLINICAL USE

Furazolidone is used in gastrointestinal infections and vaginitis. It is mainly used in developing countries to treat diarrhoeal diseases of varying etiology, but it is not the drug of choice if a specific pathogen has been identified. Use as a second-line agent in giardiasis and as part of multidrug regimens in *Helicobacter* infection has been advocated.

Preparations and dosage

Preparations: Tablets, suspension.

Dosage: Adults, oral, 100 mg, every 6 h for 7–10 days. Children, 1.25 mg/kg every 6 h (suspension available).

Limited availability in the USA and continental Europe.

NITROFURANTOIN

Molecular weight: 238.2.

A synthetic compound available only for oral administration. There are three formulations, differing in their crystalline nature: microcrystalline, macrocrystalline, and a delayed-release preparation containing a combination of the two. The macrocrystalline form is said to be less liable to give rise to the most common adverse event, nausea. However, pharmacokinetic and clinical trial evidence for this assertion is not very strong.

It is slightly soluble in water (*c.* 200 mg/L) but more so in dilute alkali. Solubility in ethanol is modest (500 mg/L), but the compound dissolves very well in dimethylformamide (80 g/L). If packaged in light-resistant containers and kept at room temperature, it is stable for more than 5 years. The yellow solution should be kept in the dark.

ANTIMICROBIAL ACTIVITY

Activity against common bacterial pathogens is shown in Table 31.1. It is active against almost all the common urinary pathogens, except *Proteus mirabilis*. It is bactericidal.

It antagonizes the activity of nalidixic acid and other quinolones in vitro, but this combination is unlikely to be used clinically.

ACQUIRED RESISTANCE

Surprisingly for an agent that has been used for so long, resistance remains uncommon. R-factor-mediated resistance has been reported, but this appears to be very unusual. The mechanism of resistance seems to be a decreased nitroreductase activity in the target organism.

There is cross-resistance within the nitrofuran group, but none with antibiotics of other chemical classes.

PHARMACOKINETICS

Oral absorption	>95%
C _{max} 100 mg oral	<2 mg/L after 1–4 h
Plasma half-life	0.5–1 h
Volume of distribution	0.6 L/kg
Plasma protein binding	60–70%

Absorption

It is absorbed mainly from the proximal small intestine and the plasma peak concentration may not be achieved for as long as 4 h. The recommendation to take the drug with food may be motivated by reducing the incidence of nausea rather than increasing bioavailability.

Bioavailability varies widely between different brands and this may not be apparent from results of standard in-vitro pharmaceutical tests. Therefore, different brands should not be substituted unless therapeutic equivalence has been formally established.

Distribution

Serum levels are low, owing to extensive metabolism and the short plasma half-life. Tissue concentrations are too low for adequate treatment of systemic infection, including pyelonephritis. Negligible concentrations are found in breast milk and only a small amount crosses the placenta.

Metabolism and excretion

About 20% of the dose is excreted in microbiologically active form in the urine, sufficient to give inhibitory concentrations against urinary pathogens for up to 6 h. With reduced renal function (creatinine clearance <60 mL/min), urinary excretion falls, and virtually ceases when creatinine clearance is below 20 mL/min. This gives rise to the risk of accumulation in the blood and inadequate urine levels. With this proviso, it can be given to elderly patients. Infants over the age of 3 months may also be treated, but in the absence of a suitable suspension, and at the recommended dosage, a 6-month baby would need to be given one-tenth of a standard 50 mg tablet.

TOXICITY AND SIDE EFFECTS

Nausea, which may be combined with anorexia or vomiting, or both, occurs in about 30% of patients taking the microcrystalline form, causing about 10% to stop treatment. The frequency of nausea is approximately halved with the macrocrystalline formulation. Nausea is due to a direct effect on the vomiting center; it occurs early in the course, and its incidence may be reduced by taking the medication with food or milk.

Pulmonary, hepatic, neurological and hematological side effects have been reported, but are very uncommon. There are two kinds of pulmonary reaction. Acute reactions are the more common, starting within 5–10 days of the first dose, or within a few hours on re-challenge. Symptoms may resemble those found in asthma, tracheobronchitis or pneumonia, and usually resolve permanently within 2 days. There may be an eosinophilia. Subacute or chronic reactions, often referred to as pneumonitis, are of more gradual onset, and resolve only

slowly when the drug is stopped. Prolonged dyspnea and cough may be accompanied by fibrosis.

Hepatic reactions follow prolonged drug usage and usually manifest as chronic active hepatitis, sometimes with cirrhosis. The prognosis is good, but recovery may take months.

Peripheral neuropathy has been reported mainly in patients with pre-existing impaired renal function. The prognosis depends upon the severity of the symptoms. Unlike hepatic and pulmonary effects, for which immunological phenomena seem to be responsible, neurological events have been attributed to a direct toxic effect of the drug, one of its metabolites or the superoxide generated in vivo.

In common with other nitrofurans, nitrofurantoin may cause hemolysis in patients who lack glucose-6-phosphate dehydrogenase.

CLINICAL USE

- Acute dysuria and frequency
- Bacteriuria in pregnancy
- Prophylaxis of recurrent cystitis (reduced dosage)

Preparations and dosage

Proprietary names: Furadantin (microcrystalline), Macrodantin (macrocrystalline), Macrobid (mixture).

Preparations: Tablets, capsules, suspension.

Dosage: Adults, oral, 50 or 100 mg every 6 h for 5 or 7 days for acute infection; 50–100 mg at night for prophylaxis. Children >3 months, 3 mg/kg per day in four divided doses; 1 mg/kg at night for prophylaxis.

Widely available.

A nitrofurantoin analog, furagin (furazidin), with similar properties and use is available in eastern Europe.

OTHER NITROFURANS

NIFURATEL

A synthetic compound available as tablets and vaginal preparations. It is poorly soluble in water, but readily soluble in dimethylformamide.

The activity is similar to that of nitrofurantoin but it is more active, especially against Gram-negative anaerobes. It also has modest, but clinically useful, activity against *Candida albicans*. Little is known about the pharmacokinetics. It structurally resembles furazolidone, and may undergo a similar degree of metabolism. It does not achieve therapeutic concentrations in the bloodstream after oral administration and it seems likely that the antibacterial activity in urine is due to active metabolites. There is little or no systemic absorption when vaginal suppositories are used.

As with other members of the group, side effects are mostly associated with the upper gastrointestinal tract. It is used to treat urinary infections and vaginal candidiasis.

Preparations and dosage

Preparations: Tablets and vaginal pessaries.

Dosage: Adults, oral, 200–400 mg every 8 h. A 250 mg vaginal pessary may be used concurrently once a day for 10 days.

Available in some countries in continental Europe.

Mendling W, Poli A, Magnani P. Clinical effects of nifuratel in vulvovaginal infections. A meta-analysis of metronidazole-controlled trials. *Arzneimittelforschung*. 2002;52:725–730.

NIFURTIMOX

A water-soluble synthetic compound available for oral use. It exhibits antibacterial activity typical of the group, but its most notable property is its activity against trypanosomes, especially *Trypanosoma cruzi*.

A plasma concentration of 0.5–1 mg/L is achieved c. 2 h after an oral dose of 15 mg/kg. The plasma half-life is 2–4 h. In common with other nitrofurans, it is rapidly and extensively metabolized, so that less than 1% of a dose is excreted intact in the urine. In renal failure, clearance is somewhat reduced but the half-life is unchanged.

Adverse events are common. Many patients experience anorexia, which may be combined with vomiting and abdominal pain. There may also be neurological reactions such as restlessness, insomnia, headache and disorientation.

It is used in the treatment of Chagas disease (South American trypanosomiasis). It has also found some use in the treatment of African sleeping sickness in combination with eflornithine (p. 419).

Preparations and dosage

Preparation: Oral.

Dosage: Adults, oral, 8–10 mg/kg per day in divided doses. Children: 1–10 years, 15–20 mg/kg per day in divided doses; 11–16 years, 12.5–15 mg/kg per day in divided doses. Treatment should last 60–120 days.

Available in South America.

NIFURTOINOL

The hydroxymethyl derivative of nitrofurantoin, formulated for oral administration. The activity is similar to that of nitrofurantoin. Little is known about the pharmacokinetic behavior. It is said to be more rapidly absorbed than nitrofurantoin and excreted into the urine to a greater extent. Available in some countries in continental Europe.

NITROFURAZONE (NITROFURAL)

A synthetic compound used in the topical treatment of wounds and burns and as an instillation for bladder washout. A nitrofurazone-impregnated urinary catheter is said to reduce infection in catheterized patients. Activity against the common bacterial pathogens is sufficient to cover most pathogens that cause infections of burns and wounds, with the important exception of *Ps. aeruginosa*. Attention has been drawn to its activity against methicillin-resistant *Staphylococcus aureus*, and its use in clearing carriage has been suggested. Slight absorption occurs from intact skin (*c.* 1%) and burned skin (5%). It is neither a primary

irritant nor a sensitizer, but some preparations contain polyethylene glycol as a vehicle, and absorption can cause problems in patients with reduced renal function. Of limited availability.

PEPTIDE ANTIOTICS

Peptides of various kinds were among the earliest antibiotics isolated from natural sources. The recovery of tyrothricin from *Bacillus brevis* was reported in 1939 and its separation into gramicidin (a linear peptide) and tyrocidine (a cyclic peptide) in 1940. Gramicidin S (Soviet), which is also produced by a strain of *B. brevis*, is a cyclic peptide similar to tyrocidine. It was developed in the former Soviet Union and is not generally available.

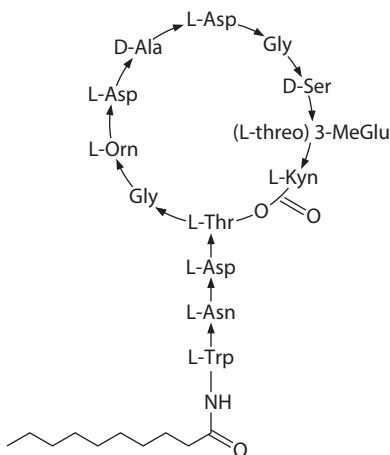

Another cyclic peptide, bacitracin, was isolated from *Bacillus licheniformis* in 1945 and named after Margaret Tracy, the young girl from whom the organism was isolated. Polymyxin B, which was discovered almost simultaneously in the USA as a product of *Bacillus polymyxa* and in the UK as a product of *Bacillus aerosporus* followed in 1947.

The disruptive activity of these peptides on cell membranes, to which they owe their mammalian toxicity, has limited their therapeutic use largely to topical application, but the polymyxins, notably as colistimethate sodium (colistin sulfomethate), are still occasionally used systemically against otherwise resistant organisms. Daptomycin, a lipopeptide originally developed and discarded in the 1980s, has been revived for the treatment of infections with resistant Gram-positive cocci.

Antibacterial oligopeptides are virtually ubiquitous throughout the natural world and are thought to play a part in native defences against infection. Such peptides include, among many others: cecropins (originally described in insects); magainins (from the skin of the toad *Xenopus laevis*); lantibiotics (lanthionine-containing peptides, like nisin, from bacteria); and defensins (from mammalian phagocytes). Many of these compounds interfere with membrane integrity and exhibit differential activity against various species. Some of them, and related synthetic oligopeptides, continue to be investigated, but none has yet emerged as a possible therapeutic agent.

DAPTOMYCIN

A semisynthetic lipopeptide derived from a fermentation product of *Streptomyces roseosporus*.

Daptomycin is a cyclic peptide with a lipophilic tail and thus resembles the polymyxins structurally. Its useful activity is restricted to Gram-positive cocci, notably *Staph. aureus* and its chief attraction is that it retains activity against multiresistant strains. Its activity in vitro is greatly potentiated by the presence of calcium (but not magnesium) ions and in these conditions it is more potently bactericidal than the glycopeptides.

PHARMACOKINETICS

Oral absorption	Poor
C_{\max} 4 mg/kg intravenous infusion	55 mg/L end infusion
Plasma half-life	8–9 h
Volume of distribution	c. 0.1 L/kg
Plasma protein binding	92–95%

Oral absorption is poor and it is administered intravenously. It is eliminated predominantly by the kidneys, about half the dose being excreted unchanged within 24 h. The plasma half-life increases in patients with impaired renal function so that the dosage interval should be extended. Around 10% of an administered dose is removed by peritoneal and hemodialysis.

TOXICITY AND SIDE EFFECTS

It is generally well-tolerated, but gastrointestinal side effects, headache and various other adverse reactions occur with varying frequency. Less commonly, but more seriously, myalgia, muscle weakness and myositis may occur requiring regular monitoring of creatine kinase during treatment. Rhabdomyolysis has been reported, but is very rare.

Preparations and dosage

Proprietary name: Cubicin.

Preparation: Injection.

Dosage: Adults, i.v., 2–6 mg/kg once daily.

Widely available.

POLYMYXINS

Polymyxin B and colistin (polymyxin E); mixtures of sulfates of polypeptides produced by strains of *B. polymyxa* and *B. polymyxa* var. *colistinus*. Colistimethate sodium (colistin sulfate/methane sulfonate). Molecular weights: polymyxin B₁ 1203; polymyxin B₂ 1189; colistimethate sodium 1748.

DAB = diaminobutyric acid

A group of basic polypeptide antibiotics with a side chain terminated by characteristic fatty acids. Five polymyxins (A–E) were originally characterized and others have since been added. Polymyxin B and colistin (polymyxin E) sulfates have been commercially developed.

By treatment with formalin and sodium bisulfite, five of the six diaminobutyric acid groups of the polymyxins can be modified by sulfomethyl groups to form undefined mixtures of the mono-, di-, tri-, tetra- and penta-substituted derivatives. Sulfomethyl polymyxins differ considerably in their

properties from the parent antibiotics: they are less active antibacterially, less painful on injection, more rapidly excreted by the kidney and less toxic. Only colistimethate sodium is now commercially available for systemic use, but polymyxin B and colistin sulfates are found as ingredients of several topical formulations.

ANTIMICROBIAL ACTIVITY

All the polymyxins have a similar antibacterial spectrum, although there are slight quantitative differences in their activity *in vitro*. They are inactive against Gram-positive organisms, but nearly all enterobacteria, except *Proteus* spp., *Burkholderia cepacia* and *Ser. marcescens*, are highly susceptible. The MIC of polymyxin B or colistin sulfate for *Esch. coli* and *Klebsiella* spp. is 0.01–1 mg/L; the corresponding concentration for *Ps. aeruginosa* is 0.03–4 mg/L. *Bacteroides fragilis* is resistant, but other *Bacteroides* spp. and fusobacteria are susceptible. Resistance of *V. cholerae* eltor to polymyxin B distinguishes it from the classic vibrio.

The sulfomethyl derivatives are generally 4–8 times less active than the sulfates, but their activity is difficult to measure precisely since on incubation they spontaneously decay to the parent compound, with a corresponding progressive increase in antibacterial activity.

Binding of polymyxins to the bacterial cell membrane can increase permeability to hydrophilic compounds, including sulfonamides and trimethoprim, producing significant synergy. Synergy with ciprofloxacin is also described. Calcium ions exert a strong pH-dependent competition for membrane binding sites, and the presence of calcium and magnesium ions in certain culture media adversely affects the bactericidal activity, notably against *Ps. aeruginosa*.

ACQUIRED RESISTANCE

There is complete cross-resistance between the polymyxins, but stable acquired resistance in normally susceptible species is very rare. Adaptive resistance, probably due to changes in cell-wall permeability, is readily achieved by passage of a variety of enterobacteria in the presence of the agents *in vitro*.

PHARMACOKINETICS

Oral absorption	Negligible
C_{\max} (colistimethate sodium) 2 mega-units (c. 16 mg colistin base) i.m.	6–7 mg/L after 2–3 h
Plasma half-life (colistimethate sodium)	c. 4–6 h
Plasma protein binding	Very low

Absorption

Polymyxins are not absorbed from the alimentary tract or mucosal surfaces, but can be absorbed from denuded areas or large burns.

Distribution

After parenteral administration of the sulfates, blood levels are usually low (1–4 mg/L 2 h after a 500 000 unit intramuscular dose). Substantially higher plasma levels are obtained from intramuscular injections of sulfomethyl polymyxins. There is some accumulation in patients receiving 120 mg every 8 h. In patients treated intravenously with a priming dose of 1.5–2.5 mg/kg followed by continuous infusion of 4.8–6.0 mg/h for 20–30 h, steady state levels were around 5–10 mg/L.

The volume of distribution is unknown, but polymyxins diffuse poorly into tissue fluids and penetration to cerebrospinal fluid is poor. As a result of binding to mammalian cell membranes (sulfomethates less so), they persist in the tissues, where they accumulate on repeated dosage, although they disappear from the serum. Polymyxin crosses the placenta, but the levels achieved are low. A small amount appears in the breast milk.

Metabolism and excretion

The sulfates are excreted almost entirely by the kidney, but after a considerable lag, with very little of the dose appearing in the first 12 h. The sulfomethyl derivatives are much more rapidly excreted, accounting for their shorter half-lives. Around 80% of a parenteral dose of colistimethate sodium is eventually found in the urine, with concentrations reaching around 100–300 mg/L at 2 h. The fate of the remainder is unknown, but no metabolic products have been described and none is excreted in the bile. Polymyxins accumulate in renal failure and are not removed by peritoneal dialysis.

TOXICITY AND SIDE EFFECTS

Pain and tissue injury can occur at the site of injection of the sulfates, but this is less of a problem with the sulfomethyl derivatives. Neurological symptoms such as paresthesia with typical numbness and tingling around the mouth, dizziness and weakness are relatively common, and neuromuscular blockade, sometimes severe enough to impede respiration, occurs. Evidence of nephrotoxicity is observed in about 20% of patients, leading to acute tubular necrosis in about 2%. Damage is more likely in patients with pre-existing renal disease. The appearance of any evidence of deterioration of renal function or of neuromuscular blockade calls for immediate cessation of treatment. All the toxic manifestations appear to be reversible, but complete recovery may be slow.

Although less toxic than the sulfate, untoward effects have been observed in up to one-quarter of those treated

with colistimethate sodium. Nephrotoxicity is common, with an increase in urea and creatinine over the first few days of treatment. Acute tubular necrosis is heralded by the appearance of proteinuria, hematuria and casts, sometimes without prior evidence of functional impairment. Renal damage usually continues to progress for up to 2 weeks after withdrawal of therapy. Renal damage is likely to increase with the dose and with the simultaneous administration of other potentially nephrotoxic agents.

Manifestations of central and peripheral neurotoxicity occur particularly in patients with impaired renal function. Neuromuscular blockade is seen principally in patients also receiving anesthetics or other agents that impair neuromuscular transmission. Complete flaccid paralysis with respiratory arrest and subsequent complete recovery has been seen in a patient with myasthenia gravis. Allergy is occasionally seen, and nebulized colistin has caused bronchial hyperreactivity with tightness in the chest in adults with cystic fibrosis. Application of colistin or polymyxin B ear drops can lead to ototoxicity.

CLINICAL USE

Colistimethate sodium

Infections due to *Ps. aeruginosa* and other Gram-negative rods resistant to less toxic agents

Cystic fibrosis (inhalation therapy for pseudomonas infection)

Polymyxin B and colistin sulfate

Component of preparations for local application

Superficial infections with *Ps. aeruginosa* and to prevent the colonization of burns

Selective decontamination of the gut (p. 531) and as a paste for control of upper respiratory tract colonization in patients on prolonged mechanical ventilation (in combination with other agents)

Preparations and dosage

Proprietary name: Aerosporin.

Preparations: Injection, ear and eye drops and ointment. Also in multi-ingredient topical preparations.

Dosage: Adults, i.v., 1.5–2.5 mg/kg per day.

Topical preparations widely available.

Proprietary name: Colomycin.

Preparations: Injection, tablets, syrup, multi-ingredient topical applications.

Dosage: Adults, oral, 1.5–3 million units every 8 h. Children, oral, 15–30 kg, 750 000 units–1.5 million units every 8 h; <15 kg, 250 000–500 000 units every 8 h. Adults i.m., i.v., 2 million units every 8 h. Children, i.m., i.v., <60 kg, 50 000 units/kg per day in three divided doses; inhalation of nebulized solution, patients >40 kg, 1 million units every 12 h, <40 kg, 500 000 units every 12 h.

Widely available.

OTHER PEPTIDE ANTIBIOTICS

BACITRACIN

A mixture of peptides produced by *Bacillus licheniformis*. Bacitracin A is the major constituent of commercial preparations. The more stable zinc salt is used in topical formulations. It has been widely used as a growth promoter in animals, but has been banned for that purpose in the European Union.

It is highly active against many Gram-positive bacteria and is mainly used as a component of topical preparations. Although strains of *Staph. aureus* are usually susceptible, they are rather less so than most other Gram-positive bacteria. *Streptococcus pyogenes* is so much more susceptible than other hemolytic streptococci that bacitracin susceptibility is used as a screening test for identification. *Clostridium difficile* and *Actinomyces* spp. are susceptible, but enterobacteria and *Pseudomonas* spp. are resistant. *Entamoeba histolytica* is inhibited by 0.6–10 mg/L.

Resistance is uncommon, but has been detected in *Staph. aureus* following topical treatment.

It is nephrotoxic and unsuitable for parenteral use. Systemic toxicity from application to skin or ulcerated areas is rare, but it may cause allergic reactions and occasional anaphylaxis has been described. It is found in many ointments and ophthalmic preparations, usually together with other components, including polymyxins, neomycin and corticosteroids.

Bacitracin is not absorbed by mouth but oral preparations have been used for suppression of gut flora, including *C. difficile*.

Nelson R, 2007; Antibiotic treatment for *Clostridium difficile*-associated diarrhoea in adults. *Cochrane Database Syst Rev*. (3):CD004610.

GRAMICIDIN

Gramicidin as used in topical formulations is a mixture of several closely related compounds, of which about 80% is in the form of gramicidin A. It is part of the tyrothricin complex originally isolated from *B. brevis*.

It is active against most species of Gram-positive bacteria, including mycobacteria. Gram-negative bacilli are completely insensitive.

It is highly toxic to erythrocytes, liver and kidney, and is used only in topical formulations, usually as one of several components.

PLEUROMUTILINS

A group of compounds with a structure and mechanism of activity that distinguishes them from other agents, hence offering the attraction of lack of cross-resistance to existing drugs. The original pleuromutilin is a naturally occurring diterpene product of *Clitopilus scypoides* (formerly *Pleurotus mutabilis*). Two of these compounds, tiamulin and valnemulin, are used in veterinary medicine. Interest now centers on other semisynthetic derivatives, of which one, retapamulin, has been marketed for human use as a topical agent.

RETAPAMULIN

A semisynthetic pleuromutilin formulated as a 1% ointment for topical use. It is active against staphylococci (MIC 0.12 mg/L), including methicillin-resistant strains, and against streptococci (MIC 0.03–0.25 mg/L), including *Str. pyogenes* and *Str. pneumoniae*. Most enterococci and Gram-negative bacilli are resistant. Propionibacteria are susceptible, suggesting that it might be useful in acne. Early indications suggest that resistance does not emerge readily, but experience with veterinary pleuromutilins indicates that chromosomal resistance may develop with extended use.

It is metabolized in the liver and rapidly excreted, precluding use in systemic infection. Systemic exposure is said to be low following topical application and it appears safe, but there are few data on absorption through broken and unbroken skin. Principal side effects noted include local irritation and occasional allergic reactions. Licensed use is presently restricted to the treatment of impetigo and uncomplicated skin infections. Possible value in methicillin-resistant *Staph. aureus* (MRSA) infection or carriage has not yet been established.

Preparations and dosage

Proprietary names: Altabax, Altargo.

Preparations: 1% ointment

Dosage: Adults and children >9 months, apply twice daily for 5 days.

Widely available.

COUMARINS

A group of naturally occurring antibiotics chemically related to the coumarin group of anticoagulants. The best known is novobiocin, but a few naturally occurring coumarins and some semisynthetic derivatives have been studied. They share a narrow range of antimicrobial activity largely directed against aerobic Gram-positive organisms. Novobiocin inhibits susceptible strains of *Staph. aureus* (including β -lactamase-producing and methicillin-resistant strains), *Str. pyogenes* and *Str. pneumoniae* at a concentration of 0.1–2 mg/L and it has been considered for the treatment of infection with multiresistant *Staph. aureus* and other Gram-positive cocci. However, since resistance arises readily and side effects are common, the general consensus is that it no longer has a place in antibacterial therapy.

There has been some revived interest in coumarins as potentiating agents of antineoplastic drugs.

OTHER ANTIBACTERIAL AGENTS

FIDAXOMICIN

Formerly known as difimicin. An 18-membered macrocyclic compound related to the tiacumycin group of antibiotics rather than conventional macrolides. It is active against staphylococci (MIC 0.5–2 mg/L) and most anaerobic Gram-positive bacilli and cocci, but Gram-negative bacilli, including Gram-negative anaerobes, are resistant. It is very poorly absorbed when given orally and most interest surrounds its activity against *C. difficile* (MIC 0.12–0.25 mg/L). Such data as are presently available from clinical trials suggest that it is as safe and effective in the treatment of *C. difficile*-associated diarrhea as vancomycin.

METHENAMINE

Methenamine (hexamine, hexamethylenetetraamine), under the name Urotropin, was successfully used in cystitis by the German physician Nicolaier in 1895. It has no intrinsic antibacterial activity and owes its effect to decomposition in acid conditions to formaldehyde, which is non-specifically microbicidal, and ammonia. It is often used in the form of organic acid salts, methenamine hippurate and methenamine mandelate, which have been claimed (unconvincingly) to keep the urinary pH low. Mandelic acid has some antibacterial activity in its own right and is sometimes given alone as a urinary antiseptic, usually as the calcium or ammonium salt. Infection with urea-splitting organisms such as *Proteus* spp. causes the urine to become alkaline and methenamine is unsuitable for these infections.

Methenamine is absorbed from the gut and mainly excreted unchanged in the urine, achieving concentrations of around 2–60 mg/L, sufficient to inhibit most bacteria and yeasts. Higher concentrations are achieved by the hippurate salt.

It is given in enteric-coated tablets to prevent the liberation of formaldehyde by gastric acid. There is little breakdown in the blood and no systemic effect or toxicity.

Some patients complain of gastrointestinal upset or frequent and burning micturition. Attempts to control these side effects with alkali will abolish the antibacterial effect of the drug. Contact dermatitis and anterior uveitis have occasionally been encountered. Prolonged administration or high dosage may produce proteinuria, hematuria and bladder changes. Methenamine should not be given to patients with acidosis, gout or hepatic insufficiency. There have been fears about the potential carcinogenicity of formaldehyde.

Methenamine and its salts are unsuitable for the treatment of acute urinary tract infection. Their main use, now largely supplanted by other agents, has been in the long-term prophylaxis of recurrent cystitis.

Preparations and dosage

Preparation: Tablets.

Dosage: Adults, oral, 1 g every 8–12 h. Children, oral, 6–12 years, 500 mg every 12 h (maximum dose, 2 g per day).

Widely available.

CHAPTER**32**

Antifungal agents

David W. Warnock

Effective drugs are available for a wide range of fungal infections, covering most of the major systemic pathogens and providing a choice for many conditions. In the more common superficial infections it is possible to cure many patients with topical treatment, and the details of administration are often more important than the choice of agent. There are now few conditions for which there is no effective treatment.

There are four main families of antifungal agents: the allylamines, the azoles, the echinocandins and the polyenes. In addition, there is a miscellaneous group of drugs that includes flucytosine, griseofulvin and various agents that are used for topical treatment. Resistance, although not a major problem, has been recorded with some azole antifungals and with the echinocandins, usually in situations where the drugs have been given for long periods of time in the face of persistent infection.

ALLYLAMINES

A group of synthetic compounds effective in the topical and oral treatment of dermatophytes and superficial forms of candidosis. Two drugs, naftifine and terbinafine, are in clinical use.

NAFTIFINE

A topical antifungal used as a 1% cream for the treatment of dermatophyoses, including tinea pedis, tinea corporis and tinea cruris.

Preparation and dosage

Proprietary name: Naftin, Exoderil.

Preparation: Topical.

Dosage: For fungal skin infections dosage and duration of treatment varies according to condition.

Available in a number of countries, including the USA; not available in the UK.

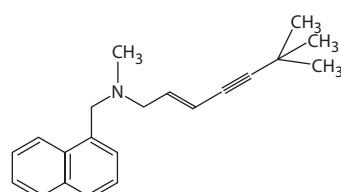

Further information

- Gupta AK, Ryder JE, Cooper EA. Naftifine: a review. *J Cutan Med Surg.* 2008;12:51–58.

TERBINAFINE

Molecular weight (free base): 291.4; (hydrochloride): 327.9.

A synthetic allylamine available as the hydrochloride for oral and topical administration.

ANTIFUNGAL ACTIVITY

Terbinafine is active against a wide range of pathogenic fungi, including dermatophytes (*Epidermophyton*, *Microsporum* and *Trichophyton* spp.), various *Candida* spp., *Aspergillus* spp., some dimorphic fungi (*Blastomyces dermatitidis*, *Histoplasma capsulatum* and *Sporothrix schenckii*) and many dematiaceous fungi.

ACQUIRED RESISTANCE

Resistance has not been reported.

PHARMACOKINETICS

Oral absorption	70–80%
C_{\max} 250 mg oral	c. 1 mg/L after 2 h
Plasma half-life	c. 17 h
Volume of distribution	1000 L
Plasma protein binding	>99%

Blood concentrations increase in proportion to dosage. It is lipophilic and is rapidly and extensively distributed to body tissues. It reaches the stratum corneum by diffusion through the dermis and epidermis, and secretion in sebum. Diffusion from the nail bed is the major factor in its rapid penetration of nails. It is metabolized by the liver and the inactive metabolites are mostly excreted in the urine. The elimination half-life is prolonged in patients with hepatic or renal impairment.

INTERACTIONS

It is a potent competitive inhibitor of the human hepatic cytochrome P₄₅₀ CYP-2D6 enzyme system, and concomitant administration with drugs predominantly metabolized by this system (e.g. tricyclic antidepressants, neuroleptics, antihypertensives, opioids and antiarrhythmics) should be carefully monitored. Blood concentrations are reduced following concomitant administration with drugs such as rifampicin (rifampin) that induce the hepatic cytochrome P₄₅₀ enzyme system. Conversely, levels are increased if it is given with drugs such as cimetidine that inhibit hepatic metabolism.

TOXICITY AND SIDE EFFECTS

These include abdominal discomfort, loss of appetite, nausea, diarrhea, headache, impairment of taste, rash

and urticaria. Serious skin reactions, including Stevens–Johnson syndrome, and rare hepatotoxic reactions, including jaundice, cholestasis and hepatitis, are occasionally encountered.

CLINICAL USE

Tinea pedis, tinea corporis, tinea cruris, tinea capitis
Onychomycosis caused by dermatophytes

Preparations and dosage

Proprietary name: Lamisil.

Preparations: Tablets, cream, oral granules.

Dosage: Adults, oral, 250 mg per day for 2–6 weeks in tinea pedis, 2–4 weeks in tinea cruris, 2–4 weeks in tinea corporis, at least 4 weeks in tinea capitis, 6–12 weeks or longer in nail infections. Children, oral granules, 250 mg per day if >35 kg, 187.5 mg per day if 25–35 kg, 125 mg per day if <25 kg for 6 weeks in tinea capitis.

Widely available.

AZOLE

A large group of synthetic agents, which includes drugs used in bacterial and parasitic infections (5-nitroimidazoles, Ch. 24; benzimidazoles, Ch. 34). Antifungal azoles have in common an imidazole or triazole ring with N-carbon substitution. The activity is essentially fungistatic, but some of the newer triazoles exert fungicidal effects at therapeutic concentrations. They are effective in the topical treatment of dermatophytoses and superficial forms of candidosis; several are suitable for systemic administration.

Several molecular mechanisms of resistance have been elucidated. These include overexpression of efflux pump genes, point mutations in the gene that encodes the target enzyme, lanosterol demethylase, and overexpression of this gene. Changes in other enzymes involved in ergosterol biosynthesis, such as sterol desaturase, may also contribute to azole resistance.

INTERACTIONS

Azoles are metabolized by the human hepatic cytochrome P₄₅₀ enzyme system, and are potent inhibitors of CYP-3A4; some also inhibit CYP-2C9 and CYP-2C19. Administration with drugs that are metabolized by these enzymes can result in increased concentrations of the azole, the interacting drug, or both. Administration with drugs that are potent inducers of the human cytochrome P₄₅₀ enzyme system, such as rifampicin, results in a marked reduction in blood levels, especially with itraconazole and ketoconazole.

Among systemically administered azoles, fluconazole and voriconazole weakly inhibit CYP-3A4, whereas itraconazole, ketoconazole and posaconazole are potent inhibitors of the enzyme.

FLUCONAZOLE

Molecular weight 306.3.

A synthetic bis(triazole) available for oral or parenteral administration. A prodrug formulation, fosfluconazole, is available for intravenous use in Japan.

ANTIFUNGAL ACTIVITY

The spectrum is limited, but includes most *Candida* spp., *Cryptococcus* spp., dermatophytes and dimorphic fungi (*Blastomyces dermatitidis*, *Coccidioides* spp., *Histoplasma capsulatum* and *Paracoccidioides brasiliensis*). Strains of *C. krusei* appear to be insensitive.

ACQUIRED RESISTANCE

Resistant strains of *C. albicans* have been isolated from AIDS patients given long-term treatment for oral or esophageal candidosis. Strains of *C. glabrata* frequently become resistant during short courses of treatment. There are a few reports of fluconazole-resistant strains of *Cryptococcus neoformans* recovered

from AIDS patients with relapsed meningitis. Most, but not all, *C. albicans* and *C. glabrata* strains resistant to fluconazole are cross-resistant to other azoles.

PHARMACOKINETICS

Oral absorption	>93%
C _{max} 50 mg oral	c. 1 mg/L after 2 h
Plasma half-life	25–30 h
Volume of distribution	0.6–0.8 L/kg
Plasma protein binding	<10%

Absorption

Oral absorption is rapid (1–3 h) and is not affected by food or intragastric pH. Blood concentrations increase in proportion to dosage. Maximum serum concentrations increase to about 2–3 mg/L after repeated dosing with 50 mg.

Distribution

It is widely distributed, achieving therapeutic concentrations in most tissues and body fluids. Concentrations in cerebrospinal fluid (CSF) are 50–60% of the simultaneous serum concentration in normal individuals and even higher in patients with meningitis.

Metabolism and excretion

More than 90% of an oral dose is eliminated in the urine: about 80% as unchanged drug and 10% as inactive metabolites. The drug is cleared by glomerular filtration, but there is significant tubular reabsorption. The plasma half-life is prolonged in renal failure, necessitating adjustment of the dosage. Fluconazole is removed during hemodialysis and, to a lesser extent, during peritoneal dialysis. In children the volume of distribution and plasma clearance are increased, and the half-life is considerably shorter (15–25 h).

INTERACTIONS

It is a potent inhibitor of CYP-2C9 and CYP-2C19, and administration with other drugs metabolized by these P₄₅₀ enzymes should be avoided.

TOXICITY AND SIDE EFFECTS

These are rare, but untoward reactions include nausea, abdominal discomfort, diarrhea and headache. Transient abnormalities of liver enzymes and rare serious skin reactions, including Stevens–Johnson syndrome, have been reported.

CLINICAL USE

Mucosal, cutaneous and systemic candidosis
Coccidioidomycosis
Cryptococcosis
Dermatophytosis
Pityriasis versicolor

Preparation and dosage

Proprietary names: Diflucan, Prodif (Japan).

Preparations: Capsules, oral suspension, i.v. infusion.

Dosage: Adults, oral, vaginal candidosis or balanitis, 150 mg as a single dose; oropharyngeal candidosis, 200 mg on the first day, followed by 100 mg once daily for at least 14 days; esophageal candidosis, 200 mg on the first day, followed by 100 mg once daily for at least 3 weeks. Tinea pedis, corporis, cruris, pityriasis versicolor, 50 mg per day for 2–4 weeks. Systemic candidosis, cryptococcal meningitis and other forms of cryptococcosis, oral or i.v. infusion, 200–400 mg on the first day, then 100–400 mg per day; treatment is continued according to response. For the prevention of relapse of cryptococcal meningitis in AIDS patients, 200 mg per day, indefinitely. Prevention of fungal infections in neutropenic patients, 400 mg per day.

Children >1 year, oral, i.v. infusion, superficial candidosis, 3 mg/kg per day; systemic candidosis and cryptococcosis, 6–12 mg/kg per day (maximum dose, 400 mg per day).

Widely available.

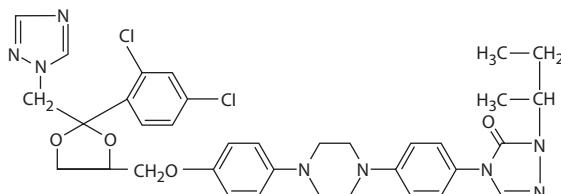

Further information

Pfaller MA, Diekema DJ. Twelve years of fluconazole in clinical practice: global trends in species distribution and fluconazole susceptibility of bloodstream isolates of *Candida*. *Clin Microbiol Infect*. 2004;10(suppl 1):11–23.

ITRACONAZOLE

Molecular weight: 705.6.

A synthetic dioxolane triazole available for oral or parenteral administration.

ANTIFUNGAL ACTIVITY

The spectrum includes dermatophytes, dimorphic fungi (*Blast. dermatitidis*, *Coccidioides* spp., *Hist. capsulatum*, *Paracocc.*

brasiliensis, *Penicillium marneffei* and *Spor. schenckii*), molds (including *Aspergillus* spp.), dematiaceous fungi and yeasts (*Candida* spp. and *Cryptococcus* spp.).

ACQUIRED RESISTANCE

This is uncommon, but fluconazole-resistant *C. albicans* and *C. glabrata* are often cross-resistant to itraconazole. There are reports of itraconazole-resistant strains of *A. fumigatus*.

PHARMACOKINETICS

Oral absorption	30% (capsules); 55% (solution)
C_{\max} 100 mg oral	0.1–0.2 mg/L after 2–4 h
Plasma half-life	20–30 h
Volume of distribution	11 L/kg
Plasma protein binding	>99%

Absorption

Absorption is improved if the drug is given with food or an acidic beverage. In contrast, absorption is reduced if it is given together with compounds that reduce gastric acid secretion. Higher concentrations are obtained with repeated dosing, but there is much individual variation. Incorporation into a solution of hydroxypropyl-β-cyclodextrin enhances bioavailability and leads to much higher blood levels in neutropenic individuals and persons with AIDS. This formulation is better absorbed if given without food. Increases in dosage produce disproportionate changes in blood concentrations.

Distribution

Levels in the CSF are low, but concentrations in lung, liver and bone are 2–3 times higher than in serum, and concentrations in the genital tract are 3–10 times higher. High concentrations are also found in the stratum corneum, as a result of drug secretion in sebum. The drug persists in the skin and nails for weeks to months after treatment is discontinued.

Metabolism and excretion

It is degraded by the liver into a large number of (mostly inactive) metabolites which are excreted with the bile and urine. Itraconazole is unusual because the major metabolite, hydroxyitraconazole, is bioactive and has a similar spectrum of activity as the parent compound. In the steady state, this metabolite is found at serum concentrations about two-fold higher than those of the parent drug. About 80–90% of the intravenous carrier, hydroxypropyl-β-cyclodextrin, is excreted unchanged in the urine. No adjustment of dosage is required in hepatic or renal failure, or during hemodialysis or peritoneal dialysis.

INTERACTIONS

Itraconazole and its metabolites potently inhibit CYP-3A4, and it should not be given with drugs metabolized by this enzyme. Concomitant administration with drugs that induce the cytochrome P₄₅₀ system, such as phenytoin, phenobarbital (phenobarbitone), carbamazepine, rifamycins and nevirapine, results in a marked reduction in blood levels of the azole.

TOXICITY AND SIDE EFFECTS

Unwanted effects are more common with oral solution than with capsules, and are more severe. They include nausea, abdominal discomfort, dyspepsia, diarrhea, headache, pruritus and skin rash. Rare side effects include Stevens–Johnson syndrome, transient abnormalities of liver enzymes, reversible idiosyncratic hepatitis and hypokalemia.

Intravenous itraconazole has been associated with congestive heart failure. Neither intravenous nor oral itraconazole should be used to treat infections in patients with evidence of ventricular dysfunction unless the expected benefit clearly exceeds the risk. Patients with risk factors for congestive heart failure should be treated with caution and their condition monitored.

CLINICAL USE

Aspergillosis

Systemic mycoses with dimorphic fungi (blastomycosis, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, penicilliosis)

Subcutaneous mycoses (chromoblastomycosis, sporotrichosis)

Mucosal and cutaneous candidosis.

Dermatophytosis

Phaeohyphomycosis

Pityriasis versicolor

Preparations and dosage

Proprietary name: Sporanox.

Preparations: Capsules, oral solution, i.v. infusion.

Dosage: Adults, oral, oropharyngeal candidosis, 100 mg per day (200–400 mg per day in AIDS or neutropenia) for 15 days. Vaginal candidosis, 200 mg every 12 h for 1 day. Pityriasis versicolor, 200 mg per day for 7 days; tinea corporis, tinea cruris, 100 mg per day for 15 days; tinea pedis, tinea manuum, 100 mg per day for 30 days or 200 mg every 12 h for 7 days. Onychomycosis, 200 mg once daily for 3 months or 200 mg every 12 h for 7 days, repeated once after 21 days for fingernails and repeated twice at 21-day intervals for toenails. Aspergillosis and other systemic or subcutaneous fungal infections, oral or i.v. infusion, 200 mg every 12 or 24 h; treatment is continued according to response. For the prevention of relapse of histoplasmosis or penicilliosis in AIDS patients, 200 mg per day, indefinitely. Prevention of fungal infections in neutropenic patients, 200–400 mg per day. Widely available.

Maertens J, Boogaerts M. The place for itraconazole in treatment. *J Antimicrob Chemother.* 2005;56(suppl 1):i33–i38.

KETOCONAZOLE

Molecular weight: 531.4.

A synthetic dioxolane imidazole available for oral and topical use.

ANTIFUNGAL ACTIVITY

The spectrum includes dermatophytes, some dimorphic fungi and *Candida* spp.

ACQUIRED RESISTANCE

Resistance has been documented in patients treated for chronic mucocutaneous candidosis and AIDS patients with oropharyngeal or esophageal candidosis. Some fluconazole-resistant *C. albicans* and *C. glabrata* are cross-resistant to ketoconazole.

PHARMACOKINETICS

Oral absorption	Variable
<i>C</i> _{max} 400 mg oral	c. 5–6 mg/L after 2 h
Plasma half-life	6–10 h
Volume of distribution	0.36 L/kg
Plasma protein binding	>95%

It is erratically absorbed after oral administration. Absorption is favored by an acid pH. Food delays absorption, but does not significantly reduce the peak serum concentration. Absorption is reduced if it is given with compounds that reduce gastric acid secretion. Penetration into CSF is generally poor and unreliable, although effective concentrations have been

recorded with high doses in some cases of active meningitis. It is extensively metabolized by the liver, and the metabolites are excreted in the bile. Less than 1% of an oral dose is excreted unchanged in the urine.

INTERACTIONS

It is a potent inhibitor of CYP-3A4 and administration with other drugs metabolized by this enzyme can lead to potentially dangerous levels of the azole, the interacting drug, or both. Concomitant administration with rifampicin results in a marked reduction in blood levels of the azole.

TOXICITY AND SIDE EFFECTS

Unwanted effects include nausea, vomiting, abdominal pain, headache, rashes, urticaria and pruritus. Transient abnormalities of liver enzymes, interference with testosterone synthesis (leading to gynecomastia, alopecia and oligospermia) and rare fatal hepatic damage have been reported.

CLINICAL USE

Mucosal candidosis
Pityriasis versicolor
Seborrheic dermatitis
Non-life-threatening forms of blastomycosis, coccidioidomycosis, histoplasmosis and paracoccidioidomycosis

Preparations and dosage

Proprietary name: Nizoral.
Preparations: Tablets, suspension, topical cream, shampoo.
Dosage: Adult, oral, 200–400 mg per day for 14 days. Children, oral, 3 mg/kg per day.
Widely available.

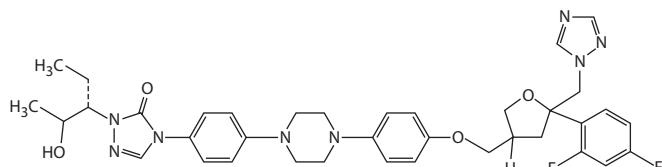

Further information

Sugar AM, Alsip SG, Galgiani JN, et al. Pharmacology and toxicity of high-dose ketoconazole. *Antimicrob Agents Chemother*. 1987;31:1874–1878.

POSACONAZOLE

Molecular weight: 700.8.

A synthetic triazole available for oral administration.

ANTIFUNGAL ACTIVITY

The spectrum includes dimorphic fungi (*Blast. dermatitidis*, *Coccidioides* spp., *Hist. capsulatum*, *Pen. marneffei*, and *Spor. schenckii*), molds (*Aspergillus* spp., *Mucor* spp., *Rhizomucor* spp. and *Rhizopus* spp.), some dematiaceous fungi and yeasts (*Candida* spp. and *Cryptococcus* spp.).

ACQUIRED RESISTANCE

This has not yet been described.

PHARMACOKINETICS

C_{max} 200 mg oral	0.5 mg/L after 4 h
Plasma half-life	35 h
Volume of distribution	1774 L
Plasma protein binding	>98%

Absorption

Oral absorption is slow. Absorption from the gastrointestinal tract is improved if the drug is given with a high-fat meal. Blood concentrations increase in proportion to dosage up to 800 mg.

Distribution

It is extensively distributed into body tissues.

Metabolism and excretion

It is not as extensively metabolized by the hepatic cytochrome P₄₅₀ system as other triazole antifungals. More than 70% of an administered dose is eliminated in the feces, predominantly as unchanged drug. The remainder is excreted as glucuronidated derivatives in the urine. Posaconazole is a substrate for intestinal P-glycoprotein,

an adenosine triphosphate-dependent plasma membrane transporter responsible for drug efflux from cells. Multiple peaks in blood concentrations have been observed, suggesting that effluxed drug is reabsorbed into the systemic circulation.

INTERACTIONS

Because it is primarily metabolized through glucuronidation and is a substrate for P-glycoprotein efflux, drugs that inhibit or induce these clearance pathways may increase or decrease blood concentrations of posaconazole. It inhibits the CYP-3A4 system, and co-administration may lead to increased serum concentrations of drugs metabolized by this enzyme. When posaconazole is discontinued, dosage of the other drugs may need to be decreased.

TOXICITY AND SIDE EFFECTS

It is generally well tolerated even for long periods. Unwanted effects include gastrointestinal discomfort and mild to moderate, transient abnormalities of liver enzymes. Rare side effects include cholestasis and hepatic failure.

CLINICAL USE

- Invasive aspergillosis
- Fusarium* infection
- Chromoblastomycosis and mycetoma
- Coccidioidomycosis
- Oropharyngeal candidosis
- Prophylaxis of invasive fungal infections in patients at serious risk

With the exception of oropharyngeal candidosis and prophylaxis, use is presently restricted to patients with disease that is refractory to other antifungal drugs, or who are intolerant to them.

Preparation and dosage

Proprietary name: Noxafil.

Preparation: Oral suspension.

Dosage: Adults, oral, oropharyngeal candidosis, 200 mg (5 mL) once a day on the first day, then 100 mg (2.5 mL) once daily for 13 days with food. Invasive fungal infections, 400 mg (10 mL) every 12 h with food. Prevention of invasive fungal infections, 200 mg (5 mL) every 8 h with food. Not recommended for children under 18 years.

Widely available.

Raad II, Graybill JR, Bustamante AB, et al. Safety of long-term oral posaconazole use in the treatment of refractory invasive fungal infections. *Clin Infect Dis.* 2006;42:1726–1734.

Rachwalski EJ, Wieczorkiewicz JT, Scheetz MH. Posaconazole: an oral triazole with an extended spectrum of activity. *Ann Pharmacother.* 2008;42:1429–1438.

VORICONAZOLE

Molecular weight: 349.3.

A synthetic triazole formulated for oral and parenteral use.

ANTIFUNGAL ACTIVITY

The spectrum includes most fungi that cause human disease: dimorphic fungi (*Blast. dermatitidis*, *Coccidioides* spp., *Hist. capsulatum*, *Paracocc. brasiliensis*, *Pen. marneffei* and *Spor. schenckii*), molds (*Aspergillus* spp., *Fusarium* spp. and *Scedosporium* spp.), dematiaceous fungi and yeasts (*Candida* spp., *Cryptococcus* spp. and *Trichosporon* spp.).

ACQUIRED RESISTANCE

Some fluconazole- and itraconazole-resistant strains of *Candida* and *Aspergillus* spp. show reduced susceptibility to voriconazole.

PHARMACOKINETICS

Oral absorption	96%
C_{\max} 400 mg oral	c. 2 mg/L after 2 h
Plasma half-life	c. 6 h
Volume of distribution	4.6 L/kg
Plasma protein binding	58%

Absorption

Oral absorption is rapid and almost complete, and is unaffected by intragastric pH. In adults, there is a disproportionate increase in blood concentrations with increasing oral and

parenteral dosage, due to partial saturation of first-pass metabolism. In children given low dosages of the drug, proportional changes in drug levels are seen.

Distribution

It is widely distributed into body tissues and fluids, including brain and CSF.

Metabolism and excretion

It is extensively metabolized by the liver. More than 80% of a dose appears in the urine, but less than 2% is excreted in unchanged form. It is metabolized by several different hepatic cytochrome P₄₅₀ enzymes. Some people with point mutations in the genes encoding these enzymes are poor metabolizers while others are extensive metabolizers. Drug levels are as much as four-fold lower in individuals who metabolize the drug more extensively.

INTERACTIONS

Like fluconazole, voriconazole inhibits several cytochrome P₄₅₀ enzymes, and there is considerable potential for the drug and its metabolites to increase the serum concentrations of other drugs metabolized by this system. Blood levels of voriconazole are significantly reduced by administration with drugs that induce hepatic cytochrome P₄₅₀ enzyme activity.

TOXICITY AND SIDE EFFECTS

Unwanted effects include mild to moderate visual disturbance, rashes, and transient abnormalities of liver enzymes. Rare side effects include life-threatening hepatitis.

Clinical use

Acute and chronic invasive aspergillosis
Serious invasive *Candida* infections
Serious infections caused by *Scedosporium* and *Fusarium* spp.

OTHER AZOLES

In addition to the systemic agents, numerous imidazoles are presently available for topical use. They include:

- **Bifonazole.** Used for the topical treatment of dermatophytoses and pityriasis versicolor.
- **Butoconazole.** Used for the topical treatment of vaginal candidosis.
- **Clotrimazole.** Used for the topical treatment of dermatophytoses, and oral, cutaneous and genital candidosis.
- **Econazole nitrate.** Used for the topical treatment of dermatophytoses, and oral, cutaneous and genital candidosis. It has also been used to treat corneal infection.
- **Fenticonazole nitrate.** Used for the topical treatment of vaginal candidosis.
- **Isoconazole nitrate.** Used for the topical treatment of dermatophytoses, and cutaneous and vaginal candidosis.
- **Miconazole nitrate.** Used for the topical treatment of dermatophytoses, pityriasis versicolor, and oral, cutaneous and genital candidosis. (Formerly also available for intravenous use.)
- **Oxiconazole.** Used for the topical treatment of dermatophytoses and cutaneous candidosis.
- **Sertaconazole nitrate.** Used for the topical treatment of dermatophytoses and vaginal candidosis.
- **Sulconazole nitrate.** Used for the topical treatment of dermatophytoses and cutaneous candidosis.
- **Terconazole.** Used for the topical treatment of dermatophytoses, and cutaneous and vaginal candidosis.
- **Tioconazole.** Used for the topical treatment of dermatophytoses (including nail infections), and cutaneous and vaginal candidosis.

Preparations and dosage

Proprietary name: Vfend.
Preparations: Film-coated tablets (50 mg and 200 mg); lyophilized powder (200 mg) for reconstitution for infusion.
Dosage: Adult, oral, 200–400 mg every 12 h for 24 h, then 100–300 mg every 12 h; i.v. 6 mg/kg every 12 h for 24 h, then 4 mg/kg every 12 h. Not recommended for children under 2 years.
Widely available.

Preparations and dosages

- Bifonazole**
Proprietary names: Amycor, Mycospor.
Preparation: Topical.
Dosage: For fungal skin infections dosage and duration of treatment varies according to condition.
Widely available.
- Butoconazole**
Proprietary name: Femstat.
Preparations: Pessaries, vaginal cream.
Dosage: Adults, pessaries, 100 mg per day for 3–6 consecutive days.
Widely available.

Further information

Maschmeyer G, Haas A. Voriconazole: a broad spectrum triazole for the treatment of serious and invasive fungal infections. *Future Microbiol*. 2006;1:365–385.

Preparations and dosages—cont'd

Clotrimazole

Proprietary names: Canesten, Gyne-Lotrimin, Lotrimin, Mycelex.

Preparations: Pessaries, vaginal cream, oral troche, topical.

Dosage: Adults, pessaries, 500 mg as a single dose, or 200 mg per day for 3 consecutive days, or 100 mg per day for 6 days. Oral troches, 10 mg five times daily for 2 weeks or longer. For fungal skin infections dosage and duration of treatment varies according to condition.

Widely available.

Econazole nitrate

Proprietary names: Ecostatin, Gyno-Pevaryl, Pevaryl, Spectazole.

Preparations: Pessaries, topical.

Dosage: Adults, pessaries, 150 mg per day for 3 consecutive days. For fungal skin infections dosage and duration of treatment varies according to condition.

Widely available.

Fenticonazole nitrate

Proprietary name: Lomexin.

Preparation: Pessaries.

Dosage: Adult, pessaries, 600 mg as a single dose or 200 mg per day for 3 consecutive days.

Widely available.

Isoconazole

Proprietary names: Fazol, Travogen, Travogyn.

Preparations: Pessaries, topical.

Dosage: Adult, pessaries, 600 mg as a single dose or 300 mg per day for 3 days. For fungal skin infections dosage and duration of treatment varies according to condition.

Widely available.

Miconazole nitrate

Proprietary names: Daktarin, Femeron, Gyno-Daktarin, Micatin, Micozole, Monistat.

Preparations: Pessaries, vaginal cream, oral gel, topical.

Dosage: Adults, pessaries, 200 mg per day for 7 consecutive days, or 100 mg per day for 14 days; oral gel, 125 mg every 6 h. Children 2–6 years, 125 mg every 12 h; infants <2 years, 62.5 mg every 12 h. For fungal skin infections dosage and duration of treatment varies according to condition.

Widely available.

Oxiconazole

Proprietary names: Oxistat, Oxizole.

Preparation: Topical.

Dosage: For fungal skin infections dosage and duration of treatment varies according to the condition being treated.

Widely available.

Sertaconazole nitrate

Proprietary name: Ertaczo

Preparation: Topical.

Dosage: For fungal skin infections dosage and duration of treatment varies according to condition.

Widely available.

Sulconazole nitrate

Proprietary name: Exelderm.

Preparation: Topical.

Dosage: For fungal skin infections dosage and duration of treatment varies according to the condition being treated.

Widely available.

Terconazole

Proprietary name: Terazol.

Preparations: Pessaries, vaginal cream.

Dosage: Adults, pessaries, 80 mg per day for 3 consecutive days.

Widely available.

Tioconazole

Proprietary names: Trosyd, Trosyl, Vagistat.

Preparations: Pessaries, nail solution, cream.

Dosage: Adults, pessaries, 300 mg as a single dose. For fungal skin and nail infections dosage and duration of treatment varies according to the condition being treated.

Widely available.

ECHINOCANDINS

Semisynthetic cyclic lipopeptides that interfere with the synthesis of the cell wall of susceptible fungi (p. 19). They are active against *Candida* spp. resistant to azoles and amphotericin B. Three agents of this type – anidulafungin, caspofungin and micafungin – have been licensed for use in systemic fungal infections.

Echinocandins do not interact with the human hepatic cytochrome P₄₅₀ enzyme system, and their use has been associated with very few significant drug interactions.

Further information

Wagner C, Graninger W, Presteri E, et al. The echinocandins: comparison of their pharmacokinetics, pharmacodynamics and clinical applications. *Pharmacology*. 2006;78:161–177.

ANIDULAFUNGIN

Molecular weight: 1140.3.

A semisynthetic lipopeptide derived from a fermentation product of *Aspergillus nidulans*. Formulated for intravenous infusion.

ANTIFUNGAL ACTIVITY

It is active against *Aspergillus* spp., *Candida* spp. and the cyst stage of *Pneumocystis jirovecii*. Resistance has not yet been reported.

PHARMACOKINETICS

C_{max} 100 mg 1-h infusion	c. 9 mg/L end infusion
Plasma half-life	18–27 h
Volume of distribution	0.6 L/kg
Plasma protein binding	84%

Blood concentrations increase in proportion to dosage. The steady state is achieved on the first day after a loading dose (twice the daily maintenance dose).

Distribution

Levels in the CSF are negligible.

Metabolism and excretion

Unlike caspofungin and micafungin, anidulafungin is not metabolized by the liver, but undergoes slow non-enzymatic degradation in the blood to a peptide breakdown product which is enzymatically degraded and excreted in the feces and bile. About 30% of a dose is eliminated in the feces, of which less than 10% is unchanged drug. Less than 1% of a dose is excreted in the urine. No dosage adjustment is required in patients with hepatic or renal impairment. Anidulafungin is not cleared by hemodialysis.

Toxicity and side effects

Occasional histamine-mediated infusion-related reactions, injection site reactions and transient abnormalities of liver enzymes have been reported.

Interactions

No clinically significant interactions have yet been reported.

Clinical use

Candidemia and certain invasive forms of candidosis
Esophageal candidosis

Preparations and dosage

Proprietary names: Eraxis, Ecalta.

Preparation: i.v. infusion.

Dosage: Adult, candidemia and invasive candidosis, 200 mg on the first day, then 100 mg per day; treatment is continued according to response. Esophageal candidosis, 100 mg on the first day, then 50 mg per day for at least 2 weeks. The rate of infusion should not exceed 1.1 mg/min.

Widely available.

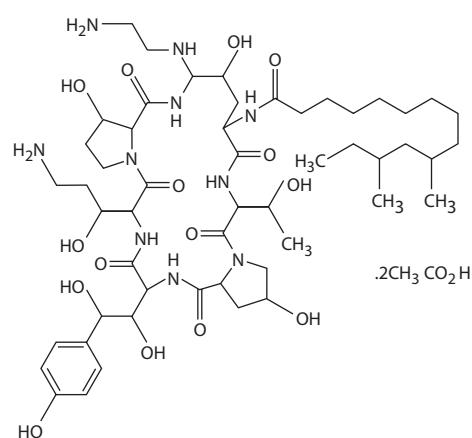

Further information

Joseph JM, Kim R, Reboli AC. Anidulafungin: a drug evaluation of a new echinocandin. *Expert Opin Pharmacother*. 2008;9:2339–2348.
Vazquez JA, Sobel JD. Anidulafungin: a novel echinocandin. *Clin Infect Dis*. 2006;43:215–222.

CASPOFUNGIN

Molecular weight: 1213.42.

A semisynthetic lipopeptide derived from a fermentation product of *Glarea lozoyensis*. Formulated as the diacetate for intravenous infusion.

ANTIFUNGAL ACTIVITY

It is active against *Aspergillus* spp., *Candida* spp. and the cyst form of *Pn. jirovecii*.

ACQUIRED RESISTANCE

This is rare, but resistant strains of *C. albicans*, *C. glabrata* and *C. parapsilosis* have been recovered from patients failing caspofungin treatment. These strains are typically cross-resistant to other echinocandins.

PHARMACOKINETICS

C_{max} 70 mg 1-h infusion	c. 10 mg/L 1 h post infusion
Plasma half-life	9–11 h
Volume of distribution	0.15 L/kg
Plasma protein binding	97%

Blood concentrations increase in proportion to dosage.

Distribution

The drug is widely distributed, the highest concentrations being found in the liver. Levels in the CSF are negligible.

Metabolism and excretion

It is slowly metabolized by the liver through non-enzymatic peptide hydrolysis and *N*-acetylation, and the two inactive metabolites are excreted in the feces and bile. No dosage adjustment is required in patients with renal impairment; however, a dose reduction to 35 mg following the 70 mg loading dose is recommended for patients with moderate hepatic impairment. Caspofungin is not cleared by hemodialysis.

INTERACTIONS

It has few documented interactions. In some patients, administration with ciclosporin (cyclosporin) results in transaminase elevations two to three times the upper limit of normal, resolving when both drugs are discontinued. Co-administration of these drugs is not recommended unless the expected benefit outweighs the risk. Caspofungin interacts with tacrolimus, reducing its serum concentrations. Tacrolimus concentrations should be monitored and the dosage adjusted if required. Caspofungin concentrations are reduced when it is given with rifampicin.

TOXICITY AND SIDE EFFECTS

Occasional histamine-mediated infusion-related reactions, injection site reactions and transient abnormalities of liver enzymes have been reported. Rare cases of significant hepatic dysfunction, hepatitis or worsening liver failure have also been described.

CLINICAL USE

Candidemia and certain invasive forms of candidosis
Esophageal candidosis
Invasive aspergillosis unresponsive to other antifungal drugs
Empirical treatment of presumed fungal infections in febrile neutropenic patients

Preparations and dosage

Proprietary name: Cancidas.

Preparation: i.v. infusion.

Dosage: Adult, i.v., 70 mg on the first day, then 50 mg per day; treatment is continued according to response.

Widely available.

Further information

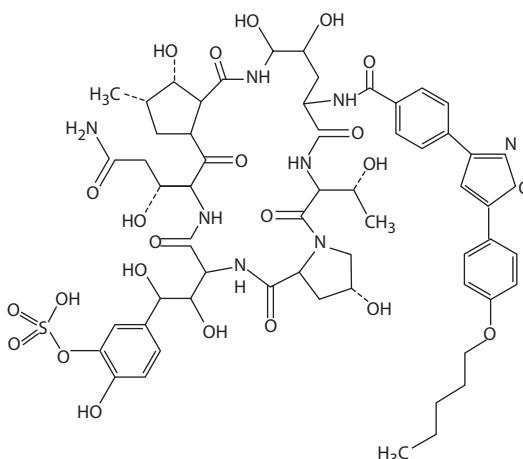

Hope WW, Shoham S, Walsh TJ. The pharmacology and clinical use of caspofungin. *Expert Opin Drug Metab Toxicol*. 2007;3:263–274.

McCormack PL, Perry CM. Caspofungin: a review of its use in the treatment of fungal infections. *Drugs*. 2005;65:2049–2068.

MICAFUNGIN

Molecular weight: 1292.26.

A semisynthetic lipopeptide derived from a fermentation product of *Coleophoma empetri*. Formulated as the monosodium salt for intravenous infusion.

ANTIFUNGAL ACTIVITY

It is active against *Aspergillus* spp., *Candida* spp. and the cyst form of *Pn. jirovecii*. Resistance has rarely been reported.

PHARMACOKINETICS

C_{\max} 50 mg 1-h infusion	c. 5 mg/L 1 h post infusion
Plasma half-life	11–15 h
Volume of distribution	0.4 L/kg
Plasma protein binding	99%

Blood concentrations increase in proportion to dosage. Unlike anidulafungin and caspofungin, a loading dose is not required.

Distribution

The drug is widely distributed, the highest concentrations being found in the liver. Levels in the CSF and urine are negligible.

Metabolism and excretion

It is metabolized by the liver and the three inactive metabolites are excreted in the feces (70%). Less than 1% of a dose is eliminated as unchanged drug in the urine. No dosage adjustment is required in patients with severe renal impairment or mild to moderate hepatic impairment. The effect of severe hepatic impairment on micafungin pharmacokinetics has not been studied. Micafungin is not cleared by hemodialysis.

INTERACTIONS

Micafungin inhibits the cytochrome P₄₅₀ CYP-3A4 metabolism of sirolimus and nifedipine, and may increase blood concentrations of these drugs. Patients receiving concurrent treatment with these drugs should be monitored for signs of toxicity, and the dosage of sirolimus or nifedipine should be reduced if necessary.

TOXICITY AND SIDE EFFECTS

Occasional histamine-mediated infusion-related reactions, injection site reactions and transient abnormalities of liver enzymes have been reported. Isolated cases of significant hepatic or renal dysfunction, hepatitis, or liver or renal failure have also been described.

CLINICAL USE

Candidemia and certain invasive forms of candidosis

Esophageal candidosis

Prophylaxis of *Candida* infections in hematopoietic stem cell transplant (HSCT) recipients

Preparations and dosage

Proprietary name: Mycamine.

Preparation: i.v. infusion.

Dosage: Adult, i.v., invasive candidosis, 100 mg per day; treatment is continued according to response. Esophageal candidosis, 150 mg per day. Prevention of *Candida* infections in HSCT recipients, 50 mg per day. Widely available.

POLYENES

Around 100 polyene antibiotics have been described, but few have been developed for clinical use. They are large amphiphilic molecules: closed macrolide rings with a variable number of hydroxyl groups along the hydrophilic side, and along the hydrophobic side a variable number of conjugated double bonds to which they owe the name ‘polyene’; e.g. tetraene (four double bonds), heptaene (seven double bonds). They bind to sterols in the membranes of susceptible fungal cells (p. 19), causing impairment of membrane function and cell death. Polyenes can also damage fungal cells through a cascade of oxidative reactions linked to lipoperoxidation of the cell membrane. Non-selective binding of polyenes to cholesterol in mammalian cell membranes may account for some of the toxic side effects.

The most important member of the group is amphotericin B, a heptaene that is administered parenterally for the treatment of systemic fungal infections.

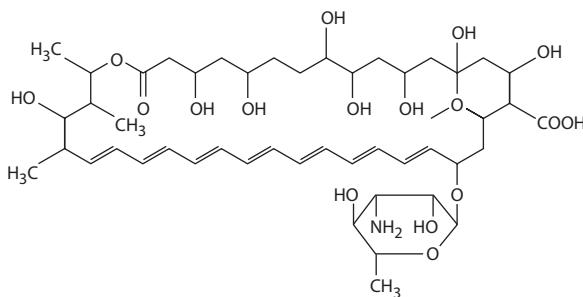

Further information

Sugar AM. The polyene macrolide antifungal drugs. In: Peterson PK, Verhoef J, eds. *The Antimicrobial Agents Annual*. Vol. 1. Amsterdam: Elsevier; 1986:229–244.

AMPHOTERICIN B

Molecular weight: 924.1.

A fermentation product of *Streptomyces nodosus* available for intravenous infusion or oral administration. The traditional micellar suspension formulation is often associated with serious toxic effects, in particular renal damage, and this has stimulated efforts to develop chemical modifications and new formulations. Three lipid-associated formulations have been licensed for use (Table 32.1):

- Liposomal amphotericin B, in which the drug is encapsulated in phospholipid-containing liposomes.
- Amphotericin B colloidal dispersion, in which the drug is packaged into small lipid disks containing cholesterol sulfate.
- Amphotericin B lipid complex, in which the drug is complexed with phospholipids to produce ribbon-like structures.

These formulations are less toxic than the micellar suspension because of their altered pharmacological distribution, allowing higher doses to be given.

ANTIFUNGAL ACTIVITY

The spectrum includes most fungi that cause human disease: *A. fumigatus*, *Blast. dermatitidis*, *Candida* spp., *Coccidioides* spp., *Cryptococcus* spp., *Hist. capsulatum*, *Paracocc. brasiliensis* and *Spor. schenckii*. Dermatophytes, *Fusarium* spp. and some other *Aspergillus* spp., including *A. terreus* and *A. flavus*, may be less susceptible, while *Scedosporium* spp., *Trichosporon asahii* (formerly *T. beigelii*) and some fungi that cause mucormycosis are resistant.

It also exhibits useful activity against *Prototheca* spp., some protozoa, including *Leishmania* spp., and the genera *Naegleria* and *Hartmanella*.

ACQUIRED RESISTANCE

Resistant strains of *C. tropicalis*, *C. lusitaniae*, *C. krusei* and *C. guilliermondii*, with alterations in the cell membrane, including reduced amounts of ergosterol, have occasionally been isolated after prolonged treatment, particularly of infections in partially protected sites, such as the vegetations of endocarditis. Significant resistance in yeasts, including *C. albicans* and *C. glabrata*, has been reported in isolates from cancer patients with prolonged neutropenia. In some cases resistant strains have caused disseminated infection. There are a few reports of amphotericin-resistant strains of *Cryp. neoformans* recovered from AIDS patients with relapsed meningitis.

PHARMACOKINETICS

Less than 10% of a parenteral dose of the conventional micellar suspension of amphotericin B remains in the blood 12 h after administration. The remainder is thought to bind to tissue cell membranes, the highest concentrations being found in the liver (up to 40% of the dose). Levels in the CSF are less than 5% of the simultaneous blood concentration. The conventional formulation has a terminal half-life of about 2 weeks. About 75% of a given dose is excreted unchanged in the urine and feces. No metabolites have been identified.

The pharmacokinetics of lipid-based formulations are quite diverse (Table 32.1). Maximal serum concentrations of the liposomal formulation are much higher than those of the conventional micellar formulation, while levels of colloidal dispersion and lipid complex formulations are lower due to more rapid distribution of the drug to tissue. Administration of lipid-associated formulations of amphotericin B results in much higher drug concentrations in the liver and spleen than are achieved with the conventional formulation. Renal concentrations of the drug are much lower and its nephrotoxic side effects are greatly reduced.

Table 32.1 Pharmacokinetics of amphotericin B formulations

	Amphotericin B	Amphotericin B lipid complex	Amphotericin B colloidal dispersion	Liposomal amphotericin B
Dose	0.5 mg/kg	5 mg/kg for 1 week	5 mg/kg for 1 week	5 mg/kg for 1 week
C_{max}	1.2 mg/L	1.7 mg/L	3.1 mg/L	83 mg/L
Plasma half-life	91 h	173 h	28.5 h	6.8 h
Volume of distribution	3–5 L/kg	131 L/kg	4.3 L/kg	0.1 L/kg
Plasma protein binding	>95%	>95%	>95%	>95%

Blood concentrations are unchanged in hepatic or renal failure. Hemodialysis does not influence serum concentrations unless the patient is hyperlipidemic, in which case there is some drug loss due to adherence to the dialysis membrane.

INTERACTIONS

Amphotericin B can augment the nephrotoxic effects of other drugs, such as aminoglycoside antibiotics, ciclosporin, interleukin-2 and certain antineoplastic agents. It can also augment corticosteroid-induced potassium loss. Reducing the risk of amphotericin B-induced nephrotoxicity is central to avoiding toxicity due to delayed clearance of other agents.

TOXICITY AND SIDE EFFECTS

Common side effects of conventional amphotericin B include hypotension, fever, rigors, chills, headache, backache, nausea, vomiting, anorexia, anemia, disturbances in renal function (including hypokalemia and hypomagnesemia), renal toxicity, abnormal liver function (discontinue treatment), rash and anaphylactoid reactions. Risk factors for nephrotoxicity include average daily dose, concomitant treatment with other nephrotoxic drugs and elevated baseline serum creatinine.

The lipid-associated formulations all lower the risk of amphotericin B-induced renal failure. However, infusion-related side effects, such as fever, rigors and hypotension, develop in up to 40% of patients treated with the colloidal dispersion, and hypoxic events also occur; as a result this formulation is not widely used. In contrast, infusion-related reactions are uncommon with liposomal amphotericin B or the lipid complex. Patients who have developed renal impairment while receiving the conventional formulation of amphotericin B have improved or stabilized when lipid-associated amphotericin B was substituted, even when the dose was increased. Renal function should be measured at regular intervals, particularly in patients receiving other nephrotoxic drugs.

CLINICAL USE

Aspergillosis

Systemic mycoses with dimorphic fungi (blastomycosis, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, penicilliosis)

Candidosis

Cryptococcosis

Hyalohyphomycosis, mucormycosis, phaeohyphomycosis

Visceral leishmaniasis

Preparations and dosage

Proprietary names: Abelcet (lipid complex), AmBisome (liposomal), Amphocil (colloidal dispersion), Amphocin, Amphotec (colloidal dispersion), Fungilin, Fungizone.

Preparations: Tablets, lozenges, oral suspension, i.v. infusion.

Dosage: Adults, oral, 100–200 mg every 6 h. Lozenges, 1–2, every 6 h. Infants and children, 1 mL of suspension every 6 h. Intravenous infusion, adults and children, 0.25 mg/kg per day, gradually increasing to 1 mg/kg per day. In severely ill patients the dose can be increased to 1.5 mg/kg per day. Lipid formulations, adults and children, i.v. infusion, 1–5 mg/kg per day.

Widely available.

OTHER POLYENES

Other clinically useful polyenes, which in general resemble amphotericin B in antifungal action and spectrum of activity, are mostly used only topically.

- **Mepartericin;** methyl partricin (heptaene). A product of *Str. aureofaciens* used for intravenous treatment of deep candidosis and for the topical treatment of vaginal candidosis. It offers no conspicuous advantages over amphotericin B as a systemic antifungal.
- **Natamycin;** pimaricin (tetraene). A product of *Str. chatanoogensis* or *Str. natalensis* used for the topical treatment of ophthalmic and bronchopulmonary infections and vaginal candidosis.
- **Nystatin** (tetraene). A product of *Str. albulus* or *Str. noursei* used for the topical treatment of oral, esophageal, gastrointestinal and genital candidosis, and gastrointestinal prophylaxis.

Preparations and dosages

Mepartericin

Preparations: Tablets, vaginal preparations, topical cream, oral suspension.

Available in continental Europe; not available in the UK.

Natamycin

Preparations: Oral suspension, ophthalmic suspension, cream, vaginal preparations, lozenges.

Dosage: Adults, oral, tablets: oral candidiasis 10 mg every 4–6 h; intestinal candidiasis 100 mg every 4–6 h.

Available in continental Europe; not available in the UK.

Nystatin

Proprietary names: Mycostatin, Nystan.

Preparations: Tablets, pastilles, oral suspension, vaginal and topical preparations.

Dosage: Adults, oral: oral candidiasis 100 000 units every 6 h; intestinal candidiasis 500 000 units every 6 h. Prophylaxis: adults, 1 million units per day; children, 100 000 units every 6 h; neonates, 100 000 units per day as a single dose. Vaginal pessaries, 1–2 at night for at least 14 nights.

Widely available.

PHARMACOKINETICS

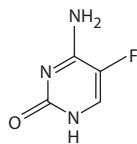

Oral absorption	Complete
C_{\max} 25 mg/kg 6-hourly oral	70–80 mg/L after 1–2 h
Plasma half-life	3–6 h
Volume of distribution	0.7–1 L/kg
Plasma protein binding	c. 12%

Absorption is slower in persons with impaired renal function, but peak concentrations are higher. Levels in the CSF are around 75% of the simultaneous serum concentration. More than 90% of a dose of flucytosine is excreted in the urine in unchanged form. The serum half-life is much longer in renal failure, necessitating modification of the dosage regimen: for patients with a creatinine clearance below 40 mL/min the dosage interval should be doubled to 12 h; in severe renal failure the dosage interval should be further increased to once daily or less, based on frequent serum drug concentration measurements.

OTHER SYSTEMIC AGENTS

FLUCYTOSINE

5-Fluorocytosine. Molecular weight: 129.1.

A synthetic fluorinated pyrimidine available for intravenous infusion or oral administration.

ANTIFUNGAL ACTIVITY

The spectrum of activity is restricted to *Candida* spp., *Cryptococcus* spp. and some fungi causing chromoblastomycosis.

ACQUIRED RESISTANCE

About 2–3 of *Candida* spp. isolates (more in some centers) are resistant before treatment starts, and resistance may develop during treatment. The most common cause of resistance appears to be loss of the enzyme uridine monophosphate pyrophosphorylase.

INTERACTIONS

Cytosine arabinoside has been reported to inactivate flucytosine. Drugs that are known to be myelosuppressive, such as zidovudine and ganciclovir, should be used with caution in individuals receiving flucytosine.

TOXICITY AND SIDE EFFECTS

Nausea, vomiting, abdominal pain and diarrhea are common. Serious side effects include myelosuppression and hepatic toxicity; they occur more frequently when serum concentrations exceed 100 mg/L.

The nephrotoxic effects of amphotericin B can result in elevated blood concentrations of flucytosine, and levels of the latter drug should be monitored when these compounds are administered together.

CLINICAL USE

Candidosis (in combination with amphotericin B or fluconazole)
Cryptococcosis (in combination with amphotericin B or fluconazole)

Monitoring of flucytosine concentrations is desirable in all patients, and mandatory in those with renal impairment.

Preparations and dosage

Proprietary names: Alcbon, Ancbon, Ancotil.

Preparations: Tablets, capsules, i.v. infusion.

Dosage: Adults, oral, i.v., 200 mg/kg per day in four divided doses. For extremely sensitive organisms, 50–150 mg/kg per day in four divided doses may be sufficient.

Widely available.

INTERACTIONS

Griseofulvin can diminish the anticoagulant effect of warfarin. Its absorption is reduced in persons receiving concomitant treatment with phenobarbital.

TOXICITY AND SIDE EFFECTS

Adverse reactions occur in about 15% of patients and include headache, nausea, vomiting, rashes and photosensitivity.

CLINICAL USE

Dermatophyte infections of hair, skin and nail

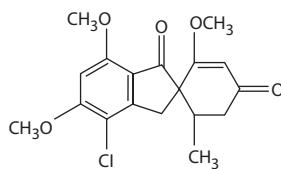

Further information

Francis P, Walsh TJ. Evolving role of flucytosine in immunocompromised patients: new insights into safety, pharmacokinetics, and antifungal therapy. *Clin Infect Dis.* 1992;15:1003–1018.

Vermes A, Guchelaar HJ, Dankert J. Flucytosine: a review of its pharmacology, clinical indications, pharmacokinetics, toxicity and drug interactions. *J Antimicrob Chemother.* 2000;46:171–179.

GRISEOFULVIN

Molecular weight: 352.8.

A fermentation product of various species of *Penicillium*, including *Pen. griseofulvum*. Available as fine-particle or ultra-fine-particle formulations for oral use.

ANTIFUNGAL ACTIVITY

The spectrum of useful activity is restricted to dermatophytes causing skin, nail and hair infections (*Epidermophyton*, *Microsporum* and *Trichophyton* spp.). Resistance has seldom been reported.

PHARMACOKINETICS

Absorption from the gastrointestinal tract is dependent on drug formulation. Administration with a high-fat meal will increase the rate and extent of absorption, but individuals tend to achieve consistently high or low blood concentrations. It appears in the stratum corneum within 4–8 h as a result of secretion in perspiration. However, levels begin to fall soon after the drug is discontinued, and within 48–72 h it can no longer be detected. It is metabolized in the liver, the metabolites being excreted in the urine. The elimination half-life is 9–21 h.

Preparations and dosage

Proprietary names: Fulcin, Fulvicin, Grifulvin V, Grisactin, Grisovin, Grisol.

Preparations: Tablets, capsules, oral suspension.

Dosage: Adults, oral, 500 mg per day as a single or divided dose. In severe infections the dose may be doubled, reducing when response occurs. Children, 10 mg/kg per day in divided doses, or as a single dose.

Widely available.

Bennett ML, Fleischer AB, Loveless JW, et al. Oral griseofulvin remains the treatment of choice for tinea capitis in children. *Pediatr Dermatol.* 2000;17:304–309.

OTHER TOPICAL AGENTS

There is a large and miscellaneous group of topical antifungal agents, all of which are effective treatments for superficial mycoses. They include the following:

- **Amorolfine hydrochloride.** A synthetic morpholine derivative that inhibits ergosterol biosynthesis. It is used for the treatment of tinea corporis, tinea cruris, tinea pedis and onychomycosis.
- **Butenafine hydrochloride.** A synthetic benzylamine derivative which acts as an ergosterol biosynthesis inhibitor. It is used for the treatment of tinea corporis, tinea cruris and tinea pedis.
- **Ciclopirox.** A synthetic pyridinone used in onychomycosis and as the olamine salt in tinea corporis, tinea cruris, tinea pedis, cutaneous candidosis and pityriasis versicolor.
- **Haloprogin.** A halogenated phenolic which is effective in tinea corporis, tinea cruris, tinea pedis and pityriasis versicolor.
- **Tolnaftate.** A thiocarbamate used in tinea cruris and tinea pedis.

Preparations and dosages

Amorolfine hydrochloride

Proprietary name: Loceryl.

Preparations: Nail solution, cream.

Dosage: For fungal skin infections, apply once daily for at least 2–3 weeks (up to 6 weeks for tinea pedis). For nail infections, apply solution 1–2 times weekly; treat fingernails for 6 months, toenails for 9–12 months.

Widely available.

Butenafine hydrochloride

Proprietary name: Mentax.

Preparation: Topical.

Dosage: For fungal skin infections dosage and duration of treatment varies according to condition.

Widely available.

Ciclopirox

Proprietary names: Loprox, Penlac.

Preparations: Nail solution, cream, powder.

Dosage: For fungal skin infections, apply twice daily for at least 2–4 weeks. For nail infections, apply solution once daily for at least 6 months.

Widely available.

Halopropin

Proprietary name: Halotex.

Preparation: Topical.

Dosage: For fungal skin infections dosage and duration of treatment varies according to condition.

Widely available.

Tolnaftate

Proprietary names: Aftate, Mycil, Tinactin.

Preparation: Topical.

Dosage: For fungal skin infections dosage and duration of treatment varies according to condition.

Widely available.

CHAPTER**33**

Antimycobacterial agents

John M. Grange

The mycobacteria causing human disease, and therefore requiring treatment by antibacterial agents, are divisible into three groups: the tuberculosis complex (principally *Mycobacterium tuberculosis*, *M. bovis* and *M. africanum* in humans); the leprosy bacillus (*M. leprae*); and various environmental saprophytes that occasionally cause human disease. Patients with AIDS are particularly likely to develop disease due to the latter species, notably the *Mycobacterium avium* complex (MAC), although the incidence of such infection has declined in regions where antiretroviral therapy is widely available.

Antimycobacterial agents include natural and semisynthetic antibiotics and synthetic agents. Some, such as rifampicin (rifampin; Ch. 27) and streptomycin (Ch. 12), are active against a wide range of bacteria, although their use is mostly restricted to the treatment of mycobacterial disease, and some are synthetic agents, mostly with activity only against mycobacteria. The four first-line drugs used in modern short-course antituberculosis regimens (Ch. 58) are rifampicin, isoniazid, pyrazinamide and ethambutol, with the latter three being synthetic agents.

Resistance to one or more of these agents requires the use of second-line drugs of which there are six classes – aminoglycosides (streptomycin, kanamycin, amikacin), cyclic peptides (capreomycin and, rarely, viomycin), thioamines (ethionamide, prothionamide), fluoroquinolones (Ch. 26), cycloserine and *p*-aminosalicylic acid.

As a result of the increasing prevalence of tuberculosis resistant to many or most of the currently available antituberculosis agents, there is a pressing need for new drugs but there was little financial incentive for the pharmaceutical industry to meet this need. This serious deficit has been addressed by the establishment of the Global Alliance for TB Drug Development by various agencies, especially the World Health Organization (WHO), and private foundations. This Alliance has facilitated the development and clinical evaluation of several new agents, the progress of which is shown on the Alliance website, <http://www.tballiance.org>. As at April 2010 PA-824, a nitroimidazole (Ch. 24), moxifloxacin, a fluoroquinolone (Ch. 26), and TMC 207, a diarylquinolone, were in clinical trial, and several other agents were undergoing preclinical evaluation. In addition, the sequencing of the entire genome of *M. tuberculosis* and innovations in computer modeling have paved the way to the

development of 'designer' agents based on unique mycobacterial structures and metabolic pathways. There is also growing interest in the use of adjunct immunotherapy to improve the treatment outcome in tuberculosis, particularly in drug-resistant cases.

The principal drugs for the treatment of leprosy (Ch. 57) are dapsone, rifampicin and clofazimine, with prothionamide for patients who will not take clofazimine. An alternative and increasingly used regimen is based on rifampicin, ofloxacin and minocycline.

Treatment of opportunist disease due to environmental mycobacteria poses serious problems as many patients have underlying complicating conditions, notably various causes of immunosuppression. Drugs and regimens (see below) that are active in vitro are often ineffective clinically against these mycobacteria and novel approaches to treatment are required.

ANTIMICROBIAL ACTIVITY

The action of antimycobacterial agents *in vivo* depends on the population dynamics of the mycobacteria within the lesions. In the case of tuberculosis, some bacilli replicate freely in the walls of well-oxygenated cavities, some replicate more slowly in acidic and anoxic tissue and within macrophages and a few are in a near-dormant 'persister' state. Isoniazid exerts a powerful and rapid bactericidal activity against the freely replicating bacilli and kills the great majority of such bacilli, with a substantial reduction of infectiousness, within a few days of commencing treatment. It has little or no effect against the near-dormant bacilli, which are killed by rifampicin. The slowly replicating bacilli in acidic, often anoxic, environments are killed by pyrazinamide, which is active only at low pH. Thus a distinction may be drawn between agents that are bactericidal in vitro and those that actually 'sterilize' lesions *in vivo*. Accordingly, the most widely used short-course antituberculosis regimen is based on a 2-month intensive phase of treatment with isoniazid, rifampicin, pyrazinamide and ethambutol, during which all except a few persisters are killed, and a 4-month continuation phase of rifampicin (which kills persisters during shorter bursts of metabolic activity) and

isoniazid to kill any rifampicin-resistant mutants that might commence replication (Ch. 58). In both tuberculosis and leprosy, the great majority of bacilli are killed during the first few weeks of therapy; prolonged therapy, with its associated problems of cost, compliance and the need for supervision, is required to kill a few remaining metabolically inactive persisters and thus prevent relapse.

In the absence of acquired drug resistance, strains of *M. tuberculosis* and related members of the tuberculosis complex are very similar in their susceptibility to the antituberculosis drugs, although strains of *M. bovis* and some strains of *M. africanum* are naturally resistant to pyrazinamide. Environmental mycobacteria show very variable resistance to antituberculosis drugs and other antimicrobial agents, and in vitro susceptibility tests do not accurately reflect clinical responses.

DRUG RESISTANCE

Mutation to drug resistance occurs at a low but constant rate in all mycobacterial populations and such mutants (Table 33.1) are readily selected if the patient is treated with a single drug. Successful therapy thus requires the use of at least two drugs to which the strain is susceptible. An exception is the use of a single drug, usually isoniazid, to prevent the emergence of active tuberculosis in infected but healthy persons who are assumed to have very small numbers of bacilli in their tissues. Emergence of drug resistance is uncommon in patients receiving a fully supervised course of modern short-course chemotherapy based on drugs of known quality.

Unfortunately, poor prescribing habits, unavailability of drugs, inadvertent use of time-expired or even counterfeit

drugs, poor supervision of therapy and unregulated ‘over-the-counter’ sales of drugs have led to the emergence of drug-resistant tubercle bacilli in many countries. Even fixed dose combination formulations occasionally lead to the development of single- or multiple-drug resistance if taken irregularly.

Tuberculosis resistant to rifampicin and isoniazid, with or without additional resistances, is termed multidrug-resistant (MDR) tuberculosis. Extensive drug resistance (XDR) has arisen in many countries and is variously defined as MDR with additional resistance to three or more of the six classes of second-line drugs, or to fluoroquinolones and at least one injectable drug (aminoglycosides and cyclic peptides). The exact definition is an academic one as, despite the establishment of regional and supraregional reference laboratories, few countries have adequate facilities for conducting drug susceptibility tests.

Drug resistance may develop in an inadequately treated patient (acquired or secondary resistance) or a person may become infected with a resistant strain (initial or primary resistance). Likewise, primary and acquired drug resistance is encountered in leprosy and the WHO has advised that all cases of leprosy should be treated by combination therapy.

The WHO recommends that periodic surveys of primary drug resistance should be undertaken as these give a good measure of the efficiency of control programs. The extent to which such surveys are carried out varies considerably from country to country: whereas in developed nations drug susceptibility tests are carried out on most or all clinical isolates of *M. tuberculosis*, such testing is often carried out only sporadically, and perhaps on unrepresentative isolates, in many developing countries.

Table 33.1 Targets of antimycobacterial agents and genes determining resistance^a

Agent	Target	Gene(s) encoding target(s) or in which mutations conferring resistance occur
p-Aminosalicylic acid	Folic acid metabolism	Unknown
Clofazimine	Uncertain	Unknown
Cyclic peptides (capreomycin and viomycin)	50S or 30S ribosomal subunit	vicA (50S) or vicB (30S)
Cycloserine	Peptidoglycan synthesis	alrA
Dapsone	Folic acid synthesis	folP1
Ethambutol	Cell wall arabinogalactan synthesis	embA, embB and embC
Isoniazid	Mycolic acid synthesis	katG, inhA gene or its promoter region, intergenic region of the oxyR-ahpC locus
Pyrazinamide	? Bacterial membrane energetics and transport	pncA
Thioacetazone (amithiozone)	Synthesis of cyclopropane rings in mycolic acid	Genes coding for cyclopropane mycolic acid synthetase enzymes
Thioamines (ethionamide and prothionamide)	Mycolic acid synthesis	inhA

^aFor details on aminoglycosides and rifampicin, see Chapters 12 and 27, respectively.

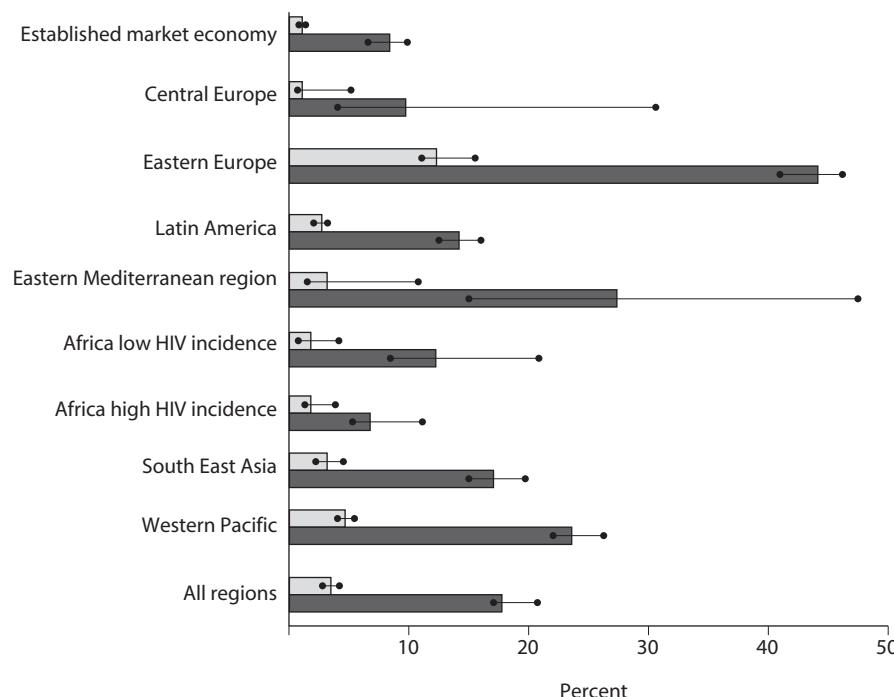

Fig. 33.1 Estimates, as a percentage, of multidrug-resistant tuberculosis among new (upper bar) and previously treated (lower bar) cases by World Health Organization epidemiological regions. Black bars show the 95% confidence ranges.

In four global surveys of resistance undertaken between 1994 and 2007, the global prevalence of various patterns of drug resistance varied enormously from region to region, with particularly high levels in certain regions. In 2008 the reported prevalence of MDR TB was over 5% in 14 regions: Armenia, Azerbaijan, the Baltic States (Estonia, Latvia, Lithuania), two provinces of China, Georgia, Moldova, three districts (Oblasts) of Russia, Ukraine and Uzbekistan. The incidence of MDR TB in new and previously treated cases in the WHO epidemiological regions is shown in Figure 33.1. The precise incidence of XDR tuberculosis is unknown as resistance to the full range of antituberculosis agents is determined in a minority of laboratories worldwide, but in June 2008 cases had been reported in 49 countries. In 2008, there were an estimated 490 000 cases of MDR TB and 40 000 cases of XDR TB.

PHARMACOKINETICS

With the exception of streptomycin, other aminoglycosides and the cyclic peptides, all the antimycobacterial agents currently in use are absorbed adequately when given orally. They are distributed to all tissues and organs and adequate amounts of the first-line antituberculosis agents cross the blood–brain barrier. Thus, in principle, standard regimens and doses are suitable for treatment of all forms of tuberculosis, although many clinicians prescribe more prolonged courses of therapy for extrapulmonary tuberculosis, particularly tuberculous meningitis, and for cases of HIV-related tuberculosis. Rifampicin,

isoniazid, pyrazinamide, ethionamide and prothionamide are either eliminated in the bile or metabolized, and may therefore be given in standard doses to patients with impaired renal function. Ethambutol and aminoglycosides, which are eliminated predominantly or entirely by the kidney, should be avoided, if possible, in patients with impaired renal function.

Only small amounts of isoniazid and even smaller amounts of the other antituberculosis drugs enter the milk, so breast feeding is not contraindicated.

TOXICITY AND SIDE EFFECTS

Unwanted side effects occur with all antituberculosis agents, but those caused by the first-line drugs (rifampicin, isoniazid, pyrazinamide, ethambutol) are less frequent and severe than those due to the older agents (streptomycin, *p*-aminosalicylic acid, thioacetazone). Side effects are particularly likely to occur in HIV-positive patients, who should never be given thioacetazone as fatal exfoliative dermatitis may occur (specific toxicities are discussed under the individual drugs). A transient and clinically insignificant rise in serum hepatic enzyme levels commonly occurs during the first few weeks of therapy and, unless the patient is known to have liver disease, routine assay of these enzymes is generally regarded as unnecessary. Clinically evident hepatitis occurs in about 1% of patients and the incidence increases with age, although it usually resolves rapidly when therapy ends; usually therapy with the same drugs can be continued. More generalized reactions, with rashes, influenza-like symptoms and sometimes lymphadenopathy and hepatic

enlargement, with or without jaundice, may occur in the first 2 months of therapy. Therapy must be stopped, the responsible drug identified by giving small challenge doses sequentially, and treatment resumed without that drug.

Interactions between the antimycobacterial drugs themselves have been described: pyrazinamide and ethionamide may increase serum concentrations of isoniazid while pyrazinamide may decrease that of rifampicin, but these effects are of no known clinical significance. More significant interactions occur between the antimycobacterial agents and drugs used for other purposes, particularly antiretroviral drugs (Chs. 36 and 43). Most recorded drug interactions involve rifampicin and quinolones but some interactions with isoniazid have been described, especially in slow acetylators (p. 390).

CLINICAL USE

Definite recommendations for the treatment of tuberculosis and leprosy have been made by the WHO (Chs 57 and 58). These regimens are also used for treating human tuberculosis due to *M. bovis* and for the rare cases of disseminated disease due to the vaccine strain bacille Calmette-Guérin (BCG), although both are naturally resistant to pyrazinamide.

Isoniazid preventive therapy has a controversial history, but the HIV pandemic, leading to a greatly enhanced risk of tuberculosis, has led to re-evaluation of its protective role. It can be safely used in HIV-infected persons as long as they do not have active tuberculosis and it prevents the risk of the latter by 33–67% for up to 4 years. It is recommended for HIV-infected persons living in regions with a prevalence of latent tuberculosis of over 30% and for all those with known latent disease or exposure to a case of infectious tuberculosis. Where available, a combination of isoniazid and antiretroviral therapy provides even greater protection.

Treatment of opportunist mycobacterial disease continues to pose problems, with a high failure rate, often due to co-existent HIV infection or other forms of immunosuppression. Disease caused by slowly growing mycobacteria, principally the *Mycobacterium avium* complex, *M. kansasi*, *M. xenopi* and *M. malmoense*, is usually treated with rifampicin (or rifabutin) and ethambutol, together with clarithromycin or a fluoroquinolone.

In the absence of clinical trials, therapy of disease due to the rapidly growing mycobacteria, principally *M. abscessus*, *M. chelonae* and *M. fortuitum*, is empirical. Limited infections such as post-injection abscesses respond to co-trimoxazole together with erythromycin. More serious infections have responded to cefoxitin with amikacin. The outcome of therapy is, however, unpredictable. In-vitro drug susceptibility tests do not give an accurate indication of clinical response.

FORMULATIONS

Compliance with antituberculosis therapy is aided by use of fixed drug combination preparations and calendar

blister-packs. Several preparations containing rifampicin + isoniazid, rifampicin + isoniazid + pyrazinamide or all four of the first-line drugs are commercially available but only those approved by the WHO should be used as in some combinations the bioavailability of the component drugs, especially rifampicin, is inadequate.

CLOFAZIMINE

Molecular weight: 473.4.

One of a number of substituted iminophenazine dyes originally synthesized as potential antituberculosis agents. It is almost insoluble in water. It stimulates various phagocyte functions including release of free oxygen radicals, but it is not clear whether this contributes to its antimicrobial activity. It also has anti-inflammatory properties, attributed to its ability to inhibit certain patterns of intracellular T-cell receptor-mediated signaling, making it a useful drug for treating leprosy reactions and possibly other autoimmune processes.

ANTIMICROBIAL ACTIVITY

The mode of action is not fully understood. It has bacteriostatic and weak bactericidal activity against several species of mycobacteria and some species of *Actinomyces* and *Nocardia*. In-vitro minimum inhibitory concentrations (MICs) are: *M. tuberculosis* 0.5 mg/L and *M. leprae* (assayed in a mouse model) 0.1–1 mg/L, but these MICs have limited clinical relevance as clofazimine shows marked differences in accumulation in various tissues. Activity against *M. leprae* is demonstrable in humans only after 50 days of therapy. Clofazimine resistance, although reported, appears to be rare.

PHARMACOKINETICS

Clofazimine is well absorbed by the intestine and is taken up by adipose tissue and cells of the macrophage/monocyte series, including those in the intestinal wall. It has a very long half-life (variously estimated as 10–70 days) and is eliminated, mostly unchanged, in the urine and feces.

TOXICITY AND SIDE EFFECTS

Clofazimine is usually well tolerated, but some patients develop nausea, abdominal pain and diarrhea, relieved to some extent by taking the drug with a meal or glass of milk. Dose-related, reversible, skin discolouration is very common and is unacceptable to some patients. Discoloration of the hair, cornea, urine, sweat and tears also occurs. Infants born to mothers receiving clofazimine are reversibly pigmented at birth. Edema of the wall of the small intestine leading to subacute obstruction is

a rare but serious complication of prolonged high-dose therapy for leprosy reactions. Deposition of clofazimine in lymph nodes may interfere with lymphatic drainage, occasionally manifesting as edema of the feet.

CLINICAL USE

Multibacillary leprosy (in combination with other anti-leprosy drugs)
Erythema nodosum leprosum (anti-inflammatory activity)

Clofazimine has been suggested as a drug for treatment of MDR tuberculosis, although its efficacy is unproven. It has been used to treat *M. ulcerans* infection (Buruli ulcer) but with limited responses. Use in disease caused by mycobacteria of the *M. avium* complex is no longer recommended as more effective and less toxic alternative agents are available.

Preparations and dosage

Proprietary name: Lamprene.

Preparation: Capsules.

Dosage: Multibacillary forms of leprosy: adults, oral, 300 mg once a month, supervised, and 50 mg per day or 100 mg on alternate days self-administered. Erythema nodosum leprosum: 300 mg once a day for no longer than 3 months.

DAPSONE

Diaminodiphenyl sulphone (DDS). Molecular weight: 248.3.

The most effective of a number of sulfonamide derivatives to be tested against leprosy. The dry powder is very stable. It is only slightly soluble in water.

ANTIMICROBIAL ACTIVITY

Dapsone is active against many bacteria and some protozoa. Fully susceptible strains of *M. leprae* are inhibited by a little as 0.003 mg/L. It is predominantly bacteristatic. Resistance is associated with mutations in the *folP1* gene involved in the synthesis of *para*-aminobenzoic acid.

ACQUIRED RESISTANCE

Resistance to high levels is acquired by several sequential mutations. As a result of prolonged use of dapsone monotherapy, acquired resistance emerged in patients with multibacillary leprosy in many countries. Initial resistance also occurs in patients with both paucibacillary and multibacillary leprosy. Thus, leprosy should always be treated with multidrug regimens. Resistance of *M. leprae* to dapsone (and other anti-leprosy drugs) may now be determined by use of DNA microarrays.

PHARMACOKINETICS

Oral absorption	>90%
C_{max} 100 mg oral	c. 2 mg/L after 3–6 h
Plasma half-life	10–50 h
Plasma protein binding	c. 50%

It is slowly but almost completely absorbed from the intestine and widely distributed in the tissues, but selectively retained in skin, muscle, kidneys and liver. It is metabolized by *N*-oxidation and also by acetylation, which is subject to the same genetic polymorphism as isoniazid (p. 390). The elimination half-life is consequently very variable, but on standard therapy the trough levels are always well in excess of inhibitory concentrations. It is mostly excreted in the urine: in the unchanged form (20%), as *N*-oxidation products (30%) and as a range of other metabolites.

TOXICITY AND SIDE EFFECTS

Although usually well tolerated at standard doses, gastrointestinal upsets, anorexia, headaches, dizziness and insomnia may occur. Less frequent reactions include skin rashes, exfoliative dermatitis, photosensitivity, peripheral neuropathy (usually in non-leprosy patients), tinnitus, blurred vision, psychoses, hepatitis, nephrotic syndrome, systemic lupus erythematosus and generalized lymphadenopathy.

The term 'dapsone syndrome' is applied to a skin rash and fever occurring 2–8 weeks after starting therapy and sometimes accompanied by lymphadenopathy, hepatomegaly, jaundice and/or mononucleosis.

Blood disorders include anaemia, methemoglobinemia, sulfhemoglobinemia, hemolysis (notably in patients with glucose-6-phosphate dehydrogenase deficiency), mononucleosis, leukopenia and, rarely, agranulocytosis. Severe anaemia should be treated before patients receive dapsone.

The incidence of adverse reactions declined in the 1960s but reappeared around 1982 when multidrug therapy was introduced, and may represent an unexplained interaction with rifampicin.

CLINICAL USE

Leprosy (multidrug regimens)

Prophylaxis of malaria, treatment of chloroquine-resistant malaria (in combination with pyrimethamine)

Prophylaxis of toxoplasmosis (in combination with pyrimethamine)

Prophylaxis (monotherapy) and treatment (in combination with trimethoprim) of *Pneumocystis jirovecii* pneumonia

Dermatitis herpetiformis and related skin disorders

Preparations and dosage

Preparation: Tablets.

Dosage: For all forms of leprosy (in combination with other anti-leprosy drugs): Adults, 100 mg per day, children 1–2 mg/kg (maximum dose, 100 mg per day). Duration of treatment depends on type of leprosy and the other agents used.

ETHAMBUTOL

Hydroxymethylpropylethylene diamine. Molecular weight (dihydrochloride): 277.2.

A synthetic ethylenediamine derivative formulated as the dihydrochloride for oral administration. The dry powder is very soluble and stable.

ANTIMICROBIAL ACTIVITY

Ethambutol is active against several species of mycobacteria and nocardiae. MICs on solid media are: *M. tuberculosis* 0.5–2 mg/L; *M. kansasii* 1–4 mg/L; other slowly growing mycobacteria 2–8 mg/L; rapidly growing pathogens 2–16 mg/L; *Nocardia* spp. 8–32 mg/L.

Resistance is uncommon and is a multistep process due to mutations in the *embA*, *embB* and *embC* gene cluster. A mutation in codon 306 of the *embB* gene predisposes to the development of resistance to a range of antituberculosis agents, possibly by affecting cell-wall permeability.

PHARMACOKINETICS

Oral absorption	c. 80%, but some patients absorb it poorly
C_{\max} 25 mg/kg oral	2–6 mg/L after 2–3 h
Plasma half-life	10–15 h
Volume of distribution	>3 L/kg
Plasma protein binding	20–30%

Absorption is impeded by aluminum hydroxide and alcohol. It is concentrated in the phagolysosomes of alveolar macrophages. It does not enter the cerebrospinal fluid (CSF) in health but CSF levels of 25–40% of the plasma concentration, with considerable variation between patients, are achieved in cases of tuberculous meningitis.

Various metabolites are produced, including dialdehyde, dicarboxylic acid and glucuronide derivatives. Around 50% is excreted unchanged in the urine, with an additional 10–15% as metabolites, and 20% is excreted unchanged in feces.

TOXICITY AND SIDE EFFECTS

The most important side effect is optic neuritis, which may be irreversible if treatment is not discontinued. This complication is rare if the higher dose (25 mg/kg) is given for no more than 2 months. National codes of practice for prevention of ocular toxicity should be adhered to; in particular, patients should be advised to stop therapy and seek medical advice if they notice any change in visual acuity, peripheral vision or

color perception, and the drug should not be given to young children and others unable to comply with this advice.

Other side effects include gastrointestinal upsets, peripheral neuritis, arthralgia, nephritis, myocarditis, hyperuricemia, dermal hypersensitivity and, rarely, thrombocytopenia and hepatotoxicity.

CLINICAL USE

Tuberculosis (initial intensive phase of short-course therapy)

Other mycobacterioses (*M. kansasii*, *M. xenopi*, *M. malmoense* and the *M. avium* complex) (with appropriate additional drugs)

Preparations and dosage

Proprietary name: Myambutol.

Preparations: Tablets (and syrup on special request).

Dosage: Adults and children, oral, 15–25 mg/kg per day for 2 months or 25–30 mg/kg three times a week or 45–50 mg/kg twice a week. If more prolonged therapy is indicated, the daily dose should not exceed 15 mg/kg; retreatment 25 mg/kg per day for the first 60 days.

Widely available.

ISONIAZID

Isonicotinic acid hydrazide (INH). Molecular weight: 137.1.

One of a number of nicotinamide analogs found to have anti-tuberculosis activity, following the observation that nicotinamide inhibited the replication of *M. tuberculosis*. It is soluble in water. The dry powder is stable if protected from light. It is a prodrug requiring oxidative activation by KatG, a mycobacterial catalase-peroxidase enzyme.

ANTIMICROBIAL ACTIVITY

Susceptibility to isoniazid is virtually restricted to the *M. tuberculosis* complex (MIC 0.01–0.2 mg/L). It is highly bactericidal against actively replicating *M. tuberculosis*. Other mycobacteria are resistant, except for some strains of *M. xenopi* (MIC 0.2 mg/L) and a few strains of *M. kansasii* (MIC 1 mg/L).

ACQUIRED RESISTANCE

Mutations in the *katG* gene, the *inhA* gene or its promoter region, and in the intergenic region of the *oxyR-ahpC* locus confer resistance to isoniazid (Table 33.1, p. 384). The relative proportions of such mutations vary geographically and are related to the distribution of the various lineages or superfamilies of *M. tuberculosis*.

Isoniazid resistance is the commonest form of drug resistance worldwide and the great majority of strains resistant to another agent are also resistant to isoniazid (see pp. 384–385).

PHARMACOKINETICS

Oral absorption	>95%
C _{max} 300 mg oral	3–5 mg/L after 1–2 h
Plasma half-life	0.5–1.5 h (rapid acetylators)
	2–4 h (slow acetylators)
Volume of distribution	0.6–0.8 L/kg
Plasma protein binding	Very low

Absorption and distribution

Isoniazid is almost completely absorbed from the gut and is well distributed. Absorption is impaired by aluminum hydroxide. Therapeutic concentrations are achieved in sputum and CSF. It crosses the placenta and is found in breast milk.

Metabolism

Isoniazid is extensively metabolized to a variety of pharmacologically inactive derivatives, predominantly by acetylation. As a result of genetic polymorphism, patients are divisible into rapid and slow acetylators. About 50% of Caucasians and Blacks, but 80–90% of Chinese and Japanese, are rapid acetylators. Acetylation status does not affect the efficacy of daily administered therapy. The rate of acetylation is reduced in chronic renal failure.

Excretion

Nearly all the dose is excreted in the urine within 24 h, as unchanged drug and metabolic products.

TOXICITY AND SIDE EFFECTS

Toxic effects are unusual on recommended doses and are more frequent in slow acetylators. Many side effects are neurological, including restlessness, insomnia, muscle twitching and difficulty in starting micturition. More serious but less common neurological side effects include peripheral neuropathy, optic neuritis, encephalopathy and a range of psychiatric disorders, including anxiety, depression and paranoia.

Neurotoxicity is usually preventable by giving pyridoxine (vitamin B₆) 10 mg per day. Pyridoxine should be given to patients with liver disease, pregnant women, alcoholics, renal dialysis patients, HIV-positive patients, the malnourished and the elderly. Encephalopathy, which has been reported in patients on renal dialysis, may not be prevented by, or respond to, pyridoxine, but usually resolves on withdrawal of isoniazid.

Isoniazid-related hepatitis occurs in about 1% of patients receiving standard short-course chemotherapy. The incidence is unaffected by acetylator status. It is more common in those aged over 35 years and preventive isoniazid monotherapy should be used with care in older people.

Less common side effects include arthralgia, a ‘flu’-like syndrome, hypersensitivity reactions with fever, rashes and, rarely, eosinophilia, sideroblastic anemia, pellagra (which responds to treatment with nicotinic acid) and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. It exacerbates acute porphyria and induces antinuclear antibodies, but overt systemic lupus erythematosus is rare.

DRUG INTERACTIONS

Isoniazid increases the plasma concentrations of phenytoin and carbamazepine, sometimes enough to cause toxicity; anti-epileptic therapy requires monitoring and adjustment of dosage as necessary. It enhances defluorination of the anesthetic enflurane. Drug interactions may be more pronounced in slow acetylators. Prednisolone reduces isoniazid levels in both slow and rapid acetylators, but the mechanism is unclear.

CLINICAL USE

Tuberculosis (intensive and continuation phases)

Prevention of primary tuberculosis in close contacts and reactivation disease in infected but healthy persons (monotherapy)

Preparations and dosage

Preparations: Tablets, elixir and injectable form.

Dosage: Adults, oral, 300 mg per day; children, 5–10 mg/kg per day (maximum dose, 300 mg per day). Neonates, 3–5 mg/kg per day (maximum dose, 10 mg/kg per day).

Widely available.

PYRAZINAMIDE

Pyrazinoic acid amide. Molecular weight: 123.1.

Like isoniazid, pyrazinamide is a synthetic nicotinamide analog, although its mode of action is quite distinct.

ANTIMICROBIAL ACTIVITY

It is principally active against actively metabolizing intracellular bacilli and those in acidic, anoxic inflammatory lesions. Activity against *M. tuberculosis* is highly pH dependent: at pH 5.6 the MIC is 8–16 mg/L, but it is almost inactive at neutral pH. Other mycobacterial species, including *M. bovis*, are resistant. Activity requires conversion to pyrazinoic acid by the mycobacterial enzyme pyrazinamidase, encoded for by the *pncA* gene, which is present in *M. tuberculosis* but not *M. bovis*. A few resistant strains lack mutations in *pncA*, indicating alternative mechanisms for resistance, including defects in transportation of the agent into the bacterial cell.

ACQUIRED RESISTANCE

Drug resistance is uncommon and cross-resistance to other antituberculosis agents does not occur. Susceptibility testing

is technically demanding as it requires very careful control of the pH of the medium, but molecular methods for detection of resistance-conferring mutations are available.

PHARMACOKINETICS

Oral absorption	>90%
C_{max} 20–22 mg/kg oral	10–50 mg/L after 2 h
Plasma half-life	c. 9 h
Plasma protein binding	c. 50%

It readily crosses the blood–brain barrier, achieving CSF concentrations similar to plasma levels. It is metabolized to pyrazinoic acid in the liver and oxidized to inactive metabolites, which are excreted in the urine, although about 70% of an oral dose is excreted unchanged.

TOXICITY AND SIDE EFFECTS

It is usually well tolerated. Moderate elevations of serum transaminases occur early in treatment. Severe hepatotoxicity is uncommon with standard dosage, except in patients with pre-existing liver disease.

Its principal metabolite, pyrazinoic acid, inhibits renal excretion of uric acid, but gout is extremely rare. An unrelated arthralgia, notably of the shoulders and responsive to analgesics, also occurs.

Other side effects include anorexia, nausea, mild flushing of the skin and photosensitization.

CLINICAL USE

Tuberculosis (a component of the early, intensive phase of short-course therapy)

Preparations and dosage

Proprietary names: Tebrazid, Zinamide.

Preparation: Tablets.

Dosage: Adult, oral, 2 g per day (>50 kg), 1.5 g per day (<50 kg); children, 25–35 mg/kg per day in 3–4 divided doses. Alternatively, adults and children, oral, 50 mg/kg three times a week or up to 75 mg/kg twice a week.

Widely available.

OTHER ANTIMYCOBACTERIAL AGENTS

PARA-AMINOSALICYLIC ACID

A salicylic acid derivative formulated as the dihydrate or sodium salt for oral administration. The activity is bacteriostatic and against extracellular bacteria. Inhibitory concentrations for *M. tuberculosis* are 0.5–10 mg/L, depending on the medium used and the inoculum size. It appears to act by interfering with folic acid metabolism. Resistance is very uncommon as the drug is rarely used.

It is well absorbed, achieving a plasma concentration of 70–80 mg/L 1–2 h after a 4 g oral dose. High tissue concentrations are achieved. The drug is rapidly acetylated in the liver and about 80% is excreted in the urine within 7 h, mostly in the acetylated form.

Adverse effects, leading to problems of compliance, occur in 10–30% of patients. Gastrointestinal effects, including abdominal pain, nausea, vomiting and diarrhea, are very common. It interferes with iodine metabolism in the thyroid, and prolonged therapy may lead to goiter, and less frequently to myxedema, which respond to thyroxine therapy. Allergic skin reactions are common. Less common side effects include blood dyscrasias, crystalluria, eosinophilic pneumonia, mal-absorption, encephalopathy and optic neuritis. It is used only in MDR tuberculosis.

Preparations and dosage

Preparations: Tablets, oral granules.

Dosage: Adults 200–300 mg/kg per day in 3 divided doses (maximum dose, 12 g per day). Children 150 mg/kg in 2–3 divided doses (maximum dose, 12 g per day).

Limited availability.

CAPREOMYCIN AND VIOMYCIN

These are naturally occurring cyclic peptide antibiotics synthesized by several *Streptomyces* species. Both are supplied as water-soluble sulfates. There is evidence that capreomycin is active against non-replicating cells of *M. tuberculosis*. They inhibit *M. tuberculosis*, including strains resistant to most other antituberculosis agents, at a concentration of 1.25–2.5 mg/L in liquid media. MICs are higher (8–16 mg/L) on egg media owing to protein binding. There is complete cross-resistance between capreomycin and viomycin and part cross-resistance of both to aminoglycosides.

They are not absorbed from the intestine and do not readily enter cells or the CSF. Intramuscular injection of 1 g gives peak serum concentrations of 20–50 mg/L. They are mostly excreted unchanged in the urine. No metabolites have been described.

Pain, induration and excessive bleeding may occur at the injection site. Cyclic peptides are ototoxic, affecting both cochlear and vestibular functions, and nephrotoxic, causing loss of K⁺, Ca²⁺ and Mg²⁺, leading to neuromuscular blockade. Anorexia, thirst and polyuria occasionally occur. These toxic effects are uncommon if the drugs are given two or three times weekly. Auditory and vestibular functions and serum potassium levels should be monitored before and regularly during therapy. Capreomycin is used for MDR tuberculosis (with other antituberculosis drugs). Viomycin is rarely, if ever, used (for the same purpose) and is of very limited availability. A derivative, enviomycin, is available in Japan and is said to be less ototoxic.

Preparations and dosage (capreomycin)

Proprietary name: Capastat.

Preparation: Injection.

Dosage: Adults, deep i.m. injection, 1 g per day (maximum dose, 20 mg/kg per day) for 2–4 months, then 1 g 2–3 times a week for the remainder of therapy. Children, 20 mg/kg per day (maximum dose, 1 g per day).

CYCLOSERINE

A fermentation product of *Strep. orchidaceus* and other related organisms now produced synthetically. Aqueous solutions are stable at pH 7.8 but the agent is rapidly destroyed in acid conditions. It is active against a wide range of Gram-negative and Gram-positive bacteria, including *Staphylococcus aureus*, streptococci, including *Enterococcus faecalis*, various enterobacteria, *Nocardia* and *Chlamydia* spp. *M. tuberculosis* is inhibited by 8–16 mg/L. Some environmental mycobacteria, including *M. avium*, are also susceptible. Its action is specifically antagonized by D-alanine, from which media for in-vitro tests should be free. Its use is limited by neurological and psychiatric side effects. Primary resistance in *M. tuberculosis* is rare and develops only slowly in patients treated with cycloserine alone. Its inclusion in combinations deters the development of resistance to other drugs. There is no cross-resistance with other therapeutic antibiotics.

It is well absorbed when given orally, achieving a concentration of c. 10 mg/L 3–4 h after a 250 mg dose. Doubling the dose approximately doubles the plasma level. Some accumulation occurs over the first 3 or 4 days of treatment. In children receiving 20 mg/kg orally, plasma levels of 20–35 mg/L have been found. It is widely distributed throughout the body fluids, including the CSF. About 50% is excreted unchanged in the glomerular filtrate over 24 h and 65–70% over the subsequent 2 days. The remainder is metabolized. There is no tubular secretion and no effect of probenecid. Cycloserine accumulates in renal failure, reaching toxic levels if dosage is uncontrolled. It can be removed by hemodialysis.

Evidence of central nervous system toxicity, including headache, somnolence, vertigo, visual disturbances, confusion, depression, acute psychotic reactions and tremors, may develop over the first 2 weeks of treatment. The effects may be exacerbated by alcohol and can be reduced, to some extent, by administering pyridoxine. Treatment should be stopped promptly if any mental or neurological signs develop. Convulsions are said to occur in about 50% of patients when the plasma concentration exceeds 20–25 mg/L, but the relationship to dose is not particularly close. No permanent damage appears to be caused. Cycloserine inhibits mammalian transaminases and this and the convulsant effects of the drug have been attributed to a metabolite, amino-oxyalanine. Use of the drug should be avoided in patients with previous fits or other neurological or psychiatric abnormalities. Rare side effects include rashes, cardiac arrhythmia and deficiency in folate and vitamin B₁₂ leading to peripheral neuritis.

It is occasionally used in MDR tuberculosis (with other antituberculosis drugs) and other mycobacterioses (with appropriate additional drugs).

Preparations and dosage

Proprietary names: Cycloserine, Seromycin.

Preparation: Capsules.

Dosage: Adults, oral, 250 mg every 12 h (maximum dose, 500 mg every 12 h) for 2 weeks. Children, initially 10 mg/kg per day, adjusted according to blood levels and response.

Further information

Wolinsky E. Statement of the Tuberculosis Committee of the Infectious Diseases Society of America. *Clin Infect Dis*. 1993;16:627–628.

ETHIONAMIDE AND PROTIONAMIDE (PROTHIONAMIDE)

These are closely related thioamides structurally similar to isoniazid. They are almost insoluble in water and are unstable on exposure to light. Their antibacterial activity and pharmacokinetics are almost identical, but protonamide is said to be better tolerated. Ethionamide is a second-line agent for treatment of MDR tuberculosis. Protonamide is seldom used in tuberculosis but is used in place of clofazimine for the treatment of leprosy in patients who find skin pigmentation caused by that drug unacceptable. It is more effective than an equivalent dose of ethionamide for killing *M. leprae*, but not as effective as some other agents (fluoroquinolones, minocycline and newer macrolides) currently used in leprosy. If given simultaneously with isoniazid, the blood levels of thioamides may be raised, resulting in more side effects unless the dosage is adjusted.

The MIC for *M. tuberculosis* on solid egg media is 0.8–1.6 mg/L; MICs for the *M. avium* complex, *M. kansassii* and *M. malmoense* are similar. There is complete cross-resistance between ethionamide and protonamide but complete cross-resistance to isoniazid does not occur and partial cross-resistance is uncommon.

They are almost completely absorbed, achieving a plasma concentration of c. 1.8 mg/L 2–3 h after a 250 mg oral dose given as an enteric-coated formulation. The uncoated drugs are less well tolerated, but produce serum levels double those of enteric-coated tablets. The plasma half-life is about 2 h. CSF concentrations approach the unbound plasma levels. Thioamides are degraded in the liver to several metabolites, including a biologically active sulfoxide and various inert compounds including nicotinic acid. Less than 1% is excreted unchanged in the urine.

The principal side effect is gastric irritation, which is more common in adults and in women. This effect is reduced by commencing with a low dose and gradually increasing to the full dose, by the use of antacids and by taking the drug at bedtime. As gastric irritation often leads to non-compliance, supervised therapy is recommended. Hypersensitivity reactions and hepatitis also occur. Rare side effects include hypothyroidism, menstrual irregularities, alopecia, convulsions, deafness, diplopia, peripheral neuropathy, mental disturbances (including depression) and, in male patients, impotence and gynecomastia.

Ethionamide is used with other antituberculosis drugs in MDR tuberculosis. Protonamide is used with other anti-leprosy drugs in non-responsive multibacillary leprosy.

Preparations and dosage

Proprietary names: Trecator (ethionamide), Peteha (prothionamide).

Preparation: Tablets.

Dosage: Adult, oral, 15–20 mg/kg per day in divided doses with meals. Children, 12–15 mg/kg per day to a maximum of 750 mg in divided doses, with meals.

THIOACETAZONE (AMITHIOZONE)

Thioacetazone (USAN amithiozone) is a synthetic compound discovered during initial work on the sulfonamides, to which it is structurally related. It is only slightly soluble in water. It is a weak bacteriostatic drug, with frequent serious side effects, particularly in HIV-positive persons to whom it must never knowingly be given. On the advice of the WHO it no longer has a place in the treatment of tuberculosis, except as a last resort in cases of extreme drug resistance.

In-vitro MICs vary considerably according to the medium used and bear little relation to in-vivo efficacy. Many strains of *M. tuberculosis* isolated in East Africa, India and Hong Kong are naturally more resistant than strains from Europe. Acquired resistance, as a result of monotherapy, is prevalent in the developing countries.

Thioacetazone is well absorbed, achieving a plasma concentration of 1–4 mg/L 2–4 h after a 100 mg oral dose.

The plasma half-life is 8–12 h. Little is known about the distribution of the drug. Several metabolites are described. About 20% is eliminated in the urine; the fate of the remainder is unknown. Rashes are common, occurring in 2–4% of patients in Africa but much more frequently in those of Chinese ethnic origin. More severe skin reactions, exfoliative dermatitis and Stevens–Johnson syndrome occur in less than 0.5% of HIV-negative patients, but there is a 10-fold increase of these reactions in HIV-positive patients, proving fatal in up to 3% of such patients. Other common side effects include gastrointestinal reactions, vertigo and conjunctivitis. Less common reactions include hepatitis, erythema multiforme, hemolytic anemia and, rarely, agranulocytosis. Prolonged therapy may rarely lead to hypertrichosis, gynecomastia and osteoporosis. It is very rarely used, but may occasionally be considered (with other antituberculosis drugs) in extremely drug resistant tuberculosis.

Preparations and dosage

Preparation: Tablets.

Dosage: Adults, oral, 150 mg per day. Children, 2.5 mg/kg (maximum dose, 150 mg per day).

Limited availability and very rarely used.

CHAPTER

34 Anthelmintics

George A. Conder

The helminths, or parasitic worms, comprise the nematodes (round-worms), trematodes (flukes), cestodes (tapeworms) and acanthocephalans (thorny-headed worms). Most anthelmintics were discovered and developed for use in the veterinary field, where helminths significantly impact health and productivity. Few companies are searching for new compounds for use in human medicine, but commercial competition has produced a steady supply of new products for the veterinarian. Three new classes of anthelmintic (cyclic octadepsipeptides, amino-acetonitrile derivatives and paraherquamides) have entered or will soon enter the veterinary market and these have potential for human medicine. In addition, some members of established classes have exhibited promising results in preliminary investigations (moxidectin for filariasis; artemisinins for schistosomiasis).

Despite the lack of new anthelmintics for human treatment, satisfactory results can be achieved with current products for nearly all helminth infections. In some cases such as for filariasis, combinations of available drugs are being used to enhance treatment. Side effects usually include gastrointestinal upsets, but these are as likely to be related to the worm burden as to the drug. As helminths are often large and/or present in large numbers, their death and disintegration after chemotherapy can result in an obstruction or an allergic-anaphylactic type reaction.

The biggest problems still remaining to be solved are treatment of infections with larval cestodes, especially *Echinococcus* spp. There is no satisfactory drug against these parasites; although benzimidazole carbamates have useful activity, they are poorly absorbed from the gut when administered orally and painful injection-site reactions preclude parenteral use. Praziquantel also may be useful in some cases for larval cestodes. Another problem is the treatment of disseminated strongyloidiasis, which occurs when patients with a latent infection are immunosuppressed (see pp. 844–845). No satisfactory chemotherapy is available for the macrofilarial stages in filarial infections, or to treat Guinea worm (*Dracunculus medinensis*) infection, although an eradication program has greatly reduced its incidence.

Although drug resistance is common in the veterinary field it is not yet a problem in human medicine, except with regard to schistosomiasis where resistance is known for hycanthone and praziquantel. This discrepancy is because anthelmintics are very widely

and frequently used in the veterinary world but much less so in human medicine, in part due to the poverty of most of the people who are infected. With increasing wealth in tropical countries where these infections are common, anthelmintics are being used much more widely and there is concern that drug resistance will develop.

BENZIMIDAZOLES

These synthetic compounds exhibit useful activity against cestodes, trematodes and nematodes. They are widely used in veterinary medicine. The first compound of this class to be marketed for human use, tiabendazole (thiabendazole), has been largely superseded by the benzimidazole carbamates, especially albendazole and mebendazole.

ACQUIRED RESISTANCE

There are no published records of any human nematode developing resistance to benzimidazole derivatives.

Since mebendazole is now available without prescription in some countries, there is a risk that resistance may develop in patients who do not complete the full course of treatment and such resistance may extend to related benzimidazoles. Experience in the veterinary world shows that if resistance to one benzimidazole occurs the parasite very rapidly becomes resistant to all members of the class.

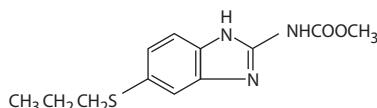

Further information

Various authors. Benzimidazole anthelmintics. *Parasitol Today*. 1990;6:106–136.

ALBENDAZOLE

Molecular weight: 265.33.

A benzimidazole carbamic acid methyl ester available for oral administration. Insoluble in water, soluble in dimethyl sulfoxide. Stable at room temperature.

ANTHELMINTIC ACTIVITY

Activity against the common intestinal nematodes is shown in Table 34.1. Albendazole is active against trichostrongyles and exhibits useful activity against tissue-dwelling larvae of *Trichinella spiralis*, larvae of animal hookworms (causing cutaneous larva migrans) and microfilariae of various filarial species. It also exhibits some activity against cysticercosis and hydatid stages of *Echinococcus granulosus* and *Echinococcus multilocularis*. It has been successfully used in infections with the protozoan *Giardia lamblia* and for microsporidiosis.

PHARMACOKINETICS

Albendazole is better absorbed after oral absorption than other benzimidazole carbamates. It is extensively metabolized to the anthelmintically active albendazole sulfoxide, producing plasma concentrations of the metabolite of about 1.3 mg/L 2–5 h after a 400 mg oral dose. The half-life is about 8 h and the major route of excretion is via the bile. Plasma protein binding of the sulfoxide is around 70%.

TOXICITY AND SIDE EFFECTS

Various mild intestinal and other upsets usually resolve without treatment. With extended use, as for larval tapeworm infections, hepatic abnormalities or leukopenia may require discontinuation of treatment. In rare cases granulocytopenia, pancytopenia, agranulocytosis or thrombocytopenia may occur. It should not be given during pregnancy since it may cause fetal harm; women should be cautioned against becoming pregnant within a month of completing treatment.

CLINICAL USE

- Intestinal worm infections
- Trichinosis (including chronic stage)
- Cutaneous larva migrans
- Hydatid disease (as an adjunct, or alternative, to surgery)
- Neurocysticercosis
- Lymphatic filariasis (alone or in combination with ivermectin)
- Giardiasis
- Microsporidiosis

Table 34.1 Activity of currently used anthelmintics against common intestinal nematodes

Agent	<i>Enterobius vermicularis</i>	<i>Ascaris lumbricoides</i>	<i>Ancylostoma duodenale</i>	<i>Necator americanus</i>	<i>Strongyloides stercoralis</i>	<i>Trichuris trichiura</i>
Piperazine	++	+++	–	–	–	–
Levamisole	–	+++	+++	+++	–	–
Pyrantel	+++	+++	+++	++	–	–
Mebendazole	+++	+++	+++	+++	++	++
Albendazole	+++	+++	+++	+++	++	++
Ivermectin	+	+++	+	+	+++	+

++, Highly effective; ++, moderately effective; +, poorly effective; –, no useful activity.

Preparations and dosage

Proprietary names: Albenza, Eskazole, Zentel, etc.

Preparation: Tablets, 200 or 400 mg.

Dosage

Ascarisis, pinworm, hookworms, trichostrongyliasis: 400 mg as a single oral dose; for pinworm, a second dose may be needed after 2–3 weeks.

Strongyloidiasis, whipworm: 400 mg orally on three consecutive days.

Echinococcosis: therapy, presurgery or postsurgery, ≥60 kg, 400 mg orally every 12 h with meals for 28 days followed by 14 tablet-free days; up to three cycles of treatment may be given; <60 kg, 15 mg/kg per day orally every 12 h with meals (maximum dose, 800 mg per day).

Neurocysticercosis: ≥60 kg, 400 mg orally every 12 h with meals for 8–30 days; <60 kg, 15 mg/kg per day orally every 12 h with meals (maximum dose, 800 mg per day).

Widely available.

is retained in the intestinal tract and passed in the feces, with the remainder, approximately 2% of the dose, excreted in the urine.

TOXICITY AND SIDE EFFECTS

Diarrhea and gastrointestinal discomfort may occur, but adverse reactions are generally mild. Woman of childbearing age should be informed of a potential risk to the fetus if treated during pregnancy, particularly during the first trimester.

CLINICAL USE

Intestinal nematode infections
Trichinosis (larval stage)

Further information

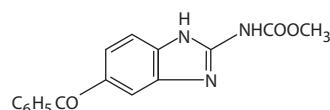

Anonymous. Albendazole. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:A51–A56.

Horton J. Albendazole: a review of anthelmintic efficacy and safety in humans. *Parasitology*. 2000;121:5113–5132.

Ottesen E. Lymphatic filariasis: treatment, control and elimination. *Adv Parasitol*. 2006;61:395–441.

MEBENDAZOLE

Molecular weight: 295.29.

A benzimidazole carbamic acid methyl ester available for oral administration. It is insoluble in water and stable at room temperature.

ANTHELMINTIC ACTIVITY

Activity against common intestinal nematodes is shown in Table 34.1.

PHARMACOKINETICS

Oral absorption is poor. Plasma concentrations achieved after oral administration of 100 mg every 12 h for three consecutive days do not exceed 0.03 mg/L. All metabolites are inactive. Most of the dose, as unchanged drug or a primary metabolite,

Preparations and dosage

Proprietary name: Vermox (many others).

Preparations: Tablets, 100 mg; suspension 100 mg/5 mL.

Dosage: Adults and children >2 years, not recommended for children <2 years of age.

Pinworm: 100 mg as a single dose; if reinfection occurs, a second dose may be needed after 2–3 weeks.

Ascarisis, hookworms and whipworm: 100 mg every 12 h on three consecutive days.

Widely available.

Further information

Anonymous. Mebendazole. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:M12–M15.

OTHER BENZIMIDAZOLES

FLUBENDAZOLE

A benzimidazole carbamate used in some countries in place of mebendazole for the treatment of ascariasis. It is even less well absorbed after oral administration than mebendazole.

Preparations and dosage

Dosage: Adults and children, oral, enterobiasis, 100 mg as a single dose, repeated if necessary after 2–3 weeks. *Ascarisis, trichuriasis and hookworm:* 100 mg every 12 h on three consecutive days. Limited availability.

TIABENDAZOLE

Thiabendazole; a thiazolyl benzimidazole available for oral administration. It is active against most common intestinal nematodes. As a result of its larvicidal and ovicidal activity, it is effective in strongyloidiasis, trichinosis, visceral larva migrans and cutaneous larva migrans.

It is well absorbed from the small intestine. Peak plasma levels are reached about 1–2 h after a single oral dose of the suspension. It is extensively metabolized in the liver to the 5-hydroxy derivative, which is inactive. Most of the drug is excreted within 24 h. About 90% is excreted in the urine, chiefly as glucuronide or sulfate conjugates; the remainder is passed in the feces.

A wide range of unpleasant side effects occur, including nausea and other gastrointestinal upsets, fever and neurological effects. It has been largely replaced by the less toxic benzimidazole carbamates. Although active against *Ascaris lumbricoides*, *E. vermicularis* and hookworms, it should not be used as primary therapy for these infections.

Preparations and dosage

Proprietary names: Mintezol, Triasox.

Preparations: Tablets, 500 mg; oral suspension 500 mg/5 mL.

Dosage: Oral, based on patient's weight.

Strongyloidiasis: Two doses a day on two successive days or 50 mg/kg as a single dose.

Trichinosis: Two doses a day on 2–4 successive days, depending on response.

Cutaneous larva migrans: Two doses a day on two successive days; repeat if active lesions are still present 2 days after completion of therapy.

Visceral larva migrans: Two doses a day on 5–7 successive days.

Widely available.

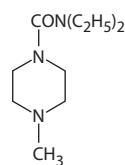

Further information

Anonymous. Thiabendazole. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:T81–T83.

MISCELLANEOUS ANTHELMINTIC AGENTS

DIETHYLCARBAMAZINE

Molecular weight (free base): 199.29; (citrate): 391.42.

A carbamyl derivative of piperazine formulated as the citrate. It is readily soluble in water and slightly hygroscopic.

ANTHELMINTIC ACTIVITY

Useful activity is restricted to filarial worms. It is adulticidal and microfilaricidal against *Loa loa*. Against *Wuchereria bancrofti* and *Brugia malayi* it is predominantly microfilaricidal, but slowly kills adult worms. It kills microfilariae, but not adults, of *Onchocerca volvulus*.

PHARMACOKINETICS

Oral absorption	>90%
C_{\max} 200 mg	1.5–2 mg/L after 2 h
Plasma half-life	c. 6–12 h
Volume of distribution	107–371 L
Plasma protein binding	Very low

Like piperazine (to which it is related), diethylcarbamazine is rapidly and completely absorbed. About half the dose is excreted unchanged in the urine; the rest is metabolized and eliminated by renal and extrarenal routes.

TOXICITY AND SIDE EFFECTS

In uninfected people, diethylcarbamazine has virtually no side effects, but in those with various forms of filariasis it has unpleasant effects primarily due to the death of blood- or skin-dwelling microfilariae. Severe reactions ('Mazzotti reactions'), most frequently of the skin, occur in patients with onchocerciasis and may also be systemic with fever, headache, prostration, nausea, joint and muscle pain, vertigo, tachycardia, cough and respiratory distress, hypotension and ocular signs. In patients with *L. loa* who harbor very large numbers of microfilariae in their blood, neurological problems may be very severe. Cardiological damage has also been reported. In patients with *W. bancrofti* and *B. malayi* high fever occurs in the first few days after treatment. Reversible proteinuria may occur.

CLINICAL USE

Filariasis

It has also been used for visceral larva migrans, but experience is limited and there is little evidence of its efficacy.

Preparations and dosage

Proprietary names: Banocide, Hetrazan, etc.

Preparation: Tablets, 50 or 100 mg.

Dosage:

Loiasis: Adults, oral, 1 mg/kg as a single dose, doubled on two successive days, and then adjusted to 2–3 mg/kg every 8 h for a further 18 days.

Wuchereria bancrofti: Adults and children >10 years of age, oral, 6 mg/kg per day for 12 days, preferably in divided doses after meals.

Brugia spp.: Adults and children >10 years of age, oral, 3–6 mg/kg per day for 6–12 days, preferably as divided doses after meals.

Limited availability.

it exhibits activity against some ectoparasites, including *Sarcoptes scabiei*.

PHARMACOKINETICS

Oral absorption	c. 60%
C_{\max} 12 mg oral	c. 30–47 ng/mL after 4 h
Plasma half-life	c. 12 h
Volume of distribution	46.9 L
Plasma protein binding	93%

It is rapidly metabolized in the liver and the metabolites are excreted in the feces over about 12 days with minimal (<1%) urinary excretion. Highest concentrations occur in the liver and fat. Extremely small amounts are found in the brain.

Further information

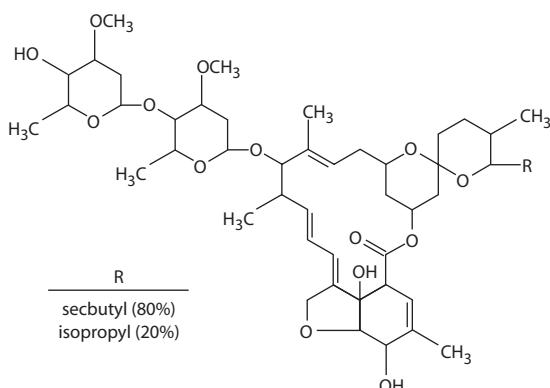

Anonymous. Diethylcarbamazine (citrate). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:D103–D106.

Mackenzie CD, Kron MA. Diethylcarbamazine: a review of its action in onchocerciasis, lymphatic filariasis and inflammation. *Trop Dis Bull*. 1985;82:R1–R37.

Maizels RM, Denham DA. Diethylcarbamazine (DEC): immunopharmacological interactions of an anti-filarial drug. *Parasitology*. 1993;105:S49–S60.

IVERMECTIN

Molecular weight: (dihydroavermectin B_{1a}): 875.1; (dihydroavermectin B_{1b}): 861.07.

A mixture of two closely related semisynthetic derivatives of avermectins, a complex of macrocyclic lactone antibiotics produced by *Streptomyces avermitilis*. In commercial preparations the ratio of the two components, dihydroavermectin B_{1a} and dihydroavermectin B_{1b}, are present within the limits 80–90% and 10–20%, respectively.

ANTHELMINTIC ACTIVITY

Activity against intestinal nematodes is shown in Table 34.1 (p. 396). It is also active against *O. volvulus* and other filarial worms, but the effect is chiefly directed against the larval forms (microfilariae). Uniquely among anthelmintic agents

TOXICITY AND SIDE EFFECTS

In the treatment of onchocerciasis mild Mazzotti-type reactions occur, with occasional neurological problems. Although it is highly effective against *L. loa*, care must be taken to avoid treating patients with high microfilarial counts: there is one report of a patient with a concomitant *L. loa* infection who died when treated for onchocerciasis. Mild gastrointestinal and nervous system signs may occur following treatment for strongyloidiasis.

CLINICAL USE

Onchocerciasis
Non-disseminated strongyloidiasis
Lymphatic filariasis (in combination with albendazole)
Scabies

If the patient is harboring *Asc. lumbricoides*, the worms will be passed in the feces. Head lice will also be killed, which is very much welcomed by the treated patients. Ivermectin has been widely used in the veterinary field, where use is also made of its effect on ectoparasites.

Preparations and dosage

Proprietary names: Mectizan, Stromectol.

Preparation: Tablets, 3 or 6 mg.

Dosage:

Onchocerciasis: ≥15 kg, oral, 150 µg/kg as a single dose. Re-treat at 6–12-month intervals.

Strongyloidiasis: ≥15 kg, oral, 200 µg/kg as a single dose on two consecutive days.

Ivermectin should not be used during pregnancy or in nursing mothers. Limited availability.

LEVAMISOLE

Molecular weight (free base): 204.29; (hydrochloride): 240.75.

The L-isomer of tetramisole, available as the monohydrochloride. The D-isomer has no anthelmintic activity. It is very soluble in water and is stable in the dry state.

ANTHELMINTIC ACTIVITY

Its principal activity is against *Asc. lumbricoides* and hookworms (Table 34.1, p. 396). Worms are paralyzed and passed out in the feces within a few hours.

PHARMACOKINETICS

Oral absorption	c. 90%
C_{\max} 150 mg oral	0.5 mg/L after c. 2 h
Plasma half-life	c. 4 h
Volume of distribution	100–120 L

Levamisole is rapidly absorbed from the gut and extensively metabolized in the liver. It is excreted chiefly in the urine.

TOXICITY AND SIDE EFFECTS

Nausea, gastrointestinal upsets and very mild neurological problems have been reported.

CLINICAL USE

- Ascariasis
- Hookworm infection

Levamisole has been used in rheumatoid arthritis and some other conditions that are said to respond to its immunomodulatory activity.

Preparations and dosage

Proprietary names: Ergamisol, Ketrax, Solaskil.

Preparation: Tablets, 40 or 50 mg.

Dosage:

Ascariasis: Adults, oral, 120–150 mg as a single dose; children, 3 mg/kg as a single dose.

Hookworm: Oral, 2.5–5 mg/kg as a single dose; in severe cases, a second dose may be given 7 days after the first.

Limited availability.

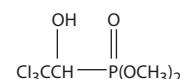

Further information

Anonymous. Levamisole (hydrochloride). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:L26–L29.

METRIFONATE

Trichlorfon (USAN). Molecular weight: 257.44.

An organophosphorus compound. It is soluble in water and stable at room temperature. At higher temperatures it decomposes to the insecticide dichlorvos.

ANTHELMINTIC ACTIVITY

Useful activity is restricted to *Schistosoma haematobium*. It has little activity against other schistosomes (Table 34.2). Although it exhibits activity against several other helminths, it is not used for their treatment.

PHARMACOKINETICS

Metrifonate is rapidly absorbed after oral administration, achieving a peak concentration in plasma within 1–2 h. It undergoes chemical transformation to dichlorvos, which is the active molecule. Dichlorvos is rapidly and extensively metabolized and excreted mainly in the urine.

TOXICITY AND SIDE EFFECTS

Various side effects such as abdominal pain, gastrointestinal upsets and vertigo occur in many patients. As the worms

Table 34.2 Activity of commonly used antischistosome agents

Agent	<i>Schistosoma mansoni</i>	<i>Schistosoma haematobium</i>	<i>Schistosoma japonicum</i>	<i>Schistosoma intercalatum</i>	<i>Schistosoma mekongi</i>
Praziquantel	+++	+++	+++	+++	+++

Oxamniquine	+++	-	-	-	-

+++; Highly effective; -; no useful activity.

release their hold of the veins in the bladder they pass through the blood system to the lungs, where they disintegrate; this may cause some of the side effects. Cholinesterase levels in the blood and on erythrocytes are depressed, but the significance of this is unknown.

CLINICAL USE

Urinary schistosomiasis (especially mass chemotherapy control programs)

Preparations and dosage

Proprietary name: Bilarcil.

Preparation: Tablets, 100 mg.

Dosage: Adults and children, oral. *S. haematobium*: three doses of 75–10 mg/kg may be given at intervals of 14 days.

Limited availability.

Diphyllobothrium latum and *Hymenolepis nana*. It is not effective against larval stages of tapeworms.

PHARMACOKINETICS

Conflicting data exist relative to the level of absorption of niclosamide from the gut. The metabolized drug is passed in the feces and urine, staining them yellow.

TOXICITY AND SIDE EFFECTS

Very few side effects have been reported, but these include mild nausea, abdominal cramps and dizziness.

CLINICAL USE

Intestinal tapeworm infections

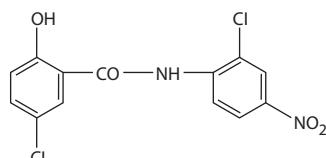

Further information

Anonymous. Trichlorfon. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:T174–T179.

NICLOSAMIDE

Molecular weight: 327.12.

A synthetic chlorinated nitrosalicylanilide available for oral administration.

ANTHELMINTIC ACTIVITY

Useful activity is restricted to intestinal tapeworms, including *Taeniarhynchus saginatus* (syn. *Taenia saginata*), *Taenia solium*,

Preparations and dosage

Proprietary names: Niclocide, Tredemine, Yomesan.

Preparation: Tablets, 500 mg.

Dosage:

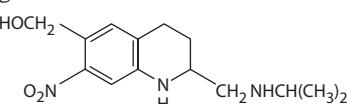

T. saginatus, *T. solium* (intestinal stage) and *D. latum*: Adults, oral, 2 g as a single dose; children 10–35 kg, 1 g as a single dose; infants <10 kg, 0.5 g as a single dose. Chronically constipated patients should receive a purgative on the evening preceding treatment.

H. nana: A 7-day treatment is recommended; adults, 2 g on the first day and 1 g on each of the next 6 days; children 10–35 kg, 1 g on the first day and 0.5 g on each of the next 6 days; infants <10 kg, a total of 2 g should be given over 7 days.

Widely available.

OXAMNIQUINE

Molecular weight: 279.33.

A synthetic quinolinemethanol, available for oral administration.

ANTHELMINTIC ACTIVITY

Activity is restricted to *Schistosoma mansoni* (Table 34.2). Some strains, particularly those in Egypt and Southern Africa, require higher doses for efficacy owing to innate tolerance.

PHARMACOKINETICS

It is rapidly absorbed after oral administration, achieving a peak concentration of 0.3–2.5 mg/L 1–3 h after an oral dose of 15 mg/kg body weight. Peak levels following intramuscular treatment at 7.5 mg/kg generally do not exceed 0.15 mg/L. It is extensively metabolized to biologically inactive 6-carboxylic and 2-carboxylic acid derivatives, which are excreted in the urine, mostly within 12 h.

TOXICITY AND SIDE EFFECTS

Dizziness, sleepiness, nausea and headache occur frequently. Other side effects are probably due to the death and disintegration of the worms in the liver. Following treatment, urine may become red.

CLINICAL USE

Infection with *S. mansoni*

Preparations and dosage

Proprietary name: Vansil.

Preparations: Capsule, 250 mg; syrup, 50 mg/mL.

Dosage:

West Africa, South America, Caribbean Islands: Adults, 15 mg/kg as a single oral dose; children <30 kg, 10 mg/kg orally every 12 h for 1 day.

East and Central Africa and Arabian Peninsula: Adults and children, 15 mg/kg orally every 12 h for 1 day.

Egypt, Southern Africa and Zimbabwe: Adults and children, 60 mg/kg orally over 2–3 days with no single dose to exceed 20 mg/kg.

Limited availability.

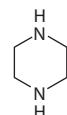

Further information

Anonymous. Oxamniquine. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:O35–O37.

PIPERAZINE

Molecular weight: piperazine: 86.14; (edetate calcium): 416.44; (anhydrous citrate): 642.65.

A synthetic chemical, most commonly formulated as the citrate, but also available as the adipate, edetate calcium and tartrate salts.

ANTHELMINTIC ACTIVITY

Activity against common intestinal nematodes is shown in Table 34.1 (p. 396). It has no other useful anthelmintic activity.

PHARMACOKINETICS

Activity against intestinal worms requires that a substantial amount remains in the gut. However, after oral administration a variable amount is rapidly absorbed from the small intestine and subsequently excreted in the urine. Its half-life is extremely variable.

TOXICITY AND SIDE EFFECTS

Some people develop hypersensitivity, requiring cessation of treatment. Transient, mild gastrointestinal or neurological symptoms may occur.

CLINICAL USE

Ascariasis
Pinworm

Preparations and dosage

Proprietary names: Many (e.g. Antepar, Pripsen).

Preparations: Various oral presentations.

Dosage:

The dosage of piperazine is generally expressed relative to piperazine hexahydrate.

Ascariasis: Adults and children >12 years, the equivalent of 75 mg/kg to a maximum of 35 g of piperazine hexahydrate as a single oral dose or divided over two consecutive days; children 2–12 years, as for adults but to a maximum of 25 g; children <2 years, the equivalent of 50 mg/kg of piperazine hexahydrate administered under medical supervision.

Alternative regimens exist.

Pinworm: Adults and children, the equivalent of 50 mg/kg of piperazine hexahydrate given orally on seven consecutive days. Treatment should be repeated at an interval of 2 weeks and all family members should be treated. Alternative regimens exist.

Widely available without prescription in many countries under numerous trade names.

ACQUIRED RESISTANCE

There is evidence that resistance to praziquantel is emerging in schistosomes, although there is debate as to whether treatment failures are due to resistance or innate tolerance.

PHARMACOKINETICS

Oral absorption	>80%
C_{max} 50 mg/kg oral	1 mg/L after 1–2 h
Plasma half-life: parent drug metabolites	1–1.5 h 4–6 h
Plasma protein binding	80%

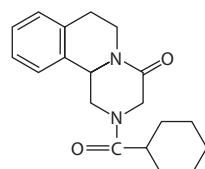

Further information

Anonymous. Piperazine. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:P137–P139.

PRAZIQUANTEL

Molecular weight: 312.41.

A synthetic pyrazinoquinoline formulated for oral administration. It is stable in the dry state, but hygroscopic.

ANTHELMINTIC ACTIVITY

All species of human schistosomes are susceptible (Table 34.2, p. 401), but there is a relative lack of efficacy against immature stages. It is also effective against adult and tissue-dwelling larval tapeworms; against the intestinal flukes *Fasciolopsis buski*, *Metagonimus yokogawai*, *Heterophyes heterophyes* and *Nanophyetus salmincola*; against *Clonorchis* and *Opisthorchis* spp. in the bile ducts; and against *Paragonimus* spp. in the lungs. It has variable activity against zoonotic *Fasciola hepatica* infections.

TOXICITY AND SIDE EFFECTS

Very few side effects have been reported. In the treatment of cerebral cysticercosis the death of cysts in the brain may cause local inflammation and edema, but this usually subsides quickly. Ocular cysticercosis should not be treated with this drug, because parasite destruction in the eye can lead to irreparable lesions. Adverse events seen in the treatment of schistosomiasis, including abdominal pain, nausea, anorexia, diarrhea and mild neurological effects, are almost certainly due to the death and disintegration of the large adult worms.

CLINICAL USE

Schistosomiasis
Other trematode infections (except <i>F. hepatica</i>)
Tapeworm infection, including cerebral cysticercosis

Treatment may need to be prolonged in cerebral cysticercosis.

Preparations and dosage

Proprietary names: Biltricide, Distocide.

Preparation: Tablets, 600 mg.

Dosage:

Adults and children >4 years.

Schistosomiasis: 20 mg/kg orally three times a day at 4–6 h intervals on 1 day or 40 mg/kg as a single dose.

Liver and lung flukes: 25 mg/kg orally three times a day at 4–6 h intervals on one day or two consecutive days.

Intestinal flukes: 25 mg/kg as a single oral dose.

Intestinal taeniasis: 5–10 mg/kg as a single oral dose.

Intestinal diphyllobothriasis: 5–10 mg/kg as a single oral dose.

Intestinal hymenolepiasis: 15–25 mg/kg as a single oral dose.

Cysticercosis: A total of 50 mg/kg per day in three divided doses on 14 consecutive days. A corticosteroid should be administered for 2–3 days before and throughout treatment.

Limited availability.

Further information

Anonymous. Praziquantel. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:P184–P189.

PYRANTEL

Molecular weight: (free base): 206.3; (pamoate): 594.68.

A tetrahydropyrimidine, formulated as the pamoate (embonate) in a 1:1 ratio and available as a suspension for oral administration. It is practically insoluble in water, but soluble in dimethyl sulfoxide. It is stable at room temperature.

ANTHELMINTIC ACTIVITY

Activity against the common intestinal nematodes is shown in Table 34.1 (p. 396). Pyrantel is less active against *Necator americanus* than against *Ancylostoma duodenale*.

PHARMACOKINETICS

By synthetic design most of the dose is passed unchanged in the feces. The portion that is absorbed (<5%) is metabolized and excreted in the urine.

TOXICITY AND SIDE EFFECTS

Pyrantel should not be used at the same time as piperazine as their modes of action are antagonistic. Gastrointestinal upsets and, rarely, very mild neurological symptoms occur.

CLINICAL USE

Ascariasis

Pinworm

Hookworm (especially *A. duodenale*)

Trichostrongyliasis

Higher and more prolonged doses may be necessary in hookworm infection caused by *N. americanus*. Pyrantel has been used in combination with an analog (oxantel) where concurrent whipworm infection was likely.

Preparations and dosage

Proprietary names: Antiminth, Combantrin.

Preparations: Tablets, 250 mg; oral suspension, 50 mg/mL.

Dosage: Adults and children >6 months, 10 mg/kg as a single oral dose; treatment for pinworm should be repeated after 2 weeks; more severe infections of *N. americanus* require 20 mg/kg as a single dose on two consecutive days, or 10 mg/kg as a single dose on 3–4 consecutive days. Widely available.

Further information

Anonymous. Pyrantel (pamoate). In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:P284–P286.

SURAMIN

A complex symmetrical molecule originally developed in Germany in the early 1920s for the treatment of African trypanosomiasis. Its useful anthelmintic activity is restricted to *O. volvulus* and it has been used to achieve a radical cure of onchocerciasis by killing the adult worms. However, it is an extremely toxic drug and its use has become increasingly uncommon since ivermectin became available. Its properties are described in Chapter 35 (pp.424–425).

OTHER ANTHELMINTIC AGENTS

Potassium antimony tartrate (tartar emetic), sodium antimony tartrate, the thioxanthone, hycanthone, and the 5-nitrothiazole, niridazole, were formerly used in the treatment of schistosomiasis, but have been largely superseded by less toxic compounds. Niridazole has also been used in Guinea worm infection, but no drug interrupts transmission, and metronidazole or benzimidazole carbamates are much safer and as useful in providing symptomatic relief.

The chlorinated hydrocarbon tetrachloroethylene has been used since the 1920s in the treatment of hookworm

infection. It is more effective in eliminating *N. americanus* than *Ancyl. duodenale* and has no useful effect against other intestinal worms. Bephenium, a quaternary ammonium compound formulated as the hydroxynaphthoate, is effective against several nematodes, including *Asc. lumbricoides* and *Ancyl. duodenale*, but not *N. americanus*. Pyrvinium, a cyanine dye formulated as the almost insoluble pamoate, was formerly used to treat pinworm infections. It is not absorbed from the gut, is very bright red in color, and stains the feces red. All of these drugs have been replaced by safer and more effective agents.

CHAPTER

35 Antiprotozoal agents

Simon L. Croft and Karin Seifert

Protozoa are unicellular, eukaryotic cells with an enormous diversity of biological characteristics. This is reflected in the requirements for different drugs and limited overlap in sensitivity. Several antiprotozoal agents developed in the 1920s and 1930s (e.g. suramin, mepacrine, chloroquine and sodium stibogluconate) are still widely used. Standard drugs for the treatment of the most neglected diseases – human African trypanosomiasis (sleeping sickness), leishmaniasis and South American trypanosomiasis (Chagas disease) – remain inadequate, although the introduction of miltefosine for leishmaniasis has seen a significant improvement in potential for treatment of this condition. There is still a need to identify more effective drugs for diseases such as cryptosporidiosis and toxoplasmosis, which have emerged as important opportunistic pathogens in immunocompromised patients.

Awareness of the impact of protozoal diseases such as malaria on the development of many countries, and the spread of drug resistance (Ch. 62), has led to initiatives to discover and develop new drugs. Large screening programs are now in place through philanthropic and public funding and the development of public–private partnerships.

ORGANOMETALS

Arsenical and antimonial compounds such as atoxyl and tartar emetic have been used for the treatment of African sleeping sickness and leishmaniasis for over a century. The compounds presently used (sodium stibogluconate, melarsoprol, meglumine antimonate) were developed in the 1940s and are considerably less toxic than their predecessors.

MELARSOPROL

Molecular weight: 398.34.

MeB. A derivative of trivalent melarsen oxide and dimercaprol (BAL), possessing a melaminy moiety. Formulated in 3.6% propylene glycol for intravenous administration. It is almost insoluble in water.

ANTIMICROBIAL ACTIVITY

It is highly and rapidly active against *Trypanosoma brucei gambiense* and *T. brucei rhodesiense* in vitro at submicromolar concentrations. It is much less active against the trypanosomes that infect domestic animals, *T. congolense* and *T. vivax*. Co-administration with eflornithine is effective against central nervous system (CNS) infection with *T. brucei* in rodent models, but clinical studies have found the combination less effective than nifurtimox–eflornithine.

ACQUIRED RESISTANCE

Up to 25% of cases of *T. brucei gambiense* in Central Africa relapse. Patients infected with *T. brucei rhodesiense* normally respond to a second course of the drug, but those with *T. brucei gambiense* do not. In laboratory-generated resistant strains, decreased sensitivity results from reduced uptake of the drug by bloodstream trypanastigotes that either lack an adenine/adenosine transporter (TbAT1) or contain a transporter gene with point mutations. There is conflicting evidence about the role of this mechanism of resistance in isolates from patients unresponsive to treatment.

PHARMACOKINETICS

Serum levels of 2–4 mg/L were achieved 24 h after administration of 3.6 mg/kg, falling to 0.1 mg/L at 120 h after the fourth daily injection. Elimination was biphasic with a half-life of 35 h. The volume of distribution was 100 L. It is rapidly metabolized by microsomal enzymes to melarsen oxide, reaching maximum plasma concentration by 15 min and eliminated with a half-life of 3.9 h. This metabolite can cross the blood–brain barrier and effect a CNS cure in mice. Levels of melarsoprol in the cerebrospinal fluid (CSF) reached around 300 µg/L, about 50 times lower than serum levels.

TOXICITY AND SIDE EFFECTS

The propylene glycol formulation can cause tissue trauma and long-term damage to veins. Drug-induced reactions include fever on first administration, abdominal colic pain, dermatitis and arthralgia. Polyneuropathy has been reported in about 10% of patients. Reactive arsenical encephalopathy is a serious side effect that occurs in around 10% of those treated, with death in 1–3% of cases. The frequency of encephalopathy increases with a rise in the white cell count or the presence of trypanosomes in the CSF. The causes of the immunological responses involved in the encephalopathy and the possible existence of two forms (reactive and hemorrhagic) are not completely resolved. Studies to identify anti-inflammatory approaches to reduce reactive encephalopathy in late-stage *T. brucei gambiense* infection have produced limited results.

CLINICAL USE

Late-stage sleeping sickness caused by *T. brucei gambiense* and *T. brucei rhodesiense*

It is not recommended for early-stage disease, in which alternatives with less serious side effects are available.

Preparations and dosage

Proprietary name: Arsobal.

Preparation: Injection.

Dosage: Adults, i.v., 3.6 mg/kg per day for 3–4 days and repeat 2–3 times with an interval of at least 7 days between courses. An alternative regimen of 10 daily doses of 2.2 mg/kg, with no interval, did not improve safety but reduced time in hospital.

Limited availability.

SODIUM STIBOGLUCONATE

Pentavalent sodium antimony gluconate.

A pentavalent antimonial of uncertain chemical composition; probably a complex mixture of polymeric forms. There is batch-to-batch variation and solutions may contain 32–34% pentavalent antimony (Sb^V). The structural formula is conjectural as studies have identified a mixture of non-complexed Sb^V and large polymeric gluconate complexes. Chemical composition also depends on concentration and time. It is freely soluble in water.

ANTIMICROBIAL ACTIVITY

It has low activity against the extracellular promastigote stage of *Leishmania* spp. in vitro, but is active against amastigotes in macrophages. The trivalent form is considered to be the toxophore, with metabolism of Sb^V to toxic Sb^{III} in the host cell macrophage and the parasite; the level of metabolism is higher in amastigotes than promastigotes. Variation in the sensitivity of different *Leishmania* species may contribute to differences in clinical response. It is more active against visceral than cutaneous leishmaniasis in animal models. Sodium stibogluconate cures CNS infections with *T. brucei* in rodents.

ACQUIRED RESISTANCE

Unresponsiveness and relapse of *L. donovani* infections in Bihar State, India (over 60% of cases), is due to increasing acquired resistance. In laboratory-generated and clinical isolates, resistant *Leishmania* promastigotes show increased levels of intracellular thiols, for example trypanothione, to which Sb^{III} is conjugated and extruded by efflux pumps.

Lack of response is also reported in patients with mucosal leishmaniasis caused by *L. braziliensis*. Relapse is common in patients with visceral leishmaniasis who are immunosuppressed, for example by HIV infection, but this is due to pathogen interaction and the immune dependence of drug activity and not acquired resistance. High mortality has been reported in treatment of these co-infection cases.

PHARMACOKINETICS

Peak concentrations of about 12–15 mg antimony/L are achieved in serum 1 h after a dose of 10 mg/kg. There is a slow accumulation in the central compartment, and tissue concentrations reach a maximum after several days. In contrast to trivalent derivatives, pentavalent antimonials are not accumulated by erythrocytes, but there is evidence of protein binding. Antimony is detected in the skin for at least 5 days after treatment. Some of the dose of Sb^V is converted to Sb^{III}, possibly by the liver or by macrophages. It is rapidly excreted into urine with a half-life of about 2 h; 60–80% of the dose appears in the urine within 6 h of parenteral administration. In a study on structurally related meglumine antimonate (*see below*) the pharmacokinetics of Sb^V and Sb^{III} were similar as measured by serum and urine levels.

TOXICITY AND SIDE EFFECTS

The toxic effects are limited by the rapid excretion, but cumulative toxicity increases in proportion to dose. Myalgia, arthralgia, anorexia and electrocardiographic changes have been reported with high-dose regimens. In particular, development of ventricular tachyarrhythmias associated with prolongation of the QT interval has been recorded. Hepatocellular damage, hepatic and renal functional impairment and pancreatitis have also been reported. The changes are reversible on discontinuation of treatment.

CLINICAL USE

Visceral, cutaneous and mucocutaneous leishmaniasis

The combination with paromomycin has been used in unresponsive cases and in relapses of visceral and cutaneous leishmaniasis.

Preparations and dosage

Proprietary name: Pentostam.

Preparation: Injection.

Dosage: Adults, i.m., i.v., 10–20 mg/kg per day with a maximum of 850 mg for at least 20 days; the dose varies with different geographical regions.

Limited availability; not available in the USA.

MEGLUMINE ANTIMONATE

N-Methylglucamine antimonate; methylaminoglucitol antimonate. The Sb^V content varies around 28% between batches. The major moieties are Sb^V–ligand complexes which are zwitterionic in solution.

The activity, pharmacology and toxicology are similar to those of sodium stibogluconate, with which it is essentially interchangeable.

CLINICAL USE

Treatment of visceral and cutaneous leishmaniasis

Studies in Central and South America have indicated that the combination with interferon- γ is effective in the treatment of visceral and cutaneous leishmaniasis cases unresponsive to antimony alone.

Preparations and dosage

Proprietary name: Glucantime.

Preparation: Injection.

Dosage: Adults, i.m., i.v., 20 mg/kg per day for 20–28 days. The course can be repeated.

Limited availability, not available in the UK.

QUINOLINES

Quinine and related alkaloids have been the mainstay of anti-malarial chemotherapy since the 17th century, originally in the form of *Cinchona* bark. Synthetic quinolines were developed in the 1920s and 1930s. The most important of these, the 4-aminoquinoline chloroquine, has succumbed to global

resistance in *Plasmodium falciparum*. Quinine is still used for the therapy of severe malaria. The search for new derivatives led to the discovery of mefloquine. Amodiaquine, another 4-aminoquinoline, is active against chloroquine-resistant strains of *P. falciparum*, but is not recommended for prophylaxis. Identification of the structure–function relationships for activity and resistance has enabled the development of quinolines active against chloroquine-resistant *P. falciparum*; two bis(quinolines), piperaquine and hydroxypiperaquine, have been used in the treatment of drug-resistant malaria in China and are in development in co-formulations with artemisinin derivatives. The 8-aminoquinoline primaquine is used for the radical cure of benign tertian malaria. Others of this class are in clinical trial: tafenoquine for malaria and sitamaquine for visceral leishmaniasis.

Tekwani BL, Walker LA. 8-Aminoquinolines: future role as antiprotozoal drugs. *Curr Opin Infect Dis*. 2006;19:623–631.

CHLOROQUINE

Molecular weight: 319.9.

A synthetic 4-aminoquinoline, formulated as the phosphate or sulfate for oral administration and as the hydrochloride or sulfate for parenteral use. The salts are soluble in water.

ANTIMICROBIAL ACTIVITY

Chloroquine accumulates 300-fold in infected erythrocytes and acts against the early erythrocytic stages of all four species of *Plasmodium* that cause human malaria. It is also active against the gametocytes of *P. vivax*, *P. ovale* and *P. malariae*, but not against the hepatic stages or mature erythrocytic schizonts and merozoites.

ACQUIRED RESISTANCE

Resistance of *P. falciparum* is widespread and has become a major problem. The mechanism appears to be either decreased uptake or increased efflux of the drug by the parasite, or both. Changes in genes encoding a P-glycoprotein homolog, *Pfmdr1*,

and another putative transporter, *Pfcrt*, are associated with resistance. Reversal of resistance with, for example, verapamil or probenecid has been demonstrated in experimental models, but human trials have been disappointing. Chloroquine-resistant *P. vivax* has been reported in South America and South East Asia.

PHARMACOKINETICS

Oral absorption	80–90%
C_{max} 300 mg oral	0.25 mg/L after 1–6 h
Plasma half-life	c. 9 days (mean)
Volume of distribution	200 L/kg
Plasma protein binding	50–70%

There is extensive tissue binding and a high affinity for melanin-containing tissues. Chloroquine is extensively metabolized to a biologically active monodesethyl derivative that forms about 20% of the plasma level of the drug. The mean elimination half-life results from an initial phase (3–6 days), a slow phase (12–14 days) and a terminal phase (40 days). Renal clearance is about 50% of the dose.

TOXICITY AND SIDE EFFECTS

Minor side effects such as dizziness, headache, rashes, nausea and diarrhea are common. Pruritus occurs in up to 20% of Africans taking chloroquine. Long-term treatment can induce CNS effects and cumulative dosing over many years may cause retinopathy. Rarely, photosensitization, tinnitus and deafness have occurred.

CLINICAL USE

Prophylaxis and treatment of all types of malaria
Hepatic amebiasis (in sequential combination with dehydroemetine)

A combination with azithromycin has been suggested for intermittent preventive treatment.

Preparations and dosage

Proprietary names: Avloclor, Nivaquine.
Preparations: Tablets, syrup, injection.

Dosage: Treatment of benign malarias: adult, oral, 600 mg chloroquine base as initial dose then a single dose of 300 mg after 6–8 h, then a single dose of 300 mg per day for 2 days. Children, oral, initial dose of 10 mg/kg of chloroquine base then a single dose of 5 mg/kg after 6–8 h, then a single dose of 5 mg/kg per day for 2 days. Malaria prophylaxis: consult specialist guidelines.

Widely available.

AMODIAQUINE

Molecular weight: 355.86.

A mono-Mannich-base 4-aminoquinoline, formulated as the dihydrochloride dihydrate or free base for oral administration.

It is active against *P. falciparum* and *P. vivax* and is more active than chloroquine for the treatment of uncomplicated *P. falciparum* malaria. Chloroquine-resistant strains may remain susceptible, but resistance to amodiaquine is also spreading in some regions of Africa. The pharmacological properties are similar to those of chloroquine. The terminal elimination half-life is 1–3 weeks. It is rapidly and extensively metabolized to the desethyl derivative which has reduced antiplasmoidal activity.

Prophylactic use has been abandoned because of agranulocytosis and hepatotoxicity due to formation of a quinone-imine metabolite.

A fixed dose combination with artesunate and derivatives (for example, isoquine) with altered metabolism and reduced toxicity is in development.

CLINICAL USE

Treatment of falciparum malaria

Preparations and dosage

Preparation: Tablets. Also co-formulation artesunate–amodiaquine tablets.

Dosage: Amodiaquine recommended at 30 mg/kg (range 25–35 mg/kg) given over 3 days (e.g. 10 mg/kg/day). Artesunate: amodiaquine fixed dose combination at 4 mg/kg (range 2–10 mg/kg) artesunate and 10 mg/kg (range 7.5–15 mg/kg) amodiaquine once daily for 3 days.

Limited availability.

MEFLOQUINE

Molecular weight (free base): 378.3; (hydrochloride): 414.8.

A synthetic 4-quinolinemethanol, formulated as the hydrochloride for oral administration. It is slightly soluble in water.

ANTIMICROBIAL ACTIVITY

Mefloquine is a lipophilic drug with a high affinity to membranes. A concentration of 10–40 nM has rapid dose-related activity against erythrocytic stages of *Plasmodium* spp., including strains resistant to chloroquine, sulfonamides and pyrimethamine. The C-11 (hydroxy) enantiomers have equal antimalarial activity. It also exhibits activity against bacteria (including methicillin-resistant *Staphylococcus aureus*), and some fungi and helminths.

ACQUIRED RESISTANCE

Resistance in *P. falciparum* is widespread in South East Asia where high-grade resistance was found in 15% of patients and low-grade resistance in about 50%. There is cross-resistance with quinine and halofantrine, and an inverse relationship with chloroquine resistance has been reported. The molecular basis of resistance remains unclear but polymorphisms of the *pfdm1* gene, associated with chloroquine resistance, led to increased sensitivity to mefloquine. Resistant strains of *P. falciparum* appeared in Africa before the drug was used in that continent, perhaps because of quinine abuse or intrinsic resistance. In South East Asia, declining response rates to combination therapy with mefloquine and artesunate are reported.

PHARMACOKINETICS

Oral absorption	70–80%
C_{\max} 1 g oral	1 mg/L after 2–12 h
Plasma half-life	20 days
Volume of distribution	16–25 L/kg
Plasma protein binding	98%

Mefloquine is concentrated two- to five-fold in erythrocytes. The major metabolites do not have antimalarial activity. Pregnant women require larger doses than non-pregnant women to achieve comparable blood levels. It is predominantly excreted in the bile. Less than 10% is excreted in urine.

TOXICITY AND SIDE EFFECTS

At prophylactic doses risks of serious toxicity are about 1 in 10 000, similar to chloroquine. Doses used in therapy are more commonly associated with nausea, dizziness, fatigue, mental confusion and sleep loss. Psychosis, encephalopathy and convulsions are seen in about 1 in 1200–1700 patients. Mefloquine(+), the enantiomer with potential lower toxicity, is currently in development.

CLINICAL USE

Antimalarial prophylaxis in areas of chloroquine resistance
Treatment of uncomplicated multidrug-resistant malaria

A mefloquine–artesunate co-formulation is available. Mefloquine has been used for the treatment of cutaneous leishmaniasis in South America.

Preparations and dosage

Proprietary names: Lariam, Mephaquine.

Preparation: Tablets. Co-formulation mefloquine–artesunate tablets.

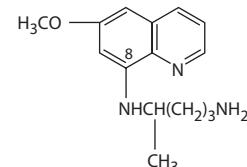

Dosage: Malaria treatment, oral, 20–25 mg/kg as a single dose or in 2–3 divided doses 6–8 h apart. A lower dose of 15 mg/kg may suffice for partially immune individuals. Malaria prophylaxis, see specialist guidelines. Widely available.

Sidhu AB, Uhlemann AC, Valderramos SG, et al. Decreasing *pfmdr1* copy number in *Plasmodium falciparum* malaria heightens susceptibility to mefloquine, lumefantrine, halofantrine, quinine and artemisinin. *J Infect Dis.* 2006;194:528–535.

Simpson JA, Watkins ER, Price RN, et al. Mefloquine pharmacokinetic–pharmacodynamic models: implications for dosing and resistance. *Antimicrob Agents Chemother.* 2000;44:3414–3424.

PRIMAQUINE

Molecular weight (free compound): 259.3; (diphosphate): 455.3.

A synthetic 8-aminoquinoline, formulated as the diphosphate for oral administration.

ANTIMICROBIAL ACTIVITY

Primaquine is highly active against the hepatic stages of the malaria life cycle, including the latent hypnozoite stage of *P. vivax*. It has poor activity against erythrocytic stages of malaria parasites, other than gametocytes. The isomers have similar antiplasmodial activity but differ in toxicity. It exhibits activity against *Pneumocystis jirovecii* and, in experimental models, against *Babesia* spp. and the intracellular stages of *Leishmania* spp. and *Trypanosoma cruzi*.

ACQUIRED RESISTANCE

Failure rates of up to 35% have been reported in South East Asia in patients treated with a standard course for *P. vivax* infections.

PHARMACOKINETICS

Oral absorption	>75%
C_{\max} 45 mg oral	0.2 mg/L after 2–3 h
Plasma half-life	4–10 h
Volume of distribution	2 L/kg
Plasma protein binding	Extensive

Further information

Carrara VI, Zwang J, Ashley EA, et al. Changes in the treatment responses to artesunate–mefloquine on the northwestern border of Thailand during 13 years of continuous deployment. *PLoS ONE.* 2009;4:e4551.

Gutman J, Green M, Durand S, et al. Mefloquine pharmacokinetics and mefloquine–artesunate effectiveness in Peruvian patients with uncomplicated *Plasmodium falciparum* malaria. *Malar J.* 2009;8:58.

Bioavailability is variable after oral administration. There is extensive tissue distribution. About 60% of the dose is metabolized to carboxyprimaquine, which can reach levels 50 times that of the parent drug; this metabolite has a half-life of 16 h, a low tissue distribution and is detectable at 120 h. Methoxy and hydroxy metabolites are also detectable. Less than 4% of the original dose is excreted unchanged in urine.

TOXICITY AND SIDE EFFECTS

At standard doses side effects are mild: abdominal cramps, anemia, leukocytosis and methemoglobinemia. However, primaquine is often associated with serious adverse effects due to the toxic metabolites 5-hydroxyprimaquine or 6-methoxy-8-aminoquinoline which are considered to be directly responsible for complications such as hemolytic anemia. Toxicity is worse in people deficient of glucose-6-phosphate dehydrogenase (G6PD) or glutathione synthetase. Adverse effects can be further increased by the repeated administration of high doses, due to its limited oral bioavailability.

CLINICAL USE

Radical cure of malaria caused by *P. vivax* or *P. ovale*

Mild or moderately severe infections with *Pn. jirovecii* (in combination with clindamycin).

Because of its gametocytocidal properties, primaquine has been used rarely in a single dose to prevent the spread of chloroquine-resistant *P. falciparum*.

Preparations and dosage

Dosage: Malaria treatment, adults, oral, 15 mg per day for 14–21 days (after chloroquine). Children, oral, 250 µg/kg per day as per adult. Malaria prophylaxis, see specialist guidelines.

Limited availability in the UK.

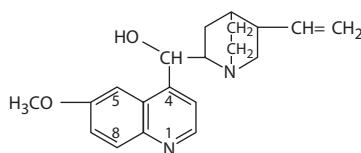

Further information

Bolchoz U, Budinsky RA, McMillan DC, Jollow DJ. Primaquine-induced hemolytic anemia: formation and hemotoxicity of the arylhydroxylamine metabolite 6-methoxy-8-hydroxyaminoquinoline. *J Pharmacol Exp Ther.* 2001;297:509–515.
Vale N, Moreira R, Gomes P. Primaquine revisited six decades after its discovery. *Eur J Med Chem.* 2009;44:937–953.

QUININE

Molecular weight (free base): 324.4.

A quinolinemethanol from the bark of the *Cinchona* tree; the laevorotatory stereoisomer of quinidine. Formulated as the sulfate, bisulfate or ethylcarbonate for oral use and as the dihydrochloride for parenteral administration. The salts are highly soluble in water.

ANTIMICROBIAL ACTIVITY

Quinine inhibits the erythrocytic stages of human malaria parasites at <1 mg/L, but not the liver stages. It is active against the gametocytes of *P. vivax*, *P. ovale* and *P. malariae*, but not *P. falciparum*. The dextrorotatory stereoisomer, quinidine, is more active than quinine, but epiquinine (cinchonine) and epiquinidine (cinchonidine) have much lower antimalarial activities.

ACQUIRED RESISTANCE

Resistance is now widespread in South East Asia, where some strains are also resistant to chloroquine, sulfadoxine-pyrimethamine and mefloquine. Cross-resistance with mefloquine has been demonstrated in *P. falciparum*, but genetic polymorphisms associated with chloroquine resistance are not associated with quinine resistance.

PHARMACOKINETICS

Oral absorption	80–90%
C_{\max} 600 mg oral	5 mg/L after 1–3 h
Plasma half-life	8.7 h
Volume of distribution	1.8 L/kg
Plasma protein binding	c. 70%

Quinine is well absorbed by the oral route. Intramuscular administration gives more predictable data than intravenous administration and may be more useful in children. Plasma protein binding rises to 90% in uncomplicated malaria and 92% in cerebral malaria due to high levels of acute-phase proteins. Similarly, the elimination half-life rises to 18.2 h in severe malaria. There is extensive hepatic metabolism to hydroxylated derivatives. Urinary clearance is <20% of total clearance.

TOXICITY AND SIDE EFFECTS

Up to 25% of patients experience cardiac dysrhythmia, hypoglycemia, cinchonism (tinnitus, vomiting, diarrhea, headache). Severe effects, including hypotension and hypoglycemia, are of particular importance in children, pregnant women and the severely ill. Rarely, it can induce hemolytic anemia ('black-water fever'). Quinine inhibits tryptophan uptake into cells.

CLINICAL USE

Falciparum malaria (alone or in combination with tetracycline, doxycycline, clindamycin or pyrimethamine-sulfadoxine)
Babesiosis (in combination with clindamycin)

It is particularly used in cerebral malaria if chloroquine resistance is suspected (Ch. 62). It is not recommended for treatment of uncomplicated falciparum malaria.

Preparations and dosage

Preparations: Tablets, injection.

Dosage: Treatment of falciparum malaria: Adults, oral, 600 mg of quinine salt every 8 h for 7 days; i.v., initial loading dose of 20 mg/kg quinine salt (maximum dose, 1.4 g) infused over 4 h, then after 8–12 h a maintenance dose of 10 mg/kg (maximum dose, 700 mg) infused over 4 h, every 8–12 h until oral therapy can be taken to complete the 7-day course. Children, oral, 10 mg/kg of quinine salt every 8 h for 7 days. Malaria prophylaxis: see specialist guidelines.

Widely available.

It is highly lipid-soluble and orally well absorbed. The elimination half-life is 20–30 days and there is extensive metabolism. Adverse effects are similar to chloroquine, but pruritus is uncommon.

OTHER QUINOLINES

DIIODOHYDROXYQUINOLINE

Iodoquinol (USAN). Molecular weight: 396.98. An 8-hydroxyquinoline derivative formulated for oral use.

It has weak activity against *Entamoeba histolytica* and *Dientamoeba fragilis* in vitro and in vivo. It is slowly and incompletely absorbed, with less than 10% of an oral dose reaching the circulation. Absorbed drug is metabolized to sulfate or glucuronide conjugates and excreted.

Side effects include nausea, diarrhea, rashes and cramps. Other halogenated hydroxyquinolines have been shown to cause subacute myelo-optic neuropathy from prolonged dosage and are banned in some countries. It is used in asymptomatic or mild intestinal amebiasis, but is not widely available.

PIPERAQUINE

A bisquinoline used to treat malaria in China since 1978. It is structurally related to chloroquine, but active against chloroquine-resistant *P. falciparum*. A combination with dihydroartemisinin has shown excellent tolerability and high cure rates for multidrug-resistant falciparum malaria.

TAFENOQUINE

Etaquine. A synthetic 8-aminoquinoline, formulated as the succinate for oral administration. Tafenoquine is an effective schizonticide against *P. falciparum* and *P. vivax*. It is also active against the pre-erythrocytic stages of these species and the hypnozoites of *P. vivax*. A dosage of 100 mg base corresponds to 125 mg salt. Oral absorption is slow with a maximum plasma concentration reached after 12 h. The half-life is 2 weeks, significantly longer than that of primaquine. It is not eliminated via the kidneys. Toxicity and side effects are similar to those of primaquine. Development of methemoglobinemia is common. Patients with G6PD deficiency may develop severe hemolysis.

It is in clinical development for the treatment and prophylaxis of *P. vivax* malaria and for the treatment of *P. falciparum* infection.

DIAMIDINES

Stibamidine, propamidine, pentamidine and diminazene were initially developed for the treatment of African trypanosomiasis. Pentamidine has been used extensively for early stage infections with *T. brucei gambiense*, but has also been used in the prophylaxis and treatment of *Pn. jirovecii* infections. Diminazene acetate (Berenil) is used for cattle trypanosomiasis, but is not registered for human use.

Propamidine and hexamidine have been used for the topical treatment of amoebic keratitis, often in combination, caused by *Acanthamoeba* spp.; therapeutic activity is also reported for the structurally related polyhexamethylene biguanide.

 Wilson WD, Taniau FA, Mathis A, Tevis D, Hall JE, Boykin DW. Antiparasitic compounds that target DNA. *Biochimie.* 2008;90:999–1014.

PENTAMIDINE

Molecular weight (isethionate): 592.7.

A synthetic diamidine, available as the isethionate (2-hydroxymethane sulfonate) salt for parenteral use. It is also administered by instillation of a nebulized solution directly into the lungs.

ANTIMICROBIAL ACTIVITY

Pentamidine has broad activity in experimental models against *P.falciparum*, *Toxoplasma gondii*, *Leishmania* spp., *Trypanosoma* spp. and *Babesia* spp. It also has activity against *Pn. jirovecii*.

ACQUIRED RESISTANCE

Relapse rates of 7–16% have been reported in the treatment of human African trypanosomiasis in West Africa. Patients usually respond to a subsequent course of treatment with melarsoprol. A membrane transporter is involved in cross-resistance of arsenic-resistant *T. brucei* to diamidines, affecting diminazene and stilbamidine more than pentamidine.

PHARMACOKINETICS

Oral absorption	Negligible
C_{\max} 4 mg/kg intramuscular	c. 0.5 mg/L after 1 h
Plasma half-life	c. 6.5 h
Volume of distribution	3 L/kg
Plasma protein binding	c. 70%

Pentamidine is rapidly and extensively metabolized by rat liver, and high concentrations are retained in renal and hepatic tissue for up to 6 months after administration. In humans distribution is mainly in the liver, kidney, adrenal glands and spleen, with lower accumulation in the lung. This tissue retention is

the basis for its prophylactic use. Although transport across the blood–brain barrier has been demonstrated in experimental models, it is probably unable to cross the blood–brain barrier in sufficient quantity to be trypanocidal: <1% of the plasma concentration has been measured in the CSF of sleeping sickness patients. About 15–20% of the dose is excreted in the urine but because of retention in tissues there is an extremely long terminal half-life (>12 days).

TOXICITY AND SIDE EFFECTS

Side effects range from local irritation and sterile abscess at the site of injection to transient effects (vomiting, abdominal discomfort) and serious systemic effects (hypotension, effects on the heart, hypoglycemia and hyperglycemia, leukopenia, thrombocytopenia). In a study of the treatment of South American cutaneous leishmaniasis, 17% of patients prematurely terminated treatment due to toxicity and another 30% reported side effects.

CLINICAL USE

Human African trypanosomiasis (early stages before CNS involvement)

Prophylaxis and therapy of *Pn. jirovecii* pneumonia

Visceral leishmaniasis unresponsive to pentavalent antimonials and cutaneous leishmaniasis caused by *L. guyanensis*

There is limited evidence for its use in the treatment of babesiosis.

Preparations and dosage

Proprietary name: Pentacarinat.

Preparations: Injection, nebulizer solution.

Dosage:

Visceral leishmaniasis: Adults, i.m., 3–4 mg/kg once or twice weekly until the condition resolves; i.v., 3–4 mg/kg on alternate days to a maximum of 10 injections.

Trypanosomiasis: Adults, i.m., 4 mg/kg per day or on alternate days to a total of 7–10 injections.

Pn. jirovecii pneumonia: i.v., 4 mg/kg per day for at least 14 days.

Widely available.

- van der Meide WF, Sabajo LO, Jensema AJ, et al. Evaluation of treatment with pentamidine for cutaneous leishmaniasis in Suriname. *Int J Dermatol.* 2009;48:52–58.

PROPAMIDINE

A synthetic diamidine formulated as the isethionate or as dibromopropamidine isethionate for topical administration to the eye. Resistant clinical isolates of *Acanthamoeba* have been identified. It is available over the counter in eye drops.

Its activity against bacterial pathogens is poor, but it exhibits specific activity against *Acanthamoeba* spp. Reduction in sensitivity of *Acanthamoeba* during encystation might reflect changes in drug uptake. It is still recommended for aggressive treatment of amebic keratitis (in combination with neomycin or other agents), but is not well tolerated.

Preparations and dosage

Proprietary name: Brolene.

Preparations: Ophthalmic ointment and eye drops.

Widely available.

Further information

Schuster FL, Visvesvara GS. Opportunistic amoeba: challenges in prophylaxis and treatment. *Drug Resist Updat.* 2004;7:41–51.

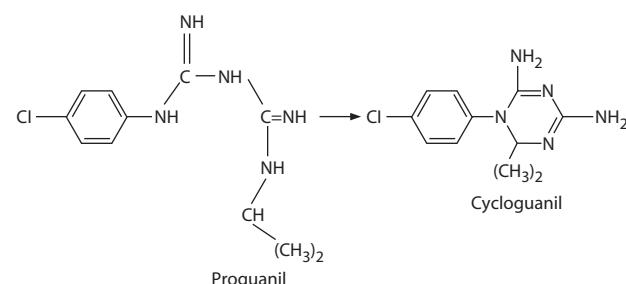

Turner NA, Russell AD, Furr JR, Lloyd D. Emergence of resistance to biocides during differentiation of *Acanthamoeba castellanii*. *J Antimicrob Chemother.* 2000;46:27–34.

BIGUANIDES

The biguanides proguanil and chlorproguanil are prodrugs, metabolized in vivo to the triazines cycloguanil and chlorcycloguanil, which have much enhanced activity in malaria treatment. Along with the diaminopyrimidines (Ch. 17), they are often referred to as antifolates due to their mechanism of action (p. 17). Proguanil is also used in combination with atovaquone, but the interaction has a different basis; antifolates do not enhance the effect of atovaquone.

PROGUANIL

Chlorguanide. Molecular weight (free base): 253.8; (hydrochloride): 290.2.

A synthetic arylbiguanide, formulated as the hydrochloride for oral use. It is slightly soluble in water.

ANTIMICROBIAL ACTIVITY

Proguanil has low antiplasmodial action, but useful activity is attributable to the metabolite cycloguanil, which inhibits the early erythrocytic stages of all four *Plasmodium* spp. that cause human malaria and the primary hepatic stage of *P. falciparum*. Proguanil acts synergistically with atovaquone and probably enhances its effect on mitochondrial membrane charge.

ACQUIRED RESISTANCE

Resistance of *P. falciparum* associated with point mutations of dihydrofolate reductase has been reported worldwide. Resistance in *P. vivax* and *P. malariae* has been reported in South East Asia. Cross-resistance with pyrimethamine is not absolute, because differential resistance can arise from different point mutations on the dihydrofolate reductase gene.

PHARMACOKINETICS

Oral absorption	>90%
C_{max} 100 mg oral	0.4 mg/L after 2–4 h
Plasma half-life	10 h
Plasma protein binding	75%

Oral absorption is slow. It is 75% protein bound and is concentrated 10- to 15-fold by erythrocytes. About 20% of the drug is metabolized to dihydrotriazene derivatives, most importantly cycloguanil, by hepatic cytochrome P_{450} processes. Cycloguanil is detectable 2 h after administration of proguanil. High proportions of ‘non-metabolizers’ have been identified in Japan and Kenya, indicating another source of resistance. About 60% of the dose is excreted in the urine.

TOXICITY AND SIDE EFFECTS

It is well tolerated at recommended doses. Gastrointestinal and renal effects have been reported at doses exceeding 600 mg per day.

CLINICAL USE

Antimalarial prophylaxis (usually in combination with chloroquine)
Treatment and prophylaxis for drug-resistant falciparum malaria (in combination with atovaquone)

Preparations and dosage

Proprietary names: Paludrine, Malarone (combination with atovaquone).

Preparation: Tablets.

For malaria prophylaxis, see specialist guidelines.

Widely available.

SESSQUITERPENE LACTONES

Artemisinin (qinghaosu), a compound derived from a plant used in traditional Chinese medicine, *Artemisia annua*, has been used extensively in East Asia and Africa for the treatment of malaria. This drug, and derivatives that have higher intrinsic antimalarial activity (artesunate, artemether and arteether), have replaced quinine as a treatment of falciparum malaria in many countries, normally in combination with other antimalarials. A semisynthetic derivative, artemisone, which has higher efficacy than artesunate and lower toxicity potential, is in development. Artemisinin and its derivatives also show broad antiprotozoal, anthelmintic and antiviral activities.

The novel structure, containing an endoperoxide bridge, has stimulated the development of semisynthetic and synthetic dioxane, trioxane and tetroxane compounds with activity against *Plasmodium* spp. and *Schistosoma* spp. Some of these synthetic trioxalanes are now in clinical development with Medicines for Malaria Venture and other organizations.

White NJ. Qinghaosu (artemisinin): the price of success. *Science*. 2008;320:330–334.

ARTEMISININ

Qinghaosu. Molecular weight (native compound): 282.3; (artemether): 298.4; (sodium artesunate): 407.4: (dihydroartemisinin): 284.3

A sesquiterpene peroxide derived from *A. annua*, chiefly used in the form of artemether, the methyl ester synthesized from dihydroartemisinin, or artesunate, the water-soluble hemisuccinate. Formulated for administration by the oral, intramuscular or intrarectal routes; artesunate can also be given intravenously.

ANTIMICROBIAL ACTIVITY

Artemisinins are active against the erythrocytic and gamete stages of chloroquine-sensitive and chloroquine-resistant strains of *P. falciparum* and other malaria parasites. Two anomers of artemether are produced on synthesis, α -artemether and β -artemether, of which the latter has higher antimalarial activity. Activity against the protozoa *Tox. gondii* and *Leishmania major* and the helminth *Schistosoma mansoni* has been demonstrated in experimental models.

ACQUIRED RESISTANCE

Resistance caused, for example, by changes in the plasmoidal endoplasmic reticulum ATPase has been shown in experimental models. There have been clinical reports of reduced susceptibility to treatment with artesunate in Cambodia.

PHARMACOKINETICS

Oral absorption	Incomplete
C_{\max} 500 mg oral	0.4 mg/L after 1.8 h
Plasma half-life (dihydroartemisinin)	40–60 min
Volume of distribution	c. 0.25 L/kg
Plasma protein binding (artemether)	77%

Artemisinins are concentrated by erythrocytes and are rapidly hydrolyzed to dihydroartemisinin. They are hydroxylated by cytochromes 2B6, 2C19 and 3A4; the derivatives induce this metabolism. After injection, peak plasma concentrations are reached within 1–3 h, when levels of dihydroartemisinin are included. The elimination half-life of intravenous artesunate is <30 min; artemether appears to have a much longer half-life (4–11 h).

TOXICITY AND SIDE EFFECTS

A few toxic effects in addition to drug-induced fever and a reversible decrease in reticulocyte counts have been reported. High-dose studies in animal models show neurotoxicity and reproducible dose-related neuropathic lesions; dihydroartemisinin is a toxic metabolite but the precise causes of neurotoxicity are not clear. Embryotoxicity of artemisinin and derivatives has been reported in rodent and primate models, probably due to depletion of erythroblasts.

CLINICAL USE

Malaria (including cerebral malaria), in combination with other antimalarials

Preparations and dosage

Preparations: Tablets, injection, suppositories.

Available in artesunate–amodiaquine, artesunate–mefloquine and artemether–lumefantrine co-formulations

Dosage: Adults, oral, 25 mg/kg on the first day, then 12.5 mg/kg on days two and three (plus mefloquine on day two to effect a radical cure). Other derivatives can also be given.

Limited availability.

MISCELLANEOUS ANTIprotozoal AGENTS

ATOVAQUONE

Molecular weight: 366.8.

A hydroxynaphthoquinone. Available as the *trans* isomer (which is more active than the *cis* form) for oral use. It is insoluble in water.

ANTIMICROBIAL ACTIVITY

It is active against erythrocytic, liver and sexual stages of malaria parasites. It shows synergy with proguanil and tetracyclines in vitro. It is also active against *Babesia* spp. and both tachyzoites and cysts of *Tox. gondii*. *Pn. jirovecii* is sensitive in vitro at 0.1–3.0 mg/L and high doses are effective in the rat.

ACQUIRED RESISTANCE

Point mutations on parasite cytochrome b, in particular at codon 268, cause resistance and readily occur when the drug is used alone. The rapid selection of resistance led to the development of the synergistic combination with proguanil. Failure of *Pn. jirovecii* prophylaxis has also been associated with cytochrome b mutations.

PHARMACOKINETICS

Oral absorption	Poor
C_{\max} 750 mg oral	27 mg/L (steady state)
Plasma half-life	70 h
Plasma protein binding	>99%

Further information

Hartwig CL, Rosenthal AS, D'Angelo J, Griffin CE, Posner GH, Cooper RA. Accumulation of artemisinin trioxane derivatives within neutral lipids of

It is highly lipophilic and is poorly absorbed from the gastrointestinal tract following oral administration. Bioavailability is improved when administered with meals, particularly those with a high fat content. Steady-state plasma concentrations are up to 50% lower in AIDS patients than in asymptomatic HIV-positive cases and the elimination half-life is lower (55 h) in patients with AIDS. The concentration in CSF is <1% of the plasma level. Unlike some other naphthoquinones it is not metabolized by human liver microsomes. Combinations with co-trimoxazole (in HIV patients) and with proguanil plus artesunate in healthy adults did not produce any changes in atovaquone pharmacokinetics.

TOXICITY AND SIDE EFFECTS

Most clinical trials of atovaquone alone have involved patients with AIDS in whom adverse effects are often difficult to detect; however, more than 20% reported fever, nausea, diarrhea and rashes. There were limited changes in hepatocellular function. In malaria, in combination with proguanil, there are few reported side effects.

CLINICAL USE

Pn. jirovecii pneumonia; alternative therapy for mild to moderate illness (prophylaxis and treatment)
Prophylaxis and treatment of malaria in combination with proguanil

It has also been used in cerebral toxoplasmosis in AIDS patients and in a few cases of human babesiosis.

Preparations and dosage

Proprietary names: Malarone (atovaquone–proguanil), Mepron (atovaquone suspension), Wellvone.

Preparations: Tablets, oral suspension.

Dosage:

Pn. jirovecii pneumonia treatment: adults, oral, 750 mg every 12 h (suspension) or every 8 h (tablets) for 21 days.

Malaria treatment: adults, oral, 1 g per day (plus proguanil 400 mg per day) for 3 days.

Malaria prophylaxis: see specialist guidelines.

Widely available.

DEHYDROEMETINE

The synthetic racemic derivative of the plant alkaloid emetine. Formulated as the hydrochloride for intramuscular administration. Like the parent compound, emetine, it inhibits *E. histolytica* at concentrations of 1–10 mg/L in vitro, but it is more active than the parent in animal models. Drug-resistance in *E. histolytica* is rare.

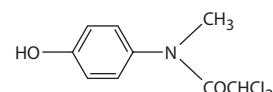

No human pharmacokinetic data are available. A half-life of 2 days, compared with 5 days for emetine, has been reported. There is selective tissue binding and accumulation in the liver, lung, spleen and kidney.

It is considerably less toxic than emetine, possibly because it is more rapidly eliminated. Nevertheless, nausea, vomiting, diarrhea and abdominal cramps frequently occur. Neuromuscular effects have also been reported. More serious cardiotoxic effects can lead to electrocardiogram (EGG) changes, tachycardia and a drop in blood pressure.

It was formerly used as a second-line treatment in severe intestinal or hepatic amebiasis, but is no longer recommended for use.

DILOXANIDE

Molecular weight (furoate): 328.1.

Dichloro(hydroxyphenyl)methylacetamide. Available as an insoluble ester, the furoate, for oral administration.

ANTIMICROBIAL ACTIVITY

Diloxanide inhibits *E. histolytica* with unusually high specificity at concentrations of 0.01–0.1 mg/L.

ACQUIRED RESISTANCE

No resistance has been reported. Patients with dysentery have lower cure rates than cyst excretors.

PHARMACOKINETICS

Human pharmacokinetic data are limited. Animal data show that diloxanide furoate is rapidly absorbed from the intestine. The furoate is hydrolyzed in the gut, leaving high intraluminal

concentrations of free diloxanide. About 75% is excreted via the kidney within 48 h, mostly as a glucuronide.

TOXICITY AND SIDE EFFECTS

It is well tolerated, but flatulence is common, and nausea and vomiting may occur.

CLINICAL USE

Asymptomatic intestinal infection with *E. histolytica*

It is also used in invasive amoebiasis in conjunction with nitroimidazoles in order to eradicate luminal cysts.

Preparations and dosage

Proprietary names: Entamizole, Furamide.

Preparation: Tablets.

Dosage: Adults, oral, 500 mg every 8 h for 10 days. Children >25 kg, oral, 20 mg/kg per day in three divided doses for 10 days.

Limited availability. Available in the UK and the USA.

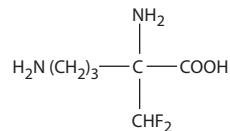

Further information

Blessmann J, Tannich E. Treatment of asymptomatic intestinal *Entamoeba histolytica* infection. *N Engl J Med*. 2002;347:1384.

Pritt BS, Clark CG. Amebiasis. *Mayo Clin Proc*. 2008;83:1154–1160.

EFLORNITHINE

α -Difluoromethylornithine. Molecular weight (free base): 182.2; (hydrochloride monohydrate): 236.6.

An analog of ornithine, formulated as the hydrochloride for intravenous infusion. It is freely soluble in water.

ANTIMICROBIAL ACTIVITY

Cultured bloodstream trypomastigotes of *T. brucei* are relatively insensitive, but high doses are effective against bloodstream and CNS infections of *T. brucei brucei* and *T. brucei gambiense* in rodents, provided a strong antibody response is also present. Eflornithine entry into the CNS can be

enhanced with suramin (see p. 424–425). *T. brucei rhodesiense* infections do not respond. Synergy with some arsenicals has been demonstrated.

Eflornithine is active against *P. falciparum* in experimental models and against *Leishmania* promastigotes and *Giardia lamblia* in culture.

ACQUIRED RESISTANCE

Acquired resistance in *T. brucei gambiense* in West Africa has not been reported. East African *T. brucei rhodesiense* strains are innately less sensitive. Reported treatment failures are thought to be associated with severity of disease.

PHARMACOKINETICS

Oral absorption	55%
C_{max} 10 mg/kg oral	c. 7 mg/L after 4 h
200 mg/kg intravenously	15.9 mg/L (87.5 nmol/mL) (mean)
Plasma half-life	3.3 h
Volume of distribution	0.34 L/kg
Plasma protein binding	Very low

Renal clearance is 83%, with most eliminated unchanged. In a study in Zaire the mean serum concentration in children under 12 years old was half that of adults, probably due to more rapid renal clearance. CNS penetration is good in adult patients, with a CSF:plasma ratio of 0.91 at the end of administration for 14 days. However, the CSF:plasma ratio in children under 12 years old was 0.58. Relapses have been recorded in patients in whom CSF levels dropped below 9 mg/L (50 nmol/mL) at the end of treatment.

TOXICITY AND SIDE EFFECTS

Osmotic diarrhea and bone marrow suppression are common, and up to 50% of sleeping sickness patients develop leukopenia. Reversible anemia and thrombocytopenia have been observed. Convulsions and seizures, different from those observed in melarsoprol-induced encephalopathy, have been reported in 4–18% of treated sleeping sickness patients but not in patients treated for *Pn. jirovecii* pneumonia. This difference might be due to the CNS inflammation associated with sleeping sickness.

CLINICAL USE

Late-stage *T. brucei gambiense* infections (including arsenic-resistant cases)

It has been used speculatively for treatment of *Pn. jirovecii* infections in AIDS patients. Co-administration with oral

nifurtimox has been added to the World Health Organization (WHO) List of Essential Medicines for second-stage sleeping sickness caused by *T. brucei gambiense*.

Preparations and dosage

Proprietary name: Ornidyl.

Preparation: Injection.

Dosage: Trypanosomiasis: adults, i.v., 400 mg/kg per day in divided doses for at least 14 days.

Limited availability.

Sanderson L, Dogruel M, Rodgers J, Bradley B, Thomas SA. The blood–brain barrier significantly limits eflornithine entry into *Trypanosoma brucei brucei* infected mouse brain. *J Neurochem.* 2008;107:1136–1146.

HALOFANTRINE

Molecular weight (free base): 500.4; (hydrochloride): 536.9.

A phenanthrene methanol, formulated as the hydrochloride for oral administration. Parenteral formulations are not available. The enantiomers have equivalent activity in vitro. Aqueous solubility is extremely low.

ANTIMICROBIAL ACTIVITY

It inhibits erythrocytic stages of chloroquine-sensitive and chloroquine-resistant *P. falciparum* and other *Plasmodium* spp. in vitro at concentrations of 0.4–4.0 mg/L. It is more active than mefloquine and the combination of proguanil and atovaquone against *P. falciparum*, but less effective than mefloquine or chloroquine against *P. vivax*.

ACQUIRED RESISTANCE

Resistance in *P. falciparum* has been reported in Central and West Africa, where it has been used widely. Cross-resistance with mefloquine has been reported in Thailand, where it has not been used.

PHARMACOKINETICS

Absorption shows high intra- and inter-subject variability and depends on co-administration with fats. Bioavailability is increased more than six-fold after a fatty meal or by lipid-based formulations. Bioavailability is significantly lower in patients with malaria than in healthy individuals. Peak plasma levels are variable and occur 3–6 h after administration. Unlike many other antimalarials, halofantrine is not concentrated by infected or uninfected erythrocytes. Distribution to lipoproteins is stereo-selective. About 20–30% of the dose is metabolized to an *N*-desbutyl derivative by cytochrome P₄₅₀ (CYP) 3A4 and 3A5. The elimination half-life of the parent drug is generally 1–2 days and that of the metabolite 3 days. Little unchanged drug is excreted in urine.

TOXICITY AND SIDE EFFECTS

Abdominal pain, diarrhea and pruritus are the most frequent. High doses (24 mg/kg) induce prolongation of the PR and QTc intervals; this is not stereo-selective. There are individual reports of fatal cardiac arrest and torsade de pointes. To reduce the risk of cardiac toxicity it should be taken on an empty stomach. It should not be administered with other antimalarials that have the potency to induce cardiac arrhythmias (mefloquine, chloroquine, quinine). Halofantrine has also been associated with intravascular hemolysis.

CLINICAL USE

Treatment of multidrug-resistant falciparum malaria

Its use has been questioned due to the existence of safer alternatives.

Preparations and dosage

Proprietary name: Halfan.

Preparation: Tablets.

Dosage: Treatment of falciparum malaria: Adults, oral, 1.5 g divided into three doses of 500 mg given at intervals of 6 h on an empty stomach; repeat the course after an interval of 1 week. Children, oral, 24 mg/kg divided into three doses as adult.

Widely available.

LUMEFANTRINE

Benflumetol. Molecular weight: 528.9

A dichlorobenzylidene derivative given orally in combination with artemether.

ANTIMICROBIAL ACTIVITY

Lumefantrine has marked blood schizonticidal activity against a wide range of plasmodia, including chloroquine-resistant *P. falciparum*. The 50% and 90% effective concentrations (EC_{50} and EC_{90}) in vitro are similar: <10 and 40 nmol/L, respectively. The racemate and the two enantiomers exhibit similar activities. Blood schizonticidal activity of desbutylbenflumetol is four to five times greater than benflumetol in vitro.

ACQUIRED RESISTANCE

Treatment with artemether-lumefantrine can select for polymorphisms in the *P. falciparum pfmdr1* gene. Resistance has been selected experimentally in murine malaria.

PHARMACOKINETICS

Bioavailability after oral administration is variable; absorption is substantially increased by co-administration with food,

particularly with a high fat content. Peak plasma concentrations occur after 6–8 h. The elimination half-life is 4–6 days. It is almost completely protein bound and metabolized mainly in the liver by CYP3A4.

TOXICITY AND SIDE EFFECTS

The most common adverse effects in combination with artemether include headache, dizziness and gastrointestinal disturbances.

CLINICAL USE

Treatment of *P. falciparum* infections (including mixed infections) in a fixed-dose combination treatment with artemether.

Preparations and dosage

Proprietary name: Coartem, Riamet (contains 20 mg artemether and 120 mg lumefantrine).

Dosage: see specialist guidelines.

MEPACRINE

Quinacrine (USAN). Molecular weight (dihydrochloride): 508.9.

A synthetic acridine derivative, formulated as the hydrochloride for oral use.

ANTIMICROBIAL ACTIVITY

Mepacrine is active against the asexual erythrocytic stage of all four *Plasmodium* spp. that infect humans and the gametocytes of *P. vivax* and *P. malariae*. The enantiomers have equal antimalarial activity. It exhibits broad activity in experimental models against *T. cruzi*, *Leishmania* spp., *E. histolytica*, *Trichomonas vaginalis*, *G. lamblia* and *Blastocystis hominis*. It is also active against tapeworms.

ACQUIRED RESISTANCE

The structural resemblance to chloroquine suggests the likelihood of cross-resistance with that drug, but evidence for this is equivocal.

PHARMACOKINETICS

Oral absorption	Good
C_{\max} 100 mg oral	50 µg/L after 1–3 h
Plasma half-life	5 days
Plasma protein binding	85%

There is extensive tissue binding and a six-fold concentration into leukocytes from plasma. About 10% of the daily dose is excreted in the urine. It is widely distributed throughout the body.

TOXICITY AND SIDE EFFECTS

Dizziness, headache and gastric problems are common. Toxic psychoses, bone marrow depression, yellow skin and exfoliative dermatitis are described. Poor toleration is noted, especially in children. It should not be used in combination with 8-aminoquinolines.

CLINICAL USE

Giardiasis
Prophylaxis of malaria
Tapeworm infections

Preparations and dosage

Preparation: Tablets.

Dosage: Adults, oral, 100 mg every 8 h for 5–7 days. A second course of treatment after 2 weeks is sometimes required. Children, oral, 2 mg/kg every 8 h.

Limited availability.

It has been superseded by other drugs, but is useful in giardiasis if treatment with nitroimidazoles fails. Intralesional injections have been tried in cutaneous leishmaniasis.

MILTEFOSINE

Hexadecylphosphocholine. Molecular weight: 407.58.

An alkylphospholipid, originally investigated as an anticancer compound, formulated for oral administration.

ANTIMICROBIAL ACTIVITY

Concentrations of 1–5 µM inhibit the promastigotes and amastigotes of *Leishmania* spp. and the epimastigotes and amastigotes of *T. cruzi*. Inhibitory concentrations against *T. brucei* spp. and *E. histolytica* are closer to 50 µM. *Acanthamoeba* spp. are variably susceptible, depending on the experimental conditions.

ACQUIRED RESISTANCE

There are no reports of clinical resistance in *Leishmania* so far. Experimental resistance has been induced in vitro against the promastigote stage of *Leishmania* and two plasma membrane proteins, LdMT and Ld Ros3, are necessary for miltefosine uptake. There is evidence that reduced sensitivity of promastigotes is passed on to intracellular amastigotes.

PHARMACOKINETICS

In rodent models the drug is almost completely absorbed after oral administration. About 90% is bound to plasma proteins. It is widely distributed in the body; studies in rats showed highest uptake in kidney, liver and spleen. In rats and dogs bioavailability was 82% and 94%, with maximum values reached after 4–48 h.

In adult human trials repeated oral dosing with 100 mg per day achieved a peak plasma concentration of 70 mg/L after 8–24 h (day 23). The half-life is 6–8 days.

TOXICITY AND SIDE EFFECTS

Mild to moderate gastrointestinal side effects are reported in 40–60% of patients. Moderate to severe nephrotoxicity was seen in 2% and 1% of patients, respectively; increases in creatinine levels were reversible. Miltefosine is contraindicated in pregnancy, based on findings of teratogenicity in rats. It causes hemolysis and cannot be given intravenously.

CLINICAL USE

Visceral leishmaniasis
Cutaneous leishmaniasis

Preparations and dosage

Proprietary name: Impavido, Miltex.
Preparation: Capsules (10 and 50 mg miltefosine).
Dosage: 2.5 mg/kg per day orally for 28 days (usually 100–150 mg per day) (maximum dose, 150 mg per day).
Available through private and public sources in India.

Studies to investigate short-course combination treatments with miltefosine are in progress.

NITAZOXANIDE

Molecular weight: 307.3

A synthetic broad-spectrum antiparasitic nitroheterocycle (2-acetyl-oxo-N-(5-nitro-2-thiazoly) benzamide), formulated for oral use.

ANTIMICROBIAL ACTIVITY

In vitro *Cryptosporidium parvum* sporocytes and oocysts are inhibited by <33 µM, and *Giardia lamblia* (*intestinalis*) trophozoites by <10 µM. The metabolite tizoxanide is more active than the parent compound against some isolates. *E. histolytica* is inhibited by 6–23 µM (parent compound) and 5.6–28 µM (metabolite), and *T. vaginalis* by 0.5–15.5 µM (parent compound) and 0.3–12.2 µM (metabolite). Activity against other microorganisms, including some helminths, bacteria (*Clostridium difficile*) and viruses (hepatitis C) has also been demonstrated.

ACQUIRED RESISTANCE

Resistance caused by altered expression of genes involved in stress response has been demonstrated in experimental studies with *G. lamblia*.

PHARMACOKINETICS

After oral administration the major circulating metabolites are tizoxanide (desacetyl nitazoxanide) and its glucuronide. Minor metabolites include salicyluric acid and tizoxanide sulfate. Maximum concentrations of the active metabolites tizoxanide and tizoxanide glucuronide are observed within 1–4 h. Following a single oral dose of 500 mg given with food, the C_{max} of both metabolites was around 10 mg/L. Tizoxanide has a half-life of around 1–2 h and is >99.9% bound to plasma proteins.

TOXICITY AND SIDE EFFECTS

Nitazoxanide appears well tolerated. Side effects may include abdominal pain, diarrhea, headache and nausea.

CLINICAL USE

It is indicated for the treatment of diarrhea caused by *G. lamblia* or *C. parvum*.

Preparations and dosage

- Proprietary name:** Alinia.
Preparations: Oral suspension, tablets.
Dosage: 1–3 years of age: 5 mL (100 mg nitazoxanide) oral suspension every 12 h with food for 3 days; 4–11 years: 10 mL (200 mg nitazoxanide) oral suspension every 12 h with food for 3 days; ≥12 years: 1 tablet (500 mg nitazoxanide) every 12 h with food for 3 days or 25 mL oral suspension (500 mg nitazoxanide) every 12 h with food for 3 days.
Available in USA.

PYRONARIDINE

Molecular weight: 518.06.

An aza-aminoacridine formulated for oral use. A Mannich-base derivative of mepacrine (see p. 421).

ANTIMICROBIAL ACTIVITY

Pyronaridine is active against the asexual erythrocytic stage of *P.falciparum* with little or no activity against gametocytes or the hepatic stage. In-vitro blood schizonticide activities are in the range of 0.001–0.03 mg/L, showing a moderate correlation to chloroquine resistance. However, this correlation varies between studies and does not seem to be clinically significant. It is also active against *P.vivax*, *P.ovale* and *P.malariae*. Antagonistic interactions with artemisinins were reported in vitro, but synergy with artesunate has been observed in rodent models.

ACQUIRED RESISTANCE

Decreasing in-vitro sensitivity has been observed in China.

PHARMACOKINETICS

Peak plasma concentrations are reached after 3–14 h depending upon the formulation; there is also considerable interindividual variation. Elimination half-lives of 63–190 h have been reported, again dependent upon the formulation.

TOXICITY AND SIDE EFFECTS

It is well tolerated and no outstanding toxic effects have been reported.

CLINICAL USE

Treatment of uncomplicated *P.falciparum* and *P.vivax* malaria

A fixed-dose combination with artesunate (Pyramax) is being developed for uncomplicated *P.falciparum* and *P.vivax* malaria.

Preparations and dosage

Not widely available. Oral formulations have been used in China and in clinical trials in Thailand and Africa.

SURAMIN

Molecular weight (hexasodium salt): 1429.21.

A sulfated naphthylamine formulated for intravenous administration. It is freely soluble in water. The dry powder is stable, but it is hygroscopic and unstable in solution.

ANTIMICROBIAL ACTIVITY

Suramin has no significant trypanocidal activity in vitro, but is effective in animals infected with *T. brucei*. Trypanosomes take up suramin bound to plasma protein by a combination of fluid phase and receptor-mediated endocytosis. It acts synergistically with nitroimidazoles and eflornithine in the elimination of trypanosomes from CSF of infected mice.

ACQUIRED RESISTANCE

Relapse rates of 30–50% have been recorded in Kenya and Tanzania but there is no evidence of resistant parasites. Stable resistance has been described in the related camel parasite *Trypanosoma evansi*.

PHARMACOKINETICS

Oral absorption	Poor
C_{\max} 1 g intravenous doses (6 doses at weekly intervals)	100 mg/L
Plasma half-life	44–54 days
Volume of distribution	20–80 L
Plasma protein binding	>99%

It is normally administered by slow intravenous infusion. It can be detected in blood for 3 months; plasma levels >100 mg/L were observed for several weeks after a 6-week course of treatment. No metabolism was observed and 80% was removed by renal clearance. Distribution to mononuclear phagocytes, especially liver macrophages, the adrenal glands and the kidney is high. It does not enter erythrocytes and penetrates the blood–brain barrier poorly.

TOXICITY AND SIDE EFFECTS

Suramin is toxic, especially in malnourished patients. A test dose of 200 mg has been recommended. Immediate febrile reactions (nausea, vomiting, loss of consciousness) can be avoided by slow intravenous administration. Intramuscular or subcutaneous injections are painful and irritating, and can be followed by fever and urticaria. Anaphylactic shock occurs in fewer than 1 in 2000 patients. Delayed reactions include renal damage, exfoliative dermatitis, anemia, leukopenia, agranulocytosis, jaundice and diarrhea.

CLINICAL USE

African sleeping sickness (early stage before CNS involvement)
Onchocerciasis

Preparations and dosage

Preparation: Injection.

Dosage: The dose schedule varies depending on the stage of the disease.
Limited availability.

ANTIBACTERIAL AND OTHER ANTIMICROBIAL AGENTS USED FOR PROTOZOAL DISEASES

Properties of the diaminopyrimidines (Ch. 17), sulfonamides (Ch. 29) nitroimidazoles (Ch. 24) and nitrofurans (Ch. 31) that are used as antiprotozoal agents are described in the appropriate chapters. Among antibiotics, tetracyclines (Ch. 30), clindamycin (Ch. 21) and certain macrolides (Ch. 22) have a place in the treatment of some protozoal diseases, including malaria and toxoplasmosis. The aminoglycoside paromomycin (Ch. 12) is sometimes used in amebiasis, leishmaniasis and in intractable cryptosporidiosis.

Antifungal polyene and azole derivatives (Ch. 32) are increasingly used in diseases caused by protozoa. Both extracellular and intracellular forms of *Leishmania* spp. and *T. cruzi* are highly sensitive to amphotericin B in vitro at concentrations below 1 mg/L. Lipid formulations, in particular liposomal amphotericin B (p. 378), are highly effective in visceral leishmaniasis. Amphotericin B is also used for the treatment of primarily amebic meningoencephalitis caused by *Naegleria fowleri*.

The imidazoles miconazole and ketoconazole (p. 370) and the triazole itraconazole (p. 369) are active against *Leishmania* spp. and *T. cruzi* in experimental models, but results have been equivocal in clinical trials. The triazoles posaconazole (p. 371) and ravuconazole are effective against *T. cruzi* in experimental models and may be useful in the treatment of Chagas disease. The anthelmintic benzimidazole albendazole (p. 396) is effective in infections caused by *G. lamblia*.

Mark Boyd and David A. Cooper

Recognition of the serious threat that the human immunodeficiency virus (HIV) presents to global health and security has stimulated an enormous investment in the development of anti-HIV therapies. This has occurred in parallel with advances in the understanding of HIV replication; in particular, the identification of steps in the replicative cycle that are unique to the virus and thus potential targets for chemotherapy (Figure 36.1).

The human immunodeficiency virus is a member of the lentivirus subfamily of human retroviruses with a double-stranded RNA genome encoding at least nine functional or regulatory proteins. There are several potential points at which the process of virus replication could be blocked:

- Entry into host-cell membranes
- Reverse-transcription of the virus genome
- Integration of virus into the host genome
- Virus assembly and maturation.

The use of combination antiretroviral therapy has resulted in significant and sustained reductions in morbidity and mortality in people with HIV infection, but no currently available therapy is curative. Once initiated, treatment is a lifelong commitment. Adverse effects and toxicities arise during long-term exposure but the causal relationship between individual drugs and specific adverse effects, and the degree to which HIV infection or immunodeficiency itself contributes to pathogenesis, continues to be difficult to define. Many other challenges remain, arising from drug interactions, problems of long-term adherence to therapy and drug resistance.

Because antiretroviral drugs act intracellularly, where relative concentrations are virtually impossible to predict or measure, little reliable information is available that relates plasma concentrations to in-vivo effectiveness. Clinical studies continue to attempt to determine the extent to which plasma drug level monitoring may be of clinical use in the treatment of HIV disease. Of all the available ART classes the

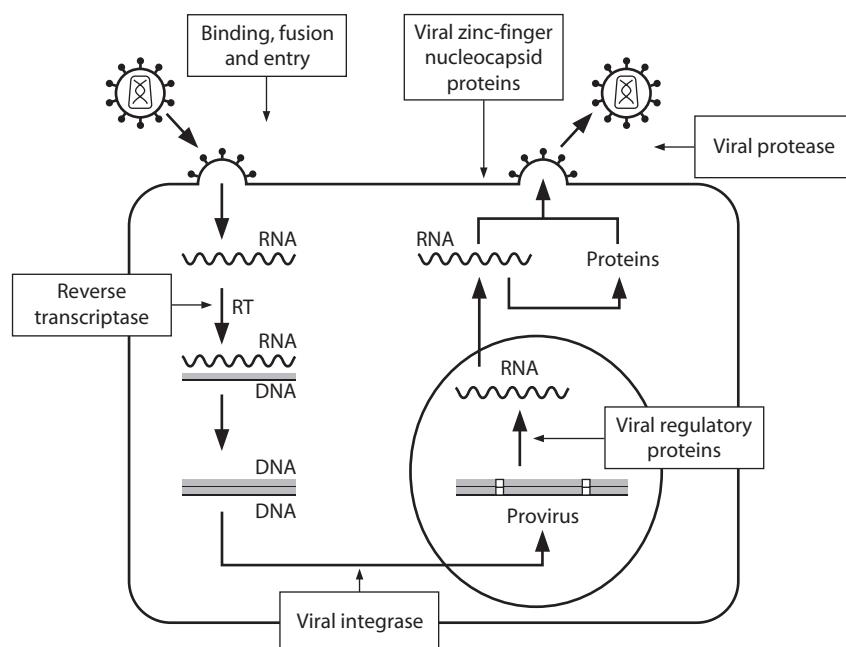

Fig. 36.1 Schematic representation of the HIV replicative cycle. Points at which antiretroviral therapies can inhibit virus replication are shown in boxed arrows.

most evidence exists for a possible role of therapeutic drug monitoring (TDM) in the management of HIV Protease Inhibitors (PIs) and Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs). In the pharmacokinetic tables that accompany each drug in this chapter C_{min} values for the PIs and NNRTIs have therefore been included.

Data on the human use of antiretroviral agents are mostly derived from developed countries in which HIV subtype B is most common. With the availability of cheap generic versions of antiretrovirals in low- and middle-income countries, data are emerging which suggest that other subtypes may be associated with different resistance pathways. Thus it seems that HIV subtype C is more likely to select for resistance to thymidine analogs through the K65R mutation. This bias in the database should be borne in mind when reading this chapter.

CLASSIFICATION

Drugs that interfere with HIV replication are categorized into five types based on where in the HIV replicative cycle they exert inhibitory effects:

- Nucleoside reverse transcriptase inhibitors (NRTIs) and nucleotide reverse transcriptase inhibitors (N(t)RTIs) are analogs of naturally occurring deoxynucleotides and compete with them for incorporation into the growing viral DNA chain.
- Non-nucleoside reverse transcriptase inhibitors (NNRTIs) bind to a site distant to the catalytic site of reverse transcriptase, inhibiting the movement of protein domains required for DNA synthesis.
- HIV protease inhibitors block enzymic cleavage of HIV *gag-pol* proteins.
- HIV entry inhibitors prevent virion entry into cells in two ways: by preventing fusion with the cellular membrane; or as antagonists of one of the two chemokine co-receptors (CCR5 and CXCR4) that HIV attaches to in combination with the CD4 molecule to gain entry into the human cell.
- HIV integrase inhibitors block the enzyme responsible for incorporation of viral DNA into the host chromosome.

INTERACTIONS

HIV protease inhibitors, NNRTIs or CCR5 antagonists should not be co-administered with certain other drugs because of the potential for serious interactions or loss of efficacy. These interactions are described in detail at the US Department of Health and Human Services website (<http://aidsinfo.nih.gov/content-files/AdultandAdolescentGL.pdf>), which is updated regularly. Readers are also referred to the website of the Liverpool HIV Pharmacology Group at the University of Liverpool (<http://www.hiv-druginteractions.org>), another useful and frequently updated tool, and to Chapter 6 in this book.

NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

NRTIs are dideoxynucleosides that undergo intracellular phosphorylation to yield triphosphates, which inhibit HIV-1 and HIV-2 replication.

In addition to sharing a common mode of action, these drugs have a number of overlapping toxicities that may arise through a common pathway. They inhibit some mammalian DNA polymerases, in particular those found exclusively within mitochondria. Interference with mitochondrial replication and function is likely to be a mechanism through which several significant toxicities, including fatal and non-fatal cases of lactic acidosis with hepatomegaly, are mediated. Laboratory investigations indicate that the potency of this class of drugs for inhibition of cellular DNA polymerases is: zalcitabine ≥ didanosine ≥ stavudine > zidovudine > abacavir = tenofovir = lamivudine = emtricitabine.

Resistance is well described, often associated with failure of combination therapy to control viral replication. Resistant isolates may show varying degrees of cross-resistance to other drugs within the class, and a switch to an apparently active alternative drug(s) within the class can be accompanied by selection of highly resistant variants at the cost of only minimal evolutionary changes to the virus.

ABACAVIR

Molecular weight: 670.76.

A synthetic analog of guanine formulated for oral use.

ANTIVIRAL ACTIVITY

Abacavir has activity against HIV-1, HIV-2 and human T-cell lymphotropic virus type-1 (HTLV-1).

ACQUIRED RESISTANCE

Resistance is associated with specific changes in codons 184 with 65, 74 or 115 in the HIV reverse transcriptase codon region.

PHARMACOKINETICS

Oral absorption	83%
C_{\max} 300 mg oral twice daily	3.0 ± 0.89 mg/L
600 mg once daily	4.26 mg/L
Plasma half-life	1.5 h
Volume of distribution	0.8 L/kg
Plasma protein binding	c. 49%

Absorption

After oral administration abacavir sulfate undergoes rapid and extensive absorption unaffected by food.

Distribution

It penetrates well into the cerebrospinal fluid (CSF) and is an NRTI of choice if this characteristic is thought desirable. Good penetration into the male genital tract has been observed. The drug is secreted into human breast milk.

Metabolism

It is primarily metabolized in the liver, mainly by alcohol dehydrogenase and glucuronidation.

Excretion

Around 83% of the dose is eliminated in the urine, <2% as unchanged drug; the remainder is excreted in the feces.

Dose adjustment is unnecessary in renal impairment. It can be used in moderate hepatic impairment, but is contraindicated if dysfunction is severe.

TOXICITY AND SIDE EFFECTS

Life-threatening hypersensitivity reactions occur in 5–8% of all individuals, necessitating discontinuation of the drug. Typically patients present within the first 6 weeks of starting treatment with fever, rash or other symptoms that worsen in severity with continued drug exposure. Hypersensitivity is associated with carriage of the major histocompatibility complex class I allele HLA-B57*01 and screening for this allele can significantly reduce the incidence of this effect.

Current or recent (within the preceding 6 months) use of abacavir has been associated with a risk of myocardial infarction, but studies have yielded conflicting data.

CLINICAL USE

Treatment of HIV infection in adults and children (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Ziagen.

Preparations: Tablets (300 and 600 mg), oral solution (20 mg/mL). The oral solution contains sorbitol, which is metabolized to fructose and is unsuitable for patients with hereditary fructose intolerance.

Dosage: Adults, oral, 300 mg every 12 h or 600 mg once daily. Children target dosing range: 8–10 mg/kg per dose every 12 h (maximum dose, 300 mg every 12 h).

Available alone, in combination with lamivudine, and in combination with zidovudine and lamivudine.

DIDANOSINE

Molecular weight: 236.2.

An analog of deoxyadenosine, formulated for oral administration.

ANTIVIRAL ACTIVITY

Didanosine is active against HIV-1, HIV-2 and HTLV-1.

ACQUIRED RESISTANCE

Codon changes at positions 65 or 74 in HIV reverse transcriptase are associated with reduced susceptibility.

PHARMACOKINETICS

Oral absorption	c. 40%
C_{max} 400 mg once daily	0.93 mg/L
Plasma half-life	c. 1.4 h
Volume of distribution	c. 1 L/kg
Plasma protein binding	<5%

Absorption

Bioavailability is reduced by about half when taken with food and the drug should be given at least 30 min before a meal. The peak plasma concentration achieved by enteric-coated tablets is less than half that of buffered tablets.

Distribution

Central nervous system (CNS) penetration is relatively poor. Median concentrations in semen (455 ng/mL; range <50–2190 ng/mL) are greater than those in blood (<50 ng/mL; range <50–860 ng/mL). It is secreted in breast milk.

Metabolism

Based upon animal studies it is presumed that metabolism occurs by the pathways responsible for the elimination of endogenous purines by xanthine oxidase. Metabolism may be altered in patients with severe hepatic impairment; however, no specific dose adjustment is recommended.

Excretion

Renal clearance by glomerular filtration and active tubular secretion accounts for 50% of total body clearance. Urinary

recovery accounts for about 20% of the oral dose in adults. The half-life increases three-fold in patients requiring dialysis. Patients with a creatinine clearance <60 mL/min may be at greater risk of toxicity.

TOXICITY AND SIDE EFFECTS

Most serious are pancreatitis (fatal and non-fatal), lactic acidosis and severe hepatomegaly with steatosis (fatal and non-fatal), retinopathy, optic neuritis and dose-related peripheral neuropathy. Patients with low body weight may require dose modification. A strong association with non-cirrhotic portal hypertension has been described.

The combination with stavudine should be avoided in pregnant women as fatal cases of lactic acidosis have been reported. Caution should also be exercised in patients with known risk factors for liver disease. Therapy should be stopped in patients who develop clinical or laboratory evidence of lactic acidosis or hepatotoxicity. Monitoring lactate levels prospectively is not recommended as mild hyperlactatemia occurs in asymptomatic patients and has a poor positive predictive value for the development of lactic acidosis.

Caution should be exercised in co-administering other drugs with known neurotoxicity and in patients with a history of neuropathy. Treatment should stop if symptoms and signs of neuropathy are observed, but the condition is usually reversible and patients with resolved neuropathy may be retreated at a reduced dosage. Retinal depigmentation has been observed in children and twice-yearly dilated retinal examination is recommended.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Videx.

Preparations: Enteric-coated capsules (125, 200, 250 and 400 mg). Also available as tablets (25, 50, 100, 150 and 200 mg) and as a powder for reconstitution.

Dosage: Adults, oral, 400 mg once daily (weight ≥60 kg) or 250 mg once daily (weight <60 kg). Children <3 months, 50 mg/m² per dose every 12 h; children >3 months, 120 mg/m² per dose every 12 h. Children 20–<25 kg, 200 mg once daily; 25–<60 kg, 250 mg once daily; ≥60 kg, 400 mg once daily. For patients <20 kg the recommended dose is based on age and body surface area: children aged 2 weeks–8 months should receive 100 mg/m² every 12 h; those older than 8 months should receive 120 mg/m² every 12 h.

Widely available.

EMTRICITABINE

Molecular weight: 247.2.

A synthetic nucleoside analog of cytosine, formulated for oral use.

ANTIVIRAL ACTIVITY

Emtricitabine is active against HIV-1, HIV-2 and hepatitis B virus (HBV).

ACQUIRED RESISTANCE

Resistance is associated with a substitution in the HIV-1 reverse transcriptase gene at codon 184 (M184V/I). Emtricitabine-resistant isolates are cross-resistant to lamivudine. HIV-1 isolates with the K65R substitution in the reverse transcriptase coding region have reduced susceptibility.

PHARMACOKINETICS

Oral absorption: capsules	93%
C_{\max} 200 mg oral once daily	1.8 ± 0.7 mg/L
Plasma half-life	c. 10 h
Volume of distribution	1.4 ± 0.3 L/kg
Plasma protein binding	<4%

Absorption and distribution

It is rapidly and extensively absorbed. There is moderate CNS penetration. The estimated semen:plasma ratio is approximately 4. There are presently no data on levels in breast milk.

Metabolism and excretion

It does not inhibit human cytochrome P₄₅₀ enzymes. About 80% is excreted in the urine, the rest in feces. Renal clearance is greater than the estimated creatinine clearance, suggesting elimination by both glomerular filtration and active tubular secretion. There may be competition for elimination with other compounds that are renally excreted. Exposure is significantly increased in renal insufficiency, but dose reductions are not generally recommended. It is unlikely that a dose adjustment would be required in the presence of hepatic impairment.

TOXICITY AND SIDE EFFECTS

At least 10% of patients suffer headache, diarrhea, nausea, fatigue, dizziness, depression, insomnia, abnormal dreams, rash, abdominal pain, asthenia, increased cough and rhinitis. Skin hyperpigmentation is common (≥10%) in pediatric patients. Emtricitabine competes with lamivudine for the enzymes involved in intracellular phosphorylation; their co-administration is contraindicated.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs)

Preparations and dosages

Proprietary name: Emtriva.

Preparations: Capsules (200 mg), oral solution (240 mg/24 mL).

Dosage: Adults: one 200 mg capsule or 24 mL solution orally once daily. Children, 0–3 months, 3 mg/kg oral solution once daily; 3 months–17 years, 6 mg/kg up to a maximum of 240 mg (24 mL); children weighing >33 kg who can swallow an intact capsule, 4.8–6 mg/kg once daily or one 200 mg capsule once daily.

Available alone, in combination with tenofovir, and in combination with tenofovir and efavirenz.

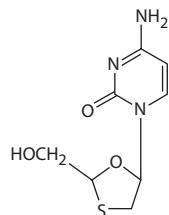

Further information

- Anderson PL. Recent developments in the clinical pharmacology of anti-HIV nucleoside analogs. *Curr Opin HIV AIDS*. 2008;3:258–265.

LAMIVUDINE

Molecular weight: 229.3.

An analog of cytidine available for oral administration.

ANTIVIRAL ACTIVITY

Lamivudine is active against HIV-1, HIV-2, HBV and HTLV-1.

ACQUIRED RESISTANCE

A single codon change at position 184 in the HIV reverse transcriptase gene confers high-level resistance. The K65R mutation is also associated with resistance. In-vitro data indicate that lamivudine resistance may restore HIV sensitivity to zidovudine- and tenofovir-resistant virus.

PHARMACOKINETICS

Oral absorption	80–85%
C_{max} 300 mg once daily	2.0 mg/L
Plasma half-life	5–7 h
Volume of distribution	1.3 L/kg
Plasma protein binding	<36%

Absorption

It is rapidly absorbed and there is no significant difference in bioavailability when taken with food.

Distribution

It penetrates moderately well into the CNS. The semen:plasma ratio is about 9.1 (2.3–16.1). It is secreted into breast milk.

Metabolism and excretion

Less than 10% of the administered dose undergoes hepatic metabolism. Over 70% of the dose is subject to renal clearance via active tubular secretion. Dosage adjustments are not routinely recommended in the presence of renal or hepatic impairment.

TOXICITY AND SIDE EFFECTS

Lamivudine is relatively safe and non-toxic. Animal studies of very high doses did not result in any organ toxicity. In patients co-infected with HIV and HBV, cessation of lamivudine therapy may result in clinical and/or laboratory evidence of recurrent hepatic disease that may be more severe in patients with hepatic decompensation. Tests of liver function and inflammation and markers of HBV replication should be periodically monitored.

Lamivudine competes with emtricitabine for the enzymes involved in intracellular phosphorylation and co-administration is contraindicated.

Treatment of HIV infection (in combination with other antiretroviral drugs)
Treatment of hepatitis B infection

Preparations and dosage

Proprietary name: Epivir.

Preparations: Tablets (150 and 300 mg). Also available as an oral solution (10 mg/mL) and as granules (25 and 50 mg).

Dosage: Adults, oral, 150 mg every 12 h or 300 mg once daily.

Children target dosing range: 4 mg/kg every 12 h (maximum dose, 300 mg per day).

Available alone, in combination with zidovudine, and in combination with zidovudine and abacavir. Various combinations with other antiretrovirals are available in generic formulations.

Lower doses are used in hepatitis B therapy.

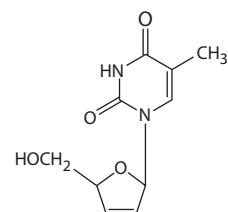

Further information

Carr A, Amin J. Efficacy and tolerability of initial antiretroviral therapy: a systematic review. *AIDS*. 2009;23:343–353.

Perry CM, Faulds D. Lamivudine: a review of its antiviral activity, pharmacokinetic properties and therapeutic efficacy in the management of HIV infection. *Drugs*. 1997;54:657–680.

STAVUDINE

Molecular weight: 224.2.

An analog of thymidine formulated for oral administration.

ANTIVIRAL ACTIVITY

Stavudine is active against HIV-1, HIV-2 and HTLV-1.

ACQUIRED RESISTANCE

Resistance to stavudine is identical to that seen for zidovudine. Mutations at positions 41, 67 and 70, and positions 210, 215 and 219 (the 'thymidine analog mutations') of the reverse transcriptase genes are associated with diminished antiretroviral efficacy.

PHARMACOKINETICS

Oral absorption	86%
C_{max} 40 mg twice daily	0.54 mg/L
Plasma half-life	1.4 h
Volume of distribution	0.66 L/kg
Plasma protein binding	<5%

Absorption and distribution

It is rapidly absorbed with or without food. CNS penetration is moderate. The estimated semen:plasma ratio is >1. It is secreted into breast milk.

Metabolism and excretion

The metabolic fate in humans has not been elucidated. Renal elimination accounts for approximately 40% of overall clearance at a rate almost twice that of endogenous creatinine, indicating glomerular filtration and active tubular secretion.

Clearance decreases as creatinine clearance decreases and the dosage should be adjusted in patients with reduced renal function. Pharmacokinetics are not significantly altered in patients with hepatic impairment.

TOXICITY AND ADVERSE EFFECTS

Toxicity includes peripheral neuropathy, lactic acidosis, hepatomegaly with steatosis and liver failure, lipoatrophy and pancreatitis. Combination therapy with didanosine results in higher frequency of these toxicities, and fatalities have been reported in pregnant women. The use of the two drugs in combination is no longer recommended. It competes with zidovudine for the same intracellular phosphorylating enzymes and co-administration is contraindicated.

CLINICAL USE

Treatment of HIV infection in adults and children

Preparations and dosage

Proprietary name: Zerit.

Preparations: Capsules (15, 20, 30 and 40 mg). Also available as a powder (1 mg/mL) for reconstitution and in granules (5 and 10 mg).

Dosage: Adults weighing at least 60 kg, oral, 40 mg every 12 h. Adults weighing <60 kg, 30 mg every 12 h. The World Health Organization (WHO) recommends the use of 30 mg every 12 h in adults and adolescents regardless of body weight. Children target dosing range: 1 mg/kg per dose every 12 h.

Available in various dual or triple combinations from generic manufacturers.

Further information

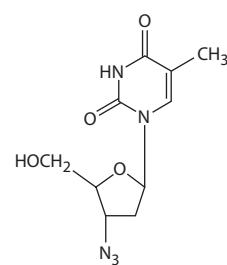

Anonymous. Stavudine. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:S94–S98.

Hill A, Ruxrungtham K, Hanvanich M, et al. Systematic review of clinical trials evaluating low doses of stavudine as part of antiretroviral treatment. *Expert Opin Pharmacother*. 2007;8:679–688.

ZIDOVUDINE

Molecular weight: 267.2.

An analog of thymidine formulated for oral or intravenous use.

ANTIVIRAL ACTIVITY

Zidovudine is active against HIV-1, HIV-2 and HTLV-1.

ACQUIRED RESISTANCE

As with stavudine, mutations at position 41, 67 and 70, and positions 210, 215 and 219 (the ‘thymidine analog mutations’) of the reverse transcriptase genes are associated with diminished antiretroviral efficacy.

PHARMACOKINETICS

Oral absorption	65%
C_{max} 300 mg twice daily	2.3 mg/L
Plasma half-life	1.1 h
Volume of distribution	1.6 L/kg
Plasma protein binding	34–38%

Absorption and distribution

It is absorbed rapidly and almost completely following oral administration. Absorption is not significantly affected by food. It appears to undergo widespread body distribution. CNS penetration is fairly good. The semen:plasma ratio varies from 0.95 to 13.5 (mean 5.9). It is secreted into breast milk.

Metabolism and excretion

Following hepatic metabolism (glucuronidation), elimination is primarily renal. After oral administration, urinary recovery of zidovudine and its glucuronide metabolite accounted for 14% and 74% respectively of the dose, with a total urinary recovery of 90%.

In severe renal impairment, clearance was about half that reported in subjects with normal renal function. Accumulation may occur in patients with hepatic impairment due to decreased glucuronidation.

TOXICITY AND ADVERSE EFFECTS

In common with other drugs in this class, use has been associated with episodes of fatal and non-fatal lactic acidosis and hepatomegaly with steatosis. Careful clinical evaluation is needed in patients with evidence of hepatic abnormality. Myelosuppression may occur within the first 4–6 weeks of therapy. Hematological parameters should be monitored during this period, with prompt dose modification or switch if abnormalities are observed. Treatment with reduced doses may be attempted in some patients once bone marrow recovery has been observed. Myopathy is rarely seen with the use of the current dosing regimens.

Co-administration with drugs known to cause nephrotoxicity, cytotoxicity or which interfere with red or white blood cell number and function may increase the risk of toxicity.

Probenecid and trimethoprim may reduce renal clearance of zidovudine, and other drugs that are metabolized by glucuronidation may interfere with its metabolism.

CLINICAL USE

Treatment of HIV infection in adults and children (in combination with other antiretroviral drugs)

Reduction of maternal transmission of HIV to the fetus

Preparations and dosage

Proprietary name: Retrovir.

Preparations: Capsules (100 and 250 mg), tablets (300 mg), syrup (10 mg/mL), granules (25 and 50 mg), injection.

Dosage: Adults, oral, 500–600 mg per day in two divided doses. The optimal dose in children has not been established, although a dose of 180–240 mg/m²/dose every 12 h has been advocated by some investigators.

Available alone, in combination with lamivudine, and in combination with lamivudine and abacavir. Various combinations with other antiretrovirals are available in generic formulations.

Further information

Anonymous. Zidovudine. In: Dollery C, ed. *Therapeutic Drugs*. 2nd ed. Edinburgh: Churchill Livingstone; 1999:Z12–Z18.

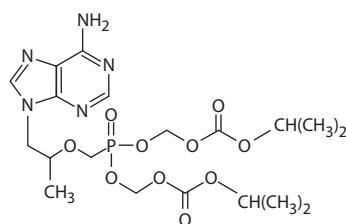

Volmink J, Siegfried NL, van der Merwe L, Brocklehurst P. Antiretrovirals for reducing the risk of mother-to-child transmission of HIV infection. *Cochrane Database Syst Rev*. 2007;(1):CD003510.

NUCLEOTIDE ANALOGS

Nucleotides are monophosphorylated derivatives of nucleosides. Phosphorylation of nucleosides normally occurs within the cytoplasm of cells entering mitotic division and represents the rate-limiting step in the synthesis of bases for addition to growing nucleic acid chains. Nucleotides are actively taken up by most cells irrespective of the stage in the cell cycle. Several such drugs have been synthesized and some have activity against HIV reverse transcriptase. They also inhibit mitochondrial DNA polymerases.

TENOFOVIR

Molecular weight (disoproxil fumarate salt): 635.5.

An acyclic nucleoside phosphonate, formulated as the disoproxil fumarate salt for oral administration.

ANTIVIRAL ACTIVITY

Tenofovir is effective against simian immunodeficiency virus (SIV), HIV-1, HIV-2, HBV and HTLV-1.

ACQUIRED RESISTANCE

HIV variants with the K65R mutation and the K70E mutation in the reverse transcriptase demonstrate reduced susceptibility to tenofovir.

PHARMACOKINETICS

Oral absorption	c. 25%
C_{\max} 300 mg once daily	0.3 mg/L
Plasma half-life	17 h
Volume of distribution	1.3 ± 0.6 L/kg at 3.0 mg/kg intravenous dose
Plasma protein binding	<0.7% (in vitro)

Absorption and distribution

Oral bioavailability is poor, but is enhanced by administration as the disoproxil prodrug. It may be taken with or without food. CSF penetration is likely to be minimal due to the anionic charge of the molecule at physiological pH. It accumulates in semen at higher concentrations than in plasma. It is not known if it is distributed into breast milk.

Metabolism and excretion

Tenofovir is not metabolized and is principally eliminated by the kidneys by a combination of glomerular filtration and active tubular secretion. In patients with renal dysfunction the dose should be adjusted accordingly.

Compounds such as cidofovir, aciclovir (acyclovir), valaciclovir, ganciclovir, valganciclovir and probenecid may compete for renal excretion. Tenofovir levels are increased when prescribed with some HIV protease inhibitors. The co-administration of tenofovir with didanosine leads to didanosine accumulation which is thought to occur through inhibition

of purine nucleoside phosphorylase. This has been associated with impaired immune recovery and several cases of lactic acidosis and pancreatitis. If tenofovir is combined with didanosine the dose of didanosine should be reduced to 200 mg (<60 kg) or 250 mg (≥60 kg) per day and the patient monitored for symptoms of didanosine toxicity.

TOXICITY AND SIDE EFFECTS

In clinical trials of antiretroviral treatment-naive participants, the most commonly reported adverse events were mild to moderate gastrointestinal upset (nausea 8%, diarrhea 11%), headache (14%) and depression (11%). Tenofovir has the potential to result in nephrotoxicity, particularly through proximal tubular damage, but the risk of clinically significant renal dysfunction appears relatively low and seems to occur mainly in subjects with other identifiable risks for renal impairment. Minor elevations in serum creatinine and reductions in creatinine clearance occur, but rarely require drug discontinuation.

A few (<0.1%) cases of osteomalacia and decreased bone density have been reported.

CLINICAL USE

Treatment of HIV infection in adults and children (in combination with other antiretroviral drugs)

Preparations and dosages

Proprietary name: Viread.

Preparation: Tablets (300 mg).

Dosage: Adults, oral, 300 mg per day in a single daily dose.

Available alone, in combination with emtricitabine, and in combination with emtricitabine and efavirenz.

Pozniak A. Tenofovir: what have over 1 million years of patient experience taught us? *Int J Clin Pract*. 2008;62:1285–1293.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

This group of structurally unrelated compounds selectively inhibits HIV-1 reverse transcriptase through allosteric inhibition following binding to the enzyme at regions remote from the

active site. The unique mechanism of action results in a pattern of resistance distinct from other antiretroviral drug classes.

These drugs can inhibit or induce cytochrome P₄₅₀ isozymes. As a consequence, use with several medications is contraindicated or cautioned. Importantly, nevirapine and efavirenz can reduce methadone concentrations by up to half, resulting in clinical features of opiate withdrawal that require careful management.

Waters L, John L, Nelson M. Non-nucleoside reverse transcriptase inhibitors: a review. *Int J Clin Pract*. 2007;1:105–118.

DELAVIRDINE

Molecular weight: 552.68.

A complex piperazine derivative, formulated for oral administration.

ANTIVIRAL ACTIVITY

Delavirdine is active against HIV-1 but not HIV-2.

ACQUIRED RESISTANCE

The predominant amino acid substitution associated with resistance is at position 236 of the HIV reverse transcriptase.

PHARMACOKINETICS

Oral absorption	Not known/available
C _{max}	400 mg oral thrice daily
C _{min}	400 mg oral thrice daily
Plasma half-life	c. 6 h
Volume of distribution	c. 0.7 L/kg
Plasma protein binding	c. 98%

Absorption and distribution

It is rapidly absorbed following oral administration. Food has no significant effect on absorption. It is distributed predominantly into blood plasma and CNS penetration is poor.

The semen:plasma ratio is about 0.02. It is not known if it is distributed into breast milk.

Metabolism and excretion

Several metabolites are formed by the CYP3A4 isoform of cytochrome P₄₅₀ and it is a potent inhibitor of this enzyme system. Around 44% of the drug is recovered in feces and 51% in urine, about 5% as unchanged drug. Given the predominant hepatic metabolism, caution should be exercised in patients with impaired hepatic function.

TOXICITY AND SIDE EFFECTS

Around 18% of patients experience a diffuse, maculopapular, erythematous and often pruritic rash. Dose titration does not appear to reduce the incidence of this side effect. The rash usually first appears within 1 month of commencing therapy and resolves within 2 weeks without dose modification. In about 4% of cases it is severe enough to warrant discontinuation of treatment.

CLINICAL USE

Treatment of HIV disease in adults and children over 12 years of age (in combination with other antiretroviral agents)

Delavirdine has fallen out of favor with the increasing preference for antiretrovirals than can be dosed twice or once daily.

Preparations and dosage

Proprietary name: Rescriptor.

Preparation: Tablets (100 and 200 mg).

Dosage: Adults, oral, 400 mg every 8 h.

Widely available.

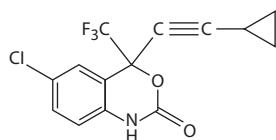

Further information

Scott LJ, Perry CM. Delavirdine: a review of its use in HIV infection. *Drugs*. 2000;60:1411–1444.

EFAVIRENZ

Molecular weight: 315.68.

A synthetic heterocyclic compound formulated for oral administration.

ANTIVIRAL ACTIVITY

Efavirenz is active against HIV-1 but not HIV-2.

ACQUIRED RESISTANCE

One or more single-codon substitutions in the HIV reverse transcriptase genome at positions 100, 103, 106, 108, 181, 188, 190 and 225 confer reduced susceptibility. Many, but not all, of these point mutations confer reduced susceptibility to other non-nucleoside reverse transcriptase inhibitors.

PHARMACOKINETICS

Oral absorption	Not known/available
C_{\max} 600 mg oral once daily	c. 4.07 mg/L
C_{\min} 600 mg oral once daily	c. 1.77 mg/L
Plasma half-life	c. 45 h
Volume of distribution	c. 2.4 L/kg
Plasma protein binding	>99%

Absorption and distribution

Bioavailability following a standard high-fat meal was increased by an average of 50%, but was unaffected by a standard meal. Distribution into body tissues and fluids has not been fully characterized. It penetrates moderately well into the CNS. The semen:plasma ratio is 0.09 (0.03–0.43). The mean concentration in breast milk is 3.51 mg/L; significant linear correlations have been found between maternal plasma and breast milk.

Metabolism and excretion

It is metabolized by cytochrome P₄₅₀ systems to hydroxylated intermediates and excreted after subsequent glucuronidation. Metabolites are not active against HIV.

It is excreted principally in the feces, both as metabolites and unchanged drug. Up to 34% is recovered in the urine, <1% as unchanged drug. Given this, the impact of renal impairment on efavirenz is likely to be minimal. Caution is recommended in patients with mild–moderate liver disease; it is contraindicated in patients with severe hepatic impairment.

Dose adjustment is unnecessary when it is co-administered with HIV protease inhibitors or rifampicin (rifampin).

TOXICITY AND SIDE EFFECTS

The most common (>5%, moderate–severe) adverse effects associated with efavirenz therapy are rash, dizziness, nausea, headache, fatigue, insomnia and vomiting. Rash occurs in up to 26% of patients, mostly in the first 2 weeks of therapy. It usually resolves within 1 month, but is sufficiently severe to limit treatment in a few cases.

Dizziness, insomnia, somnolence, impaired concentration, abnormal dreaming and other CNS disturbances have been reported in around 52% of clinical trial participants, with events of moderate to severe intensity occurring in about 3% of patients. Rare (0.2% of patients) episodes of severe delusional or inappropriate behavior and severe acute depression have also been reported. The symptoms commonly begin in the first 2 weeks of treatment but often resolve or substantially improve within a month.

Elevations in serum hepatic transaminase to levels more than five times the upper limit of normal are observed in about 3% of patients and 8% of those co-infected with viral hepatitis B or C.

CLINICAL USE

Treatment of HIV-1 infection in adults and children (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary names: Stocrin, Sustiva.

Preparations: Capsules (50, 100, 200 and 600 mg), oral solution (30 mg/mL).

Dosage: Adults, oral, 600 mg once a day. Children target dosing range: 15–18.75 mg/kg solid form or 19.5 mg/kg syrup given once daily. Dosage has not been established for children <3 years. In order to alleviate some of the CNS side effects it is recommended the daily dose be taken at bedtime.

Available alone or in combination with tenofovir and emtricitabine, zidovudine and lamivudine, and stavudine and lamivudine.

Further information

van Leth F, Phanuphak P, Ruxrungtham K, et al. Comparison of first-line anti-retroviral therapy with regimens including nevirapine, efavirenz, or both drugs, plus stavudine and lamivudine: a randomised open-label trial, the 2NN Study. *Lancet.* 2004;363:1253–1263.

Vrouenraets SM, Wit FW, van Tongeren J, Lange JM. Efavirenz: a review. *Expert Opin Pharmacother.* 2007;8:851–871.

ETRAVIRINE

Molecular weight: 435.31.

A comprehensive analysis of baseline resistance data from the DUET-1 and DUET-2 studies has identified a list of 17 etravirine resistance associated mutations: V901, A98G, L100L, K101E/H/I, V1061, E138A, V179D/F/T, Y181C/L/V, G190A/S, and M230L. A single K103N mutation is not associated with resistance to etravirine.

ANTIVIRAL ACTIVITY

Etravirine is active only against HIV-1.

ACQUIRED RESISTANCE

Various mutations are associated with a decreased virological response. Single codon substitutions at positions 100, 101 and 181 are considered major mutations. A single K103N mutation is not associated with resistance.

PHARMACOKINETICS

Oral absorption	Not known/available
C_{\max} 200 mg oral twice daily	c. 959 ng/mL
C_{\min} 200 mg oral twice daily	c. 469 ng/mL
Plasma half-life	c. 36 h
Volume of distribution	Not known/available
Plasma protein binding	>99%

Administration with food improves the bioavailability and reduces interpatient variability. It undergoes oxidative metabolism by cytochrome P₄₅₀ systems. Around 93.7% and 1.2% of an administered dose can be retrieved in the feces and urine, respectively, mostly as unchanged drug.

Details of distribution into CSF, semen and breast milk and recommendations for dose adjustment in patients with hepatic impairment are not yet available.

TOXICITY AND SIDE EFFECTS

In the phase III studies around 15% of patients experienced erythematous or maculopapular rashes of mild or moderate severity; most resolved with continued dosing, but treatment was discontinued in 2% of patients. Rare cases of Stevens–Johnson syndrome have been reported.

Other common adverse events are diarrhea, nausea, headache and fatigue. Dyslipidemia and raised pancreatic amylase occur in some patients.

CLINICAL USE

Treatment of HIV-1 infection in adults (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Intelence.

Preparation: Tablets (100 mg).

Dosage: Adults, oral, 200 mg every 12 h.

Widely available.

Safety and efficacy in children and adolescents are not yet established.

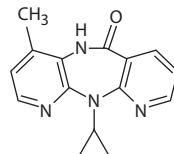

Further information

 Madruga JV, Cahn P, Grinsztejn B, et al. Efficacy and safety of TMC125 (etravirine) in treatment-experienced HIV-1-infected patients in DUET-1: 24-week results from a randomised, double-blind, placebo-controlled trial. *Lancet*. 2007;370:29–38.

NEVIRAPINE

Molecular weight (anhydrous): 266.3.

A synthetic heterocyclic compound formulated for oral use as anhydrous compound or as the hemihydrate in a liquid oral suspension.

ANTIVIRAL ACTIVITY

Nevirapine is active only against HIV-1.

ACQUIRED RESISTANCE

One or more changes within the HIV reverse transcriptase at amino acid positions 100, 103, 106, 108, 181, 188 and 190 are associated with resistance. These point mutations have also been implicated, either alone or in combination, in HIV resistance to other non-nucleoside reverse transcriptase inhibitors.

PHARMACOKINETICS

Oral absorption	c. 93%
C_{max} 200 mg twice daily	c. 5.74 mg/L
C_{min} 200 mg twice daily	c. 2.88 mg/L
Plasma half-life	c. 36 h
Volume of distribution	c. 1.21 L/kg
Plasma protein binding	c. 60%

Absorption and distribution

Nevirapine is orally very well absorbed and widely distributed. CNS penetration is good and the semen:plasma ratio is in the range of 0.6–1. It is distributed into breast milk.

Metabolism and excretion

It is extensively metabolized by cytochrome P₄₅₀ enzymes into a number of hydroxylated intermediates that are subsequently conjugated with glucuronicide.

Around 81% of the dose is excreted in urine (<5% as unchanged compound) and 10% in feces. There is no significant change in the pharmacokinetics in renal impairment. It is contraindicated in patients with severe hepatic impairment; caution should be exercised in patients with moderate hepatic dysfunction.

INTERACTIONS

Administration with boosted protease inhibitors does not require dose adjustment. Adjustment of methadone dose in patients experiencing narcotic withdrawal symptoms may be needed. Studies of the effect of rifampicin have yielded conflicting results. In general, efavirenz is preferred to nevirapine if possible.

TOXICITY AND SIDE EFFECTS

Life-threatening hepatic events, including fulminant hepatitis, have been observed in treatment-naïve patients, generally

within the first few weeks of treatment, but sometimes later. Approximately half the patients also develop skin rash, with or without fever or constitutional symptoms. Women with elevated CD4 counts (>250 cells/mm³) appear to be at highest risk. Men with pretreatment CD4 counts >400 cells/mm³ are also at increased risk. These risks exist in the absence of underlying hepatic abnormalities and, in some cases, hepatic injury continues to progress despite discontinuation of treatment. Treatment should stop, and not be restarted, in patients with clinical evidence of hepatitis. A starting dose of 200 mg per day, with escalation to full dose if no adverse reaction occurs, reduces the frequency of reaction. Single doses given to mothers or infants for prevention of perinatal HIV infection appear safe.

CLINICAL USE

Treatment of HIV-1 infection in adults and children over 2 months old (in combination with other antiretroviral therapies)

Reduction of maternal transmission of HIV to the fetus (recommended only for use in HIV-infected treatment-naïve women in labor who have had no prior HIV therapy)

Preparations and dosage

Proprietary name: Viramune.

Preparations: Tablets (200 mg), oral suspension (10 mg/mL), granules (25 and 50 mg).

Dosage: Adults, oral, 200 mg once daily for the first 14 days, followed by 200 mg every 12 h or 400 mg once daily, in combination with other antiretroviral therapies. Children target dosing range: 150–200 mg/m² per dose every 12 h, with a reduced dose for the first 2 weeks.

Available alone or in combination in generic formulations with stavudine and lamivudine, and zidovudine and lamivudine.

HIV PROTEASE INHIBITORS

Protease inhibitors are active against HIV-1 and HIV-2. As they have significant metabolic interactions, co-administration with many other drugs is either contraindicated or cautioned. Most also possess specific toxicities, some of which are treatment limiting. The extent to which protease inhibitors contribute to

the lipodystrophy syndrome is debated, but they are associated with dyslipidemia, particularly when combined with low doses of ritonavir. Some early protease inhibitors (notably indinavir) have been associated with glucose intolerance, insulin resistance and diabetes mellitus, but evidence suggests that later protease inhibitors are not. Since the description of the use of ritonavir as an agent to potently inhibit the cytochrome P₄₅₀-mediated metabolism of other HIV protease inhibitors, 'ritonavir boosting' has become a routine aspect of the prescription of protease inhibitor-containing antiretroviral regimens and clinical trials. An important limitation of this drug class in patients experiencing treatment-limiting side effects is the lack of recommended reductions in unit dose. For such patients treatment regimens that may include an alternative protease inhibitor must be prescribed. Efforts have been made to determine whether the use of lower unit doses of a protease inhibitor, particularly when administered in combination with ritonavir-boosting for pharmacokinetic enhancement, may offer equal potency and improved tolerability for use in specific populations. However, to date no adequately powered comparative studies have been conducted to help guide recommendations and policy.

While virus isolates from patients who are no longer responding to treatment with single protease inhibitors usually possess resistance mutations within the protease amino acid sequence, regimens containing ritonavir-boosted protease inhibitors usually do not, at least in settings in which routine virological monitoring is performed frequently (i.e. 3–4 times per year). When resistance mutations are selected, mutations to one protease inhibitor may confer high-level resistance to others. Increasing levels of viral resistance appear usually to be conferred by increasing numbers of primary mutations.

AMPRENAVIR

Molecular weight: 505.6; (fosamprenavir): 625.7.

A synthetic compound formulated as the calcium salt of the oral prodrug fosamprenavir.

ANTIVIRAL ACTIVITY

Amprenavir is active against HIV-1 and, to a lesser extent, HIV-2.

ACQUIRED RESISTANCE

Mutations at position 50, 76 and 84 of the protease enzyme gene are associated with significantly reduced susceptibility.

PHARMACOKINETICS

Oral absorption	Not known/available
C _{max} 700 mg + ritonavir 100 mg twice daily	c. 6.08 mg/L
C _{min} 700 mg + ritonavir 100 mg twice daily	c. 2.12 mg/L
Plasma half-life	c. 7.7 h
Volume of distribution	c. 430 L
Plasma protein binding	c. 90%

Absorption

Fosamprenavir is rapidly and almost completely hydrolyzed to amprenavir and inorganic phosphate by cellular phosphatases in the gut epithelium as it is absorbed. Absolute bioavailability has not been established. It can be taken without regard to food.

Distribution

It penetrates moderately well into the CNS. The semen:plasma ratio is negligible. It is not known if it is distributed into breast milk.

Metabolism and excretion

It is extensively metabolized by the cytochrome P₄₅₀ (CYP) 3A4 enzyme system. Two major metabolites have been identified that appear to result from the oxidation of the tetrahydrofuran and aniline moieties.

Around 14% of a dose is eliminated in the urine and 75% in feces, <3% as unchanged drug. Metabolites account for >90% of administered drug found in fecal samples. It should be used with caution and at reduced doses in adults with mild or moderate hepatic impairment; it is contraindicated in patients with severe hepatic impairment.

TOXICITY AND SIDE EFFECTS

The most common adverse events in patients receiving boosted fosamprenavir were diarrhea, nausea, headache, fatigue,

vomiting and rash. Ritonavir-boosted fosamprenavir is associated with a dyslipidemia profile characteristic of those treated with other protease inhibitors boosted with 200 mg of ritonavir.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary names: Lexiva, Telzir.

Preparations: Capsules (700 mg), oral solution (50 mg/mL).

Dosage (fosamprenavir): Adults, oral, 700 mg + ritonavir 100 mg every 12 h or 1400 mg + ritonavir 100 mg once daily. Children 6–12 years, 20 mg/kg every 12 h or 15 mg/kg every 8 h (maximum dose, 2400 mg per day in each instance). Children <6 years, no previous antiretroviral treatment: 30 mg/kg every 12 h (maximum dose, 1400 mg every 12 h) or 18 mg/kg + ritonavir 3 mg/kg every 12 h; previous antiretroviral treatment: 18 mg/kg + ritonavir 3 mg/kg every 12 h.

Limited availability.

Erratum in: *Lancet* 2006; 368: 1238.

ATAZANAVIR

Molecular weight (free base): 704.9; (sulfate) 802.9.

An azapeptide formulated as the sulfate for oral use.

ANTIVIRAL ACTIVITY

Atazanavir is active against HIV-1 group M clades A–D, AE, AG, F, G and J. Information on activity against HIV-1 groups N and O and on HIV-2 is lacking.

ACQUIRED RESISTANCE

Mutations at positions 50 (I50L), 84 (I84V) and 88 (N88S) of the protease gene are associated with resistance.

PHARMACOKINETICS

Oral absorption	c. 68%
C_{max} 400 mg once daily	c. 3.15 µg/L
300 mg + ritonavir 100 mg once daily	c. 4.47 µg/L
C_{min} 400 mg once daily	c. 0.27 µg/L
300 mg + ritonavir 100 mg once daily	c. 0.65 µg/L
Plasma half-life	c. 8.6 h (300 mg + ritonavir 100 mg)
Volume of distribution	c. Not known/available
Plasma protein binding	c. 86%

Absorption

Administration with food enhances bioavailability and reduces pharmacokinetic variability. Absorption is dependent on gastric pH. It should be given separately from proton-pump inhibitors or H₂-receptor antagonists. Buffered or enteric-coated formulations should be given (with food) 2 h before or 1 h after co-administration of didanosine.

Distribution

It penetrates moderately well into the CNS. The semen:plasma ratio is 0.11–4.42. It is distributed into breast milk.

Metabolism

It is extensively metabolized by CYP3A4. Administration with ritonavir prevents metabolism and enhances the pharmacokinetic profile.

Excretion

Following a single 400 mg dose, 79% and 13% of the dose was recovered in the feces and urine, respectively. It should be used with caution in the presence of mild hepatic impairment and should not be used in patients with more severe hepatic impairment.

TOXICITY AND SIDE EFFECTS

The most common adverse reactions ($\geq 2\%$) are nausea, jaundice/scleral icterus, rash, headache, abdominal pain, vomiting, insomnia, peripheral neurological symptoms, dizziness, myalgia, diarrhea, depression and fever.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Reyataz.

Preparation: Capsules (100, 150, 200 and 300 mg).

Dosage: Treatment-naive patients, 400 mg (or 300 mg + ritonavir 100 mg) once daily with food. Not recommended for children under 6 years.

Children 6–18 years, adjust dose according to weight.

Widely available.

DARUNAVIR

Molecular weight: 547.7.

A synthetic compound formulated as the ethanolate for oral use in combination with ritonavir.

ANTIVIRAL ACTIVITY

It is active against HIV-1 and HIV-2.

ACQUIRED RESISTANCE

Darunavir is less affected than other protease inhibitors by mutations to resistance, but subgroups with more than 10 cumulative mutations show a >10-fold (median value) decrease in susceptibility. The major resistance mutations occur at positions 50 (150V), 54 (I50M/L), 76 (L76V) and 84 (I84V) of the protease gene.

PHARMACOKINETICS (IN COMBINATION WITH RITONAVIR 100 mg)

Oral absorption	c. 82%
C_{\max} 600 mg once daily + ritonavir 100 mg twice daily	c. 6500 µg/L
C_{\min} 600 mg oral + ritonavir 100 mg twice daily	c. 3578 µg/L
Plasma half-life	c. 15 h
Volume of distribution	c. 131 L
Plasma protein binding	c. 95%

A single 600 mg dose given orally in combination with ritonavir 100 mg every 12 h increased the systemic exposure of darunavir approximately 14-fold. The relative bioavailability is 30% lower when administered with food in the presence of low-dose ritonavir. Distribution into human CSF, semen or breast milk has not yet been determined.

At least three oxidative metabolites, mediated predominantly through CYP3A4, have been identified in humans; all are at least 10-fold less active than the parent compound against HIV. Around 80% and 14% of the dose is found in the feces and urine, respectively. It should be used with caution in mild–moderate hepatic impairment and avoided in patients with more severe impairment.

TOXICITY AND SIDE EFFECTS

In phase III studies the most common adverse events were diarrhea, nausea, headache and nasopharyngitis. Patients co-infected with hepatitis B or C did not have a higher incidence of adverse events.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Prezista.

Preparation: Tablets (200, 300 and 600 mg).

Dosage: Adults, oral, 600 mg in combination with ritonavir 100 mg every 12 h in treatment-experienced patients; 800 mg in combination with ritonavir 100 mg once daily in treatment-naïve patients. Children, 6–18 years (according to weight): 20–30 kg, 375 mg + 50 mg ritonavir every 12 h; >30–40 kg, 450 mg + 100 mg ritonavir every 12 h. Widely available.

ACQUIRED RESISTANCE

The major mutations in the protease enzyme associated with loss of the antiretroviral activity occur at positions 46, 82 and 84. Generally, the level of resistance rises with the number of point mutations.

PHARMACOKINETICS

Oral absorption	c. 65%
C_{max} 800 mg thrice daily	c. 8.97 mg/L
C_{min} 800 mg thrice daily	c. 0.15 mg/L
Plasma half-life	c. 2 h
Volume of distribution	c. 0.4–1.74 L/kg
Plasma protein binding	c. 60%

INDINAVIR

Molecular weight (free base): 613.8; (sulfate): 711.88.

A synthetic compound formulated as the sulfate for oral administration.

ANTIVIRAL ACTIVITY

Indinavir is active against HIV-1 and HIV-2.

TOXICITY AND SIDE EFFECTS

The principal side effect is nephrolithiasis, including flank pain with or without hematuria. There is good evidence that indinavir directly causes nephrolithiasis as a result of crystallization in the urinary tract. Indirect hyperbilirubinemia occurs in about 10% of patients associated with inhibition of bilirubin-conjugating activity occurring as a result of competitive inhibition of uridine diphosphate (UDP)-glucuronosyltransferase.

Ritonavir-boosted indinavir is associated with a dyslipidemia profile characteristic of those treated with other protease inhibitors boosted with a 200 mg dose of ritonavir per day. Insulin resistance and hyperglycemia have also been associated with ritonavir-boosted indinavir.

CLINICAL USE

Treatment of adult HIV infection (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Crixivan.

Preparation: Capsules (100, 200, 333.33 and 400 mg).

Dosage: Adults, oral, 800 mg + ritonavir 100 mg every 12 h Children, 50 mg/kg every 8 h taken away from food; when boosted with ritonavir can be given without food restrictions.

Widely available, including generic versions.

PHARMACOKINETICS

Oral absorption	Not known/available
C_{\max} 400 mg + ritonavir 100 mg twice daily	c. 9.6 mg/L
C_{\min} 400 mg + ritonavir 100 mg twice daily	c. 5.5 mg/L
Plasma half-life	c. 5–6 h
Volume of distribution	Not known/available
Plasma protein binding	c. 98–99%

Cressey TR, Plipat N, Fregonese F, Chokephaibulkit K. Indinavir/ritonavir remains an important component of HAART for the treatment of HIV/AIDS, particularly in resource-limited settings. *Expert Opin Drug Metab Toxicol*. 2007; 3:347–361.

LOPINAVIR

Molecular weight: 628.80.

A synthetic compound, co-formulated with ritonavir for oral administration. In this formulation, ritonavir functions to inhibit the metabolic clearance of lopinavir, and does not contribute to the antiretroviral activity.

ANTIVIRAL ACTIVITY

Lopinavir is active against HIV-1 and HIV-2.

ACQUIRED RESISTANCE

Significant resistance to the antiretroviral efficacy of ritonavir-boosted lopinavir occurs as a result of amino acid substitutions at positions 32, 47 and 82 in the protease region. Protease inhibitor resistance is uncommon in patients identified with early failure of combination therapy with ritonavir boosted-lopinavir and nucleotide reverse transcriptase inhibitors.

Absorption and distribution

The absorption of lopinavir-ritonavir in capsule or liquid form is favorably affected by the presence of food, particularly if high in fat. The CNS penetration is good. It has a semen:plasma ratio of 0.07. It is distributed into breast milk.

Metabolism

Lopinavir is extensively metabolized by the CYP3A4 system, but this is inhibited by ritonavir.

Excretion

Over an 8-day period after single dosing with the combined formulation, around 10% and 83% of the administered dose is recovered in urine and feces, respectively. Less than 3% of the dose is recovered as unchanged drug in urine and 20% in feces. In mild to moderate hepatic impairment, an increase in exposure of approximately 30% is observed, but is probably not clinically relevant. It should be avoided in severe hepatic impairment.

TOXICITY AND SIDE EFFECTS

The most common adverse events seen in trials of complex anti-retroviral regimens were diarrhea, nausea, headache, fatigue, vomiting and rash. Ritonavir-boosted lopinavir is associated with a dyslipidemia profile characteristic of those treated with other protease inhibitors boosted with 200 mg of ritonavir.

CLINICAL USE

Treatment of HIV infection (in combination with ritonavir and other antiretroviral agents)

Preparations and dosages

Proprietary names: Aluvia, Kaletra.

Preparations: Tablets (lopinavir-ritonavir 200 + 50 mg and 100 + 25 mg), capsules (lopinavir-ritonavir 133.3 + 33.3 mg); oral solution (lopinavir-ritonavir 80 + 20 mg/mL).

Dosage: Adults, oral, lopinavir-ritonavir 400 + 100 mg every 12 h or 800 + 200 mg once daily. Children, 7–15 kg, lopinavir 12 mg/kg + ritonavir 3 mg/kg every 12 h; ≥15–40 kg, lopinavir 10 mg/kg + ritonavir 2.5 mg/kg every 12 h.

Widely available, including generic versions.

NELFINAVIR

Molecular weight: 663.9.

A synthetic chemical formulated as the mesylate for oral administration.

ANTIVIRAL ACTIVITY

Nelfinavir inhibits HIV-1 and HIV-2 proteases. Bioavailability is affected to only a limited degree by combination with low-dose ritonavir.

ACQUIRED RESISTANCE

Resistance is most frequently selected through a D30N mutation in the HIV protease. An L90M mutation also confers resistance.

PHARMACOKINETICS

Oral absorption	c. 70–80% (with food)
C _{max} 750 mg thrice daily	c. 3–4 mg/L
1250 mg twice daily	c. 4 mg/L
C _{min} 750 mg thrice daily	c. 1–3 mg/L
1250 mg twice daily	c. 0.7–2.2 mg/L
Plasma half-life	c. 3.5 h
Volume of distribution	c. 2–7 L/kg
Plasma protein binding	>98%

Absorption and distribution

Food improves the bioavailability and the drug should be administered with a light meal. The semen:plasma ratio is 0.07. It is distributed into breast milk.

Metabolism and excretion

One major and several minor oxidative metabolites are found in plasma. Most of an oral dose is recovered in feces as unchanged drug (22%) and metabolites (78%). The remainder is recovered in urine, mainly unchanged.

An increase in the area under the time-concentration curve (AUC) has been observed in patients with hepatic impairment, but specific dose recommendations have not been made.

TOXICITY AND SIDE EFFECTS

The most common adverse effect is diarrhea of mild to moderate severity. Other side effects include nausea, fatigue, vomiting and headache. It is associated with less dyslipidemia in comparison with ritonavir-boosted protease inhibitors.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Viracept.

Preparations: Tablets (250 and 625 mg), oral powder containing nelfinavir free base 50 mg per 1 g powder.

Dosage: Five 250 mg tablets or two 625 mg tablets every 12 h, or three 250 mg tablets every 8 h. Children ≥2 years, 45–55 mg/kg every 12 h, or 25–35 mg/kg every 8 h.

Widely available.

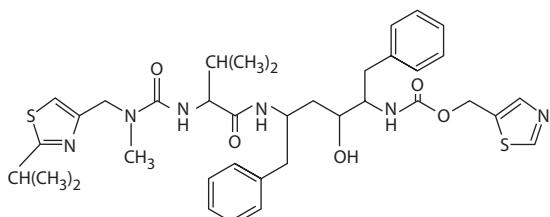

Further information

RITONAVIR

Molecular weight: 720.95.

A synthetic chemical available for oral use as soft capsules and a liquid formulation. It is now almost exclusively used as a pharmacokinetic enhancer to 'boost' the pharmacokinetic properties of HIV protease inhibitors in the treatment of HIV-1 infection in patients over 1 month in age.

ANTIVIRAL ACTIVITY

Ritonavir is active against HIV-1 and, to a lesser extent, HIV-2.

ACQUIRED RESISTANCE

At antiretroviral doses resistance is associated with the presence of specific amino acid substitutions in the HIV protease at positions 82 and 84. Concern about the risk for selection of ritonavir resistance when used at a subtherapeutic 'booster' dose has so far not been borne out by clinical experience.

PHARMACOKINETICS

Oral absorption	Not known/available
C_{\max} 600 mg twice daily	c. 11.2 mg/L
C_{\min} 600 mg twice daily	c. 3.7 mg/L
Plasma half-life	c. 3–5 h
Volume of distribution	c. 0.3–0.6 L/kg
Plasma protein binding	c. 97%

Absorption and distribution

Fasting and high-fat meals had no appreciable effect on oral absorption. It penetrates poorly into the CNS. The semen:plasma ratio is <0.04. It is distributed into breast milk.

Metabolism and excretion

Four oxidized metabolites have been identified, the major of which retains antiretroviral activity. Around 11% of the dose is excreted in urine, 4% as unchanged drug. The remainder is found in feces. Metabolites are eliminated primarily via the feces.

No dose adjustment is recommended in mild to moderate hepatic impairment. It should not be given to patients with severe hepatic impairment, nor should it be given as a pharmacokinetic enhancer to patients with decompensated liver disease.

TOXICITY AND SIDE EFFECTS

Full (antiretroviral) doses are associated with nausea, vomiting, diarrhea and fatigue in >20% of subjects. The degree to which ritonavir at low dose is associated with specific adverse events is uncertain. In HIV-negative healthy volunteers given 'booster' doses of 100 mg every 12 h, the concentration of total cholesterol, low-density cholesterol and triglycerides all increased, and the concentration of high-density cholesterol concentration fell.

CLINICAL USE

Treatment of HIV infection in adults and children >1 month old (in combination with other antiretroviral agents)

Preparations and dosage

Proprietary name: Norvir.

Preparations: Soft capsules (100 mg), oral solution (80 mg/mL).

Dosage: Adults, starting dose no less than 300 mg every 12 h, increased by 100 mg at 2–3 day intervals to 600 mg every 12 h. Children, starting dose 250 mg/m², increased by 50 mg/m² at 2–3 day intervals to 350–400 mg/m² every 12 h (maximum dose, 600 mg every 12 h). For use as a pharmacokinetic enhancer, please refer to the prescribing information for the specific protease inhibitor in this chapter.

Widely available.

SAQUINAVIR

Molecular weight: 766.95.

A peptidomimetic protease inhibitor formulated as the mesylate for oral use.

ANTIVIRAL ACTIVITY

Saquinavir is active against HIV-1 and HIV-2.

ACQUIRED RESISTANCE

Resistance is associated with an amino acid substitution at position 48 in the HIV protease (G48V). An L90M mutation also confers resistance, as it does for most protease inhibitors. Saquinavir-resistant isolates from patients on long-term therapy often show cross-resistance to other protease inhibitors.

PHARMACOKINETICS

Oral absorption	c. 4%
C_{\max} 1200 mg thrice daily	c. 1–2.2 mg/L
C_{\min} 1200 mg thrice daily	c. 0.1–0.22 mg/L
Plasma half-life	c. 7–12 h
Volume of distribution	c. 700 L
Plasma protein binding	c. 98%

Absorption and distribution

It is poorly absorbed and penetrates poorly into the CNS. The semen:plasma ratio is 0.04. It is not known if it is distributed into human breast milk.

Metabolism and excretion

It is metabolized via CYP3A4, principally to mono- and dihydroxylated derivatives. Around 88% of the dose is excreted in feces and 1% in urine. Caution should be exercised in severe renal impairment and moderate hepatic impairment; use in decompensated hepatic impairment is contraindicated.

TOXICITY AND SIDE EFFECTS

The most frequently reported adverse effects include abdominal discomfort, diarrhea and nausea. Ritonavir-boosted saquinavir is associated with a dyslipidemic profile characteristic of those

treated with a boosted protease inhibitor requiring 200 mg of the ritonavir 'booster'.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Invirase.

Preparations: Tablets (500 mg), hard gelatin capsules (200 mg).

Dosage: Two 500 mg tablets or five 200 mg capsules co-administered with 100 mg ritonavir every 12 h.

Widely available.

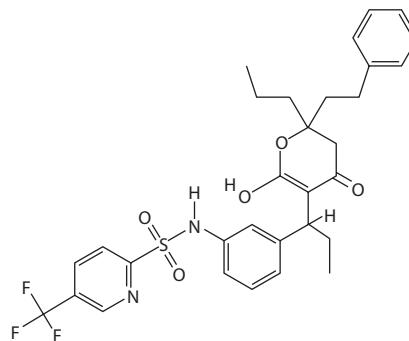

Further information

Plosker GL, Scott LJ. Saquinavir: a review of its use in boosted regimens for treating HIV infection. *Drugs*. 2003;63:1299–1324.

Walmsley S, Avihingsanon A, Slim J, et al. Gemini: a noninferiority study of saquinavir/ritonavir versus lopinavir/ritonavir as initial HIV-1 therapy in adults. *J Acquir Immune Defic Syndr*. 2009;50:367–374.

TIPRANAVIR

Molecular weight: 602.7.

A non-peptidic protease inhibitor formulated as capsules or solution for oral use.

ANTIVIRAL ACTIVITY

Tipranavir is active against HIV-1 and HIV-2.

ACQUIRED RESISTANCE

In a study of 105 viruses resistant to other protease inhibitors, 90% exhibited a more than four-fold decrease in susceptibility and 2% high-level resistance (>10-fold decrease). The predominant

emerging mutations in use with ritonavir are L33F/I/V, V82T/L and I84V. Combination of all three of these mutations is usually required for reduced susceptibility. Mutations at positions 47, 58 and 74 are also associated with resistance.

PHARMACOKINETICS

Oral absorption	Not known/available
C_{\max} 500 mg + 200 mg ritonavir twice daily	c. 57.2 mg/L (female); 46.8 mg/L (male)
C_{\min} 500 mg + 200 mg ritonavir twice daily	c. 25.1 mg/L (female); 21.5 mg/L (male)
Plasma half-life	c. 5.5 h (female); 6 h (male)
Volume of distribution	Not known/available
Plasma protein binding	>99.9%

Absorption and distribution

The combination with ritonavir may be taken with or without food. No studies have been conducted to determine the distribution into human CSF, semen or breast milk.

Metabolism and excretion

Metabolism in the presence of 200 mg ritonavir is minimal. Around 82% is excreted in the feces and 4% in the urine. In mild hepatic impairment it should be used with caution; it should not be used in moderate or severe hepatic impairment.

TOXICITY AND SIDE EFFECTS

Adverse effects include nausea, vomiting, diarrhea, fatigue and headache. In studies of ritonavir-boosted regimens higher rates of hepatotoxicity have been observed with tipranavir than with other protease inhibitors. In addition, 14 reports of intracranial bleeding (eight fatal cases) associated with tipranavir have been reported. It has been associated with dyslipidemia to a greater extent than other protease inhibitors.

CLINICAL USE

Treatment (in combination with other antiretroviral drugs) of HIV-1 infection in patients unresponsive to more than one other protease inhibitor

Preparations and dosage

Proprietary name: Aptivus.

Preparations: Capsules (250 mg), oral solution (100 mg/mL).

Dosage: Adults, oral, 500 mg + 200 mg ritonavir every 12 h, with or without food. Children, 2–18 years: dose based on body weight or body surface area, not to exceed adult dose.

Widely available.

Further information

King J, Acosta E. Tipranavir: a novel nonpeptidic protease inhibitor of HIV. *Clin Pharmacokinet*. 2006;45:665–682.

ENTRY INHIBITORS

These drugs inhibit fusion of the virion with the CD4 and CCR5 co-receptor complex on the outer surface of the human cellular membrane. The fusion inhibitor enfuvirtide prevents the formation of the pore through which HIV gains entry to the cell. Maraviroc is a specific antagonist of the CCR5 co-receptor that interacts with the gp120 envelope glycoprotein, thereby inhibiting the entrance of HIV into the cell. It is the first agent to inhibit HIV replication by targeting a host cell protein rather than a viral enzyme.

Further information

Kuritzkes DR. HIV-1 entry inhibitors: an overview. *Curr Opin HIV AIDS*. 2009;4:82–87.

ENFUVIRTIDE

Molecular weight: 4492.

A linear 36-amino acid synthetic peptide with an acetylated N-terminus and a carboxamide C-terminus. It is formulated as a lyophilized powder to be reconstituted for subcutaneous injection.

ANTIVIRAL ACTIVITY

Enfuvirtide selectively inhibits HIV-1, but has no activity against HIV-2.

ACQUIRED RESISTANCE

Resistance is mediated by amino acid substitutions within the first heptad repeat region of gp41 at amino acids 36–45. Resistance emerges fairly rapidly in patients experiencing virological failure with an enfuvirtide-containing antiretroviral regimen, and is associated with the return of the plasma HIV load toward baseline within a few weeks.

PHARMACOKINETICS

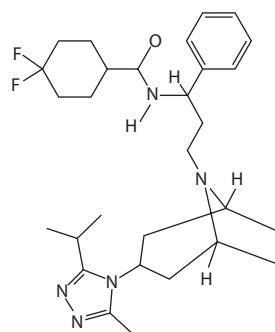

Subcutaneous absorption	c. 84.3%
C_{\max} 90 mg s/c twice daily	c. 4.59 mg/L
Plasma half-life	c. 3.8 h
Volume of distribution	5.5 L
Plasma protein binding	c. 92%

Absorption and distribution

Absorption of the 90 mg dose is comparable when injected into the subcutaneous tissue of the abdomen, thigh or arm. It does not penetrate the CSF or semen. Distribution into breast milk has not been described.

Metabolism and excretion

It probably undergoes catabolism to its constituent amino acids, with subsequent recycling of the amino acids in the body pool.

A spirodiketopiperazine formulated as tablets for oral use.

TOXICITY AND SIDE EFFECTS

It does not seem to have any long-term toxicities (including the HIV lipodystrophy syndrome) associated with other commonly used antiretrovirals. Reaction at the injection site, variously characterized by local pain, erythema, pruritus, induration, ecchymosis, nodules or cysts, is experienced by more than 90% of patients and may lead to treatment fatigue.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs) in adults and children older than 6 years who show evidence of HIV-1 replication despite ongoing antiretroviral therapy

Preparations and dosage

Proprietary name: Fuzeon.

Preparation: Vial containing 108 mg lyophilized powder for reconstitution in 1.1 mL sterile water (end volume 1.2 mL).

Dosage: 90 mg (1 mL of solution) by subcutaneous injection twice daily. Widely available.

ANTIVIRAL ACTIVITY

Maraviroc is active against HIV-1. Activity against HIV-2 has not been evaluated.

ACQUIRED RESISTANCE

In most patients (*c.* 60%) failure of response is associated with the selection of virus that can use CXCR4 as its entry co-receptor. Evidence for the selection of virus that continues to use CCR5 has also been described.

PHARMACOKINETICS

Oral absorption	<i>c.</i> 33% (300 mg dose)
C_{\max} 150 mg twice daily	<i>c.</i> 332 µg/L*
C_{\min} 150 mg twice daily	<i>c.</i> 101 µg/L*
Plasma half-life	<i>c.</i> 13.2 h (30 mg iv administration)
Volume of distribution	<i>c.</i> 194 L
Plasma protein binding	<i>c.</i> 76%

*Treatment experienced patients receiving a CYP3A inhibitor.

Absorption

The absolute bioavailability of a 100 mg dose is 23% and is predicted to be 33% after a 300 mg dose. Co-administration of a 300 mg tablet and a high-fat meal has resulted in reduced C_{\max} and AUC by 33% in healthy volunteers. However, because no food restrictions were enacted during clinical trials, maraviroc may be taken with or without food.

MARAVIROC

Molecular weight: 513.67.

Distribution

Animal experiments suggest low CSF concentrations around 10% of free plasma concentrations. It is not known whether it passes into breast milk. A study of genital tract secretions and vaginal tissue in healthy HIV-uninfected female volunteers suggest a concentration in cervicovaginal fluid more than four-fold higher than that in plasma.

Metabolism

It is a substrate for CYP3A4 and P-glycoprotein, but does not appear to inhibit or induce CYP3A4.

Excretion

Seventy-six and 19% of a radiolabeled maraviroc dose were recovered in the feces and urine, respectively.

TOXICITY AND SIDE EFFECTS

There has been some concern that CCR5 blockade may result in decreased immune surveillance and a subsequent increased risk of development of malignancies (e.g. lymphomas). Genetic deficiency of the CCR5 co-receptor is also known to be a risk factor for the development of symptomatic West Nile virus infection. No evidence for an increase in either of these potential risks has so far emerged.

The toxicity profile appears relatively benign. The most common adverse events described so far include diarrhea, fatigue, headache and nausea. In placebo-controlled studies the only differences to emerge were fever (6% versus 4% in the placebo group) and headache (2% versus 6% with placebo). Discontinuation because of adverse events was uncommon and the same in both groups.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs) in treatment-experienced patients

On November 20, 2009, the US Food and Drug Administration approved a supplemental new drug application to expand the indication for maraviroc to include combination antiretroviral treatment of treatment-naïve adults infected with CCR5-tropic HIV virus

Preparations and dosage

Proprietary name: Celentri.

Preparation: Tablets (150 and 300 mg).

Dosage: 300 mg every 12 h. Dosage adjustments are recommended in the presence of CYP3A4 inducers and inhibitors.

Widely available.

Further information

MacArthur RD, Novak RM. Reviews of anti-infective agents: maraviroc: the first of a new class of antiretroviral agents. *Clin Infect Dis.* 2008;47:236–241.

HIV INTEGRASE INHIBITORS

The HIV integrase enzyme incorporates viral DNA into the host chromosome through a three-step process: formation of the preintegration viral DNA complex; 3' processing; and strand transfer. Raltegravir inhibits the final step by preventing formation of covalent bonds between the preintegration complex and the host DNA.

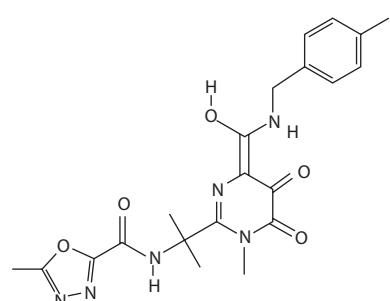

Further information

Correll T, Klibanov OM. Integrase inhibitors: a new treatment option for patients with human immunodeficiency virus infection. *Pharmacotherapy.* 2008;28:90–101.

RALTEGRAVIR

Molecular weight: 482.51.

Formulated as the potassium salt for oral administration.

ANTIVIRAL ACTIVITY

Raltegravir is active against HIV-1 and HIV-2.

ACQUIRED RESISTANCE

Several characteristic mutations leading to typical amino acid exchanges have been characterized in cell culture studies and confirmed in clinical trial participants with virological failure while receiving raltegravir in combination with other antiretrovirals. Virological failure has generally been associated with mutations at one of three residues – Y143, Q148 or N155 – usually in combination with at least one other mutation.

PHARMACOKINETICS

Oral absorption	Not known/available
C_{\max} 400 mg twice daily	c. 2.17 mg/L
Plasma half-life	c. 9 h
Volume of distribution	Not known/available
Plasma protein binding	c. 83%

Absorption and distribution

It may be administered without regard to food. There are few data regarding its capacity to penetrate into genital secretions or breast milk. A study of 25 HIV-infected individuals receiving raltegravir as a component of combination antiretroviral therapy found that 24 had detectable levels and that 50% of these reached a level exceeding the 95% inhibitory concentration reported to inhibit HIV-1 strains fully susceptible to integrase inhibition.

Metabolism and excretion

It is not a substrate, and does not appear to inhibit or induce the cytochrome P₄₅₀ enzyme complex. It is primarily metabolized through hepatic glucuronidation mediated by the UGT-1A1 enzyme. It is excreted in the feces (51%) and the urine (32%) as unaltered compound and its glucuronide.

There are no recommended dose adjustments for weight, sex and race, or for hepatic or renal insufficiency. The pharmacokinetic handling in children has not been determined.

TOXICITY AND SIDE EFFECTS

Its toxicity profile to date is remarkably benign. Clinical trial participants experienced similar types and frequencies of adverse events as those receiving placebo. The most frequently

reported adverse events were nausea, diarrhea and headache and were mostly mild to moderate in intensity. Myopathy, rhabdomyolysis and elevations of creatinine phosphokinase have been noted in a few trial participants and it should be used cautiously in combination with drugs associated with muscle toxicity.

CLINICAL USE

Treatment of HIV infection (in combination with other antiretroviral drugs)

Preparations and dosage

Proprietary name: Isentress.

Preparation: Film-coated tablets (434.4 mg, equivalent to 400 mg active drug).

Dosage: Adults 400 mg every 12 h.

Widely available.

CHAPTER

37 Other antiviral agents

Richard J. Whitley

The impact of chronic viral infections such as hepatitis B and C and HIV, together with the achievements of molecular virologists in defining the life cycle of many viral pathogens and the availability of rapid viral diagnostic procedures, have stimulated the development of effective antiviral therapy. Various ways of inhibiting viral replication have been exploited:

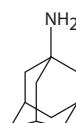

- Direct inactivation of the virus prior to cell attachment and entry
- Blocking attachment of virus to host-cell membrane receptors and penetration
- Prevention of viral uncoating
- Impeding transcription or translation into viral messenger RNA and proteins
- Interfering with glycosylation steps
- Alteration of viral assembly and prevention of release
- Inhibition of host pathways that impede these events.

This chapter addresses compounds other than antiretroviral agents that are licensed for clinical use.

ADAMANTANES

AMANTADINE

1-Aminoadamantane hydrochloride. Molecular weight (hydrochloride): 187.7.

A symmetrical synthetic C-10 tricyclic amine with an unusual cage-like structure, supplied as the hydrochloride for oral administration.

ANTIVIRAL ACTIVITY

It inhibits influenza A virus replication at concentrations of 0.2–0.6 mg/L, but has little or no activity against influenza B or C.

ACQUIRED RESISTANCE

Resistance is the consequence of mutations in amino acid positions 27, 30 and 31 in the M2 transmembrane sequence. Cross-resistance between amantadine and rimantadine is universal. Influenza H3N2 strains worldwide are now resistant, but seasonal H1N1 strains remain susceptible. Postexposure family prophylaxis results in the prompt emergence of drug resistance after onset of treatment.

PHARMACOKINETICS

Oral absorption	>90%
C _{max} 200 mg oral per day	0.4–0.9 mg/L after c. 4–6 h
Plasma half-life	9.7–14.5 h
Volume of distribution	10.4 L/kg
Plasma protein binding	65%

Absorption and distribution

Absorption after oral administration is almost complete. Levels in secretions approach plasma concentrations.

Metabolism and excretion

About 56% of a single oral dose is excreted unchanged within 24 h by the kidney. Altogether 90% of an oral dose is excreted in the urine with a mean elimination half-life of 11.8 h in subjects with normal renal function. In elderly men, the half-life is 28.9 h and in patients with renal insufficiency half-lives of 18.5 h to 33.8 days have been observed. The renal clearance is around 398 mL/min (range 112–772 mL/min), indicating active secretion as well as glomerular filtration. Less than 5% of a dose is removed during hemodialysis and average half-lives of 8.3 and 13 days have been reported in patients on chronic hemodialysis. Extreme care must be taken to ensure that drug does not accumulate to toxic levels.

INTERACTIONS

Central nervous system (CNS), gastrointestinal or other side effects provoked by anticholinergic drugs or L-dopa may be aggravated. Patients have developed visual hallucinations while concurrently taking amantadine and trihexyphenidyl (benzhexol); these respond to a reduction of the dose of trihexyphenidyl. Hemodialysis is not helpful because of the large volume of distribution.

TOXICITY AND SIDE EFFECTS

Embryotoxicity and teratogenicity have been observed in rats receiving 50 mg/kg per day, about 15 times the usual human dose. Neurological side effects include drowsiness, insomnia, light-headedness, difficulty in concentration, nervousness, dizziness and headache in up to 20% of individuals. Other side effects include anorexia, nausea, vomiting, dry mouth, constipation and urinary retention. All develop during the first 3–4 days of therapy and are reversible by discontinuing the drug. An exception to rapid onset of adverse reactions is livedo reticularis. Convulsions, hallucinations and confusion are dose related, usually occurring at levels in excess of 1.5 mg/L; convulsions may occur at a lower threshold in patients with a history of epilepsy and the drug is best avoided in such patients.

CLINICAL USE

Prevention and treatment of influenza A H1N1 infections

Preparations and dosage

Proprietary name: Symmetrel.

Preparations: Capsules, syrup.

Dosage: Treatment or prophylaxis. Adults, oral, 100 mg once or twice daily for 5–7 days. Children, 1–9 years, 4–8 mg/kg per day; 10–15 years, 100 mg per day.

Widely available.

Monto AS. Antivirals and influenza: frequency of resistance. *Pediatr Infect Dis J.* 2008;27:S110–S112.

RIMANTADINE

Molecular weight (hydrochloride): 215.7.

An analog of amantadine, supplied as the hydrochloride for oral administration.

ANTIVIRAL ACTIVITY

In cell culture and animal models rimantadine is more effective than amantadine on a weight-for-weight basis. There is complete cross-resistance with amantadine.

PHARMACOKINETICS

Oral absorption	>90%
C _{max} 100 mg oral (every 12 h)	0.4–0.5 mg/L after 2–6 h
Plasma half-life	c. 35 h
Volume of distribution	Very large
Plasma protein binding	c. 40%

Absorption and distribution

Single- and multiple-dose pharmacokinetic studies in elderly patients and young adults are remarkably similar. The steady-state concentration in nasal mucus develops by day 5 at a concentration approximately 1.5-fold higher than plasma.

Metabolism

In contrast to amantadine, rimantadine is extensively metabolized in the liver by hydroxylation and glucuronidation.

Excretion

Less than 20% is excreted unchanged in the urine and most of the breakdown products are excreted by this route. Thus, the plasma half-life is much less affected by renal dysfunction than that of amantadine.

TOXICITY AND SIDE EFFECTS

Rimantadine has significantly fewer side effects than amantadine at equivalent doses, perhaps because of differences in pharmacokinetics, since with equal doses the blood levels

are considerably lower. CNS side effects are not significantly higher than placebo.

CLINICAL USE

Prophylaxis and treatment of influenza A H1N1 infections

Since prolonged administration is well tolerated by elderly patients, the drug is preferable to amantadine.

Preparations and dosage

Proprietary name: Flumadine.

Preparations: Tablets, syrup.

Dosage: Adults, oral, 200 mg per day in single or divided doses, if >40 kg. Children, 5 mg/kg per day in 1–2 divided doses (maximum dose, 150 mg per day).

Available in continental Europe and the USA.

INTERFERONS

Interferons are low molecular weight proteins produced by mammalian cells in vitro and in vivo in response to viral infection and certain other stimuli. There are three classes:

- Interferon- α , produced by lymphocytes
- Interferon- β , produced by fibroblasts
- Interferon- γ , produced by lymphoid cells in response to mitogens.

Interferons are generally species specific and are now produced by recombinant genetic techniques. Only interferon- α is used in the context of viral disease, where its effectiveness may be due as much to immunomodulatory as antiviral properties.

INTERFERON- α

Molecular weight: approximately 19 kDa.

A human protein produced by recombinant DNA technology in *Escherichia coli*, formulated for administration by

intramuscular, subcutaneous or intralesional injection. A pegylated form, peginterferon, developed by attaching a 40 kDa branched-chain polyethylene glycol moiety to interferon- α -2a, has a prolonged half-life and is better tolerated. Potency is expressed as international units (IU), defined as the amount needed to prevent lysis of 50% of cells by vesicular stomatitis virus in tissue culture assay.

ANTIVIRAL ACTIVITY

Interferon- α renders cells resistant to infection by a wide range of viruses and mediates immunoregulation, inflammation, inhibition of cell multiplication, interaction with mixed histocompatibility genes, and differentiation. It has no effect on extracellular virus and does not prevent virus from penetrating cells. It reversibly binds to specific cellular receptors, thereby activating cytoplasmic enzymes affecting messenger RNA translation and protein synthesis; the antiviral state takes several hours to develop but persists for days. Peginterferon has the same spectrum of activity as interferon- α .

PHARMACOKINETICS

Oral absorption	Poor
C_{\max} 3 × 10 ⁶ IU intramuscularly	20 IU/mL after 2–4 h
9 × 10 ⁶ IU intramuscularly	50–100 IU/mL after 2–4 h
Plasma half-life	3–8 h
Peginterferon	36 h
Plasma protein binding	Not known

Cerebrospinal fluid (CSF) penetration is poor. It is not cleared by hemodialysis. Little or none is excreted in the urine, and its fate after release from the cell receptor is largely unknown. The extent of excretion in breast milk is unknown.

INTERACTIONS

Human hepatic cytochrome P₄₅₀ systems and oxidative drug metabolism are inhibited, causing a modest prolongation in the half-life of drugs such as theophylline.

TOXICITY AND SIDE EFFECTS

Toxicity has become increasingly apparent with the advent of purer preparations. ‘Flu’-like symptoms (fever, arthralgia, myalgia, headache, malaise, chills) occur, which can usually be ameliorated by acetaminophen (paracetamol) administration. Lymphocytopenia is common, generally arising 2–4 h

after administration of several million units. Liver function test values are frequently elevated at doses above 10^7 IU/day. These effects are rapidly reversible and tolerance may develop after several doses. Other toxic effects include gastrointestinal disturbances (anorexia, nausea, diarrhea, vomiting), weight loss, local pain, severe fatigue, alopecia, paresthesias, confusion, dizziness, drowsiness, nervousness and bone marrow suppression. Neutropenia and thrombocytopenia are dose dependent (threshold around 3×10^6 IU/day) and reversible. Hypotension may develop during, or up to 2 days after, treatment, and arrhythmias and cardiac failure have been observed.

Administration of excessive doses to pregnant rhesus monkeys in the early to mid-trimester caused abortions. Its effect on human pregnancy is unknown. Neutralizing antibodies have been reported in about 25% of treated patients but no clinical sequelae to their presence have been documented. Intralesional administration in the treatment of condylomata acuminata is generally well tolerated.

Peginterferon is also associated with fatigue, headache, myalgia and fever; most other side effects occur less frequently.

CLINICAL USE

Chronic hepatitis B
Chronic hepatitis C (in combination with ribavirin)
Condyloma acuminata (intralesional)

It may also be of benefit in hairy cell and chronic myelogenous leukemias and Kaposi's sarcoma.

Preparations and dosage

Proprietary names: Interferon- α , Intron A, Roferon A, Wellferon, Viraferon, Interferon- γ 1b, Imukin, Pegasys (peginterferon).

Preparation: Injection.

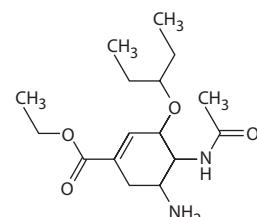

Dosage: Dose varies according to the condition being treated.

Widely available.

NEURAMINIDASE INHIBITORS

OSELTAMIVIR

Molecular weight (ethyl ester): 312.

A selective neuraminidase inhibitor, formulated as the phosphate salt of the ethyl ester for oral administration.

ANTIVIRAL ACTIVITY

Oseltamivir is active against influenza A and B, but no other virus.

ACQUIRED RESISTANCE

Mutations in the neuraminidase (H274Y) have been detected in treated patients with seasonal H1N1 infection. Cross-resistance with zanamivir has been described in vitro.

PHARMACOKINETICS

Oral absorption	c. 75%
C _{max} 75 mg oral	0.35–0.55 mg/L after 4 h
Plasma half-life	7–9 h
Plasma protein binding	Not known

The ethyl ester prodrug is hydrolyzed by hepatic esterases to release the active compound, oseltamivir carboxylate. Drug is excreted in the urine as the carboxylate derivative.

TOXICITY AND SIDE EFFECTS

Adverse events relate to the gastrointestinal tract; the most common is nausea with or without vomiting in 10% of patients. Food alleviates side effects.

- Witthoft T. Review of consensus interferon in the treatment of chronic hepatitis C. *Biologics*. 2008;2:635–643.

CLINICAL USE

Treatment and prevention of susceptible influenza A (H3N2) and B infections in adults and young children

Preparations and dosage

Proprietary name: Tamiflu.

Preparations: 75 mg tablets, capsules.

Dosage: Adults, oral, 75–150 mg per day in 1–2 divided doses. Children: 0–9 months, 3.0 mg/kg twice daily; 9 months–2 years, 3.5 mg/kg twice daily; >2 years old, 30–75 mg once or twice daily. Treatment twice daily for 5 days; prophylaxis once daily.

Widely available.

Further information
