ZANAMIVIR

Molecular weight: 332.

A synthetic neuraminidase inhibitor formulated for administration by inhalation.

ANTIVIRAL ACTIVITY

Zanamivir is active against influenza A and influenza B.

ACQUIRED RESISTANCE

Resistance is presently uncommon, including strains resistant to oseltamivir. In clinical trials the frequency was no more than 1% of exposed patients.

PHARMACOKINETICS

Oral bioavailability is poor. After inhalation local respiratory mucosal concentrations greatly exceed those that are inhibitory for influenza A and B replication. The median concentrations in the sputum exceed 1 mg/L 6 h after inhalation and remain detectable for 24 h.

TOXICITY AND SIDE EFFECTS

Most adverse effects are related to the respiratory tree. These include rhinorrhea and, rarely, bronchospasm. Nausea and vomiting have been reported at low incidence.

CLINICAL USE

Treatment of influenza A and B infections in patients over 7 years of age, and prophylaxis of patients ≥5 years of age

Preparation and dosage

Proprietary name: Relenza.

Preparation: Powder for inhalation.

Dosage: Adults and children >5 years, by inhalation, 10 mg every 12 h for 5 days. Prophylaxis, 10 mg once daily.

Widely available.

An intravenous preparation is under development

NUCLEOSIDE ANALOGS

ACICLOVIR

Acyclovir (USAN); valacyclovir (USAN). Molecular weight (acyclovir): 225; (valaciclovir): 324.

A synthetic acyclic purine nucleoside analog of the natural nucleoside 2' deoxyguanosine, formulated for oral and topical use, and as the sodium salt for intravenous infusion. Valaciclovir (the L-valyl ester) is a prodrug formulation supplied as the hydrochloride for oral use.

ANTIVIRAL ACTIVITY

Activity is restricted to viruses of the herpes group. Herpes simplex virus (HSV) types 1 and 2, simian herpes virus B and varicella zoster viruses (VZV) are susceptible to concentrations readily attainable in human plasma. The 50% inhibitory concentration (ID_{50}) is 0.1 μmol for HSV-1 and HSV-2 and 3 μmol for VZV, concentrations much below those toxic to cells. Valaciclovir is metabolized to acyclovir, and has the same antiviral profile.

Thymidine-kinase-negative HSV mutants and cytomegalovirus (CMV) do not code for thymidine kinase and are generally resistant. Although Epstein–Barr virus (EBV) may have reduced thymidine kinase activity, its DNA polymerase is susceptible to acyclovir triphosphate and shows intermediate susceptibility. Human herpes viruses 6 and 7 are less susceptible than EBV.

ACQUIRED RESISTANCE

Mutations in HSV that involve deficient thymidine kinase or an altered substrate are most common; alterations in the DNA polymerase gene also result in resistance. Resistant

mutants may be found in wild virus populations; mutants lacking thymidine kinase activity may be readily induced by passage of HSV in the presence of the drug. Resistant strains have mostly been reported in immunocompromised patients, are generally thymidine-kinase negative, and have decreased virulence. Resistant mutants that retain thymidine kinase activity appear to retain virulence. Emergence of resistant HSV strains is less frequent in immunocompetent patients, occurring in about 2% of those receiving prolonged treatment.

PHARMACOKINETICS

Oral absorption, acyclovir	c. 20%
valaciclovir	c. 60%
C_{\max} 200 mg oral 4-hourly	1.4–4 μmol after 1.5–1.75 h
5 mg/kg 8-hourly intravenous infusion	43.2 μmol steady state
10 mg/kg 8-hourly intravenous infusion	88.9 μmol steady state
Plasma half-life	3–3.3 h
Plasma protein binding	15%

Absorption

Therapeutic drug levels are readily attained after oral or intravenous administration, although concentrations achieved by an oral dose are over 90% lower than those after intravenous therapy. Accumulation of the drug is unlikely in patients without renal dysfunction.

Valaciclovir is readily absorbed and is converted rapidly and almost completely to acyclovir; absorption is unaffected by food. Peak plasma concentrations of 22 μmol are found in subjects after an oral dose of 1000 mg every 8 h; systemic exposure is comparable to that of intravenous acyclovir 5 mg/kg every 8 h. The peak plasma concentration and area under the concentration–time curve (AUC) do not increase proportionally with increasing doses, presumably due to reduced absorption. The time to peak acyclovir concentration is also dose dependent, ranging from 0.9 to 1.8 h after single oral doses of 100–1000 mg.

Distribution

Acyclovir is widely distributed in various tissues and body fluids. Delivery of the drug to the basal epidermis after topical administration is about 30–50% of that obtained by oral dosing. Acyclovir ointment penetrates the corneal epithelium. CSF concentrations are about 50% of simultaneous plasma concentrations. Vesicular fluid concentrations approximate those in plasma. The drug is actively secreted into breast milk at a concentration several times that of plasma. Placental cord blood contains levels of 69–99% of maternal plasma and the drug is 3–6 times more concentrated in amniotic fluid.

Metabolism

About 15% of an intravenous dose is metabolized in persons with normal renal function. The only significant urinary metabolite is 9-carboxymethoxymethylguanine, which has no antiviral activity. Less than 0.2% of the dose is recovered as the 8-hydroxylation product.

Excretion

Around 45–79% of a dose is recovered unchanged in urine, the percentage declining with decreasing creatinine clearance. In patients with renal failure, mean peak plasma concentrations nearly doubled and the elimination half-life increased to 19.5 h. Dosage reductions are advised for various stages of renal impairment. During hemodialysis the half-life is 5.7 h and after dialysis the plasma concentration is about 60% less than the predialysis concentration. Half-lives of 12–17 h have been reported for patients undergoing continuous peritoneal dialysis, with only 13% or less of administered drug being recovered in the 24-h dialysate. The half-life in patients undergoing arteriovenous hemofiltration/dialysis is about 20 h.

Less than 1% of a dose of valaciclovir is recovered as unchanged drug in the urine. In multidose studies the amount of aciclovir recovered across dose levels ranged from about 40% to 50%. Between 7% and 12% of the dose is found as the 9-carboxymethoxymethylguanine metabolite. Overall, aciclovir accounts for 80–85% of total urinary recovery.

TOXICITY AND SIDE EFFECTS

Few adverse reactions to topical, ocular, oral or intravenous formulations have been reported. Allergic contact dermatitis occasionally occurs with aciclovir cream. Superficial punctate keratopathy occurs in 10% of patients receiving the ophthalmic preparation; stinging or burning on application occurs in 4%. Less common complications include conjunctivitis, blepharitis and pain.

Transient increases in blood urea nitrogen and creatinine occur in 10% of patients given bolus injections. It can be largely avoided by reducing the rate of infusion, adequate hydration and dosage adjustment in renal failure. Nausea, vomiting, diarrhea and abdominal pain occasionally occur, particularly in association with a raised creatinine concentration. Acute reversible renal failure has been reported. Reconstituted aciclovir has a pH of about 11; severe inflammation and ulceration have been reported after extravasation at the infusion site. Encephalopathy, tremors, confusion, hallucinations, convulsions, psychiatric disorders, bone marrow depression and abnormal liver function have occasionally arisen. Skin rashes have been reported in a few patients but resolve on discontinuation of the drug.

Headache and nausea have been reported as side effects of valaciclovir, but occurred with similar frequency in subjects taking placebo.

Results of mutagenicity tests in vitro and in vivo indicate that aciclovir is unlikely to pose a genetic risk to humans, and the drug was not found to be carcinogenic in long-term studies in mice and rats. No detectable drug-related effects have been detected in pregnancy.

CLINICAL USE

Aciclovir

Herpes simplex keratitis
Chickenpox and herpes zoster
Herpes simplex encephalitis and neonatal herpes
Prophylaxis of HSV infections in the severely immunocompromised

Valaciclovir

Herpes zoster and genital HSV infections

Preparations and dosage

Proprietary names: Zovirax (aciclovir), Valtrex (valaciclovir).

Preparations: Tablets, suspension, i.v. infusion, cream, eye ointment (aciclovir), tablets (valaciclovir).

Dosage: Adults, children, oral, dose varies according to the condition being treated. I.v. infusion, adults, HSV or VZV, 5 mg/kg every 8 h, doubled in primary and VZV in the immunocompromised and in herpes simplex encephalitis. Children, 1–3 months, 10 mg/kg every 8 h; 3 months–12 years, 250 mg/m² every 8 h; dose doubled in the immunocompromised and HSV encephalitis; for neonatal HSV, 20 mg every 8 h for 21 days.

Valaciclovir: herpes zoster, 1000 mg every 8 h for 7 days. Episodic therapy of genital herpes, 500 mg every 8 h for 3–5 days. Suppressive treatment, 500 or 1000 mg per day in two divided doses.

Widely available.

ENTECAVIR

Molecular weight (monohydrate): 295.3.

An analog of guanosine formulated as tablets and suspension for oral use.

ANTIVIRAL ACTIVITY

Entecavir is active only against hepatitis B virus. The 50% effective dose (ED₅₀) is approximately 0.004 µM.

RESISTANCE

Development of resistance after 96 weeks of therapy was uncommon (<1%).

PHARMACOKINETICS

Oral absorption	100%
C _{max} 0.5 mg/kg oral	4.2 ng/mL
Intracellular half-life	c. 16 h
Volume of distribution	In excess of body water
Plasma protein binding	13%

Entecavir is rapidly absorbed after administration on an empty stomach, achieving peak plasma concentrations in 1–1.5 h. Plasma steady state is achieved in 6–10 days.

It is renally eliminated. Dosage adjustment is required with impaired creatinine clearance. The drug is not metabolized by cytochrome P₄₅₀. No drug interactions have been identified.

TOXICITY AND SIDE EFFECTS

Severity of adverse reactions was comparable to that of lamivudine, with headache, fatigue, upper respiratory infections and abdominal pain being most common. Lactic acidosis and hepatic steatosis were rarely observed.

CLINICAL USE

Treatment of chronic hepatitis B virus infection in patients >16 years of age

Preparations and dosage

Proprietary name: Baraclude.

Preparations: Tablets (0.5 and 1.0 mg), oral suspension (0.05 mg/mL).

Dosage: 0.5 mg per day; for known lamivudine or telbivudine resistance, 1 mg per day.

Available in Europe and the USA.

GANCICLOVIR

Molecular weight (free acid): 255; (sodium salt): 277; (valganciclovir): 354.

A synthetic 2'-deoxyguanosine nucleoside analog, supplied as the L-valine ester, valganciclovir, for oral administration and as the sodium salt for parenteral use. A slow-release ocular implant device is also available.

ANTIVIRAL ACTIVITY

Ganciclovir is phosphorylated to the monophosphate by a cellular deoxyguanosine kinase more rapidly in infected than uninfected cells. HSV and VZV thymidine kinases monophosphorylate ganciclovir, after which it is further metabolized to the active triphosphate by cellular enzymes. The UL97 open reading frame of CMV encodes a phosphonotransferase, which can regulate phosphorylation. In CMV-infected cells the concentration of the triphosphate is approximately 10-fold higher than in uninfected cells.

HSV-1 and HSV-2 are inhibited by 0.2–8.0 µmol (0.05–2.0 mg/L). Its activity is similar to that of aciclovir against HSV-1 in vitro, but is slightly superior against HSV-2. The ID₅₀ for CMV ranges from 0.5 to 11 µmol (0.125–2.75 mg/L). EBV is inhibited by 1–4 µmol and VZV by 4–40 µmol.

ACQUIRED RESISTANCE

Prolonged, repeated courses lead to the selection of resistant strains, occurring in 8% of patients receiving the drug for >3 months. Studies of laboratory-derived resistant strains indicate that drug resistance can result from alterations in the phosphonotransferase encoded by the gene region UL 27, the viral DNA polymerase (gene region UL 54), or both.

PHARMACOKINETICS

Oral absorption, ganciclovir	c. 5.4–7.1%
valganciclovir	80%
C _{max} 5 mg/kg 1-h infusion	33.2 µmol end infusion
Plasma half-life (intravenous infusion)	2.9 h
Volume of distribution	c. 1.17 L/kg
Plasma protein binding	1–2%

Absorption

After an intravenous infusion of 5 mg/kg, the plasma level after 11 h was 2.2 µmol. After repeated 5 mg/kg doses every 8 h, the mean peak serum levels were 25 µmol and mean trough levels 3.6 µmol, levels in excess of, or in the same range as, the ID₅₀ for CMV. In patients treated for 8–22 days with 1 or 2.5 mg/kg every 8 h, the mean steady-state plasma concentrations after a 1 h infusion of 1 mg/kg ranged from 7.2 µmol immediately after infusion to 0.8 µmol after 8 h. Corresponding values after a dose of 2.5 mg/kg were 19.6 and 3.2 µmol, respectively.

Multiple dosing with oral ganciclovir 1 g every 8 h resulted in peak levels of 1.1 mg/L (4.3 µmol) and a trough of 0.52 mg/L (2.1 µmol). Valganciclovir is rapidly converted to ganciclovir, doses of 900 mg producing plasma levels similar to those achieved with 5 mg/kg ganciclovir every 12 h.

Distribution

Data on distribution are limited. The levels of the drug in CSF are estimated to be 24–67% of those in plasma. Mean intravitreal levels of 14 µmol were reported for samples taken a mean of 12 h after therapy with a mean dose of 6 mg/kg per day. However, no significant correlations are noted between time after the last dose and intravitreal concentration. The observed mean value in the eye is below the concentration required to achieve 50% or 90% inhibition of CMV plaque

formation by clinical isolates, which may explain the difficulty in controlling CMV retinitis.

Metabolism and excretion

About 80% of the drug is eliminated unchanged in the urine within 24 h. Probenecid and other drugs that impact renal tubular secretion or absorption may reduce renal clearance. In severe renal impairment, the mean plasma half-life is 28.3 h. Dosage must be reduced in patients with impaired renal function. Plasma levels of the drug can be reduced by approximately 50–90% with hemodialysis. The half-life on dialysis is about 4 h. Patients undergoing dialysis should be given 1.25 mg/kg per day; therapy should also be administered after dialysis.

No significant pharmacokinetic interaction occurs when ganciclovir and foscarnet are given as concomitant or daily alternate therapy.

TOXICITY AND SIDE EFFECTS

The 50% inhibitory concentration (IC₅₀) for human bone marrow colony-forming cells is 39 (\pm 73) µmol; for other cell lines it ranges from 110 to 2900 µmol. Toxicity frequently limits therapy. Marrow suppression may develop on as little as 5 mg/kg on alternate days and is exacerbated when the drug is given with zidovudine. Neutropenia of <1000/mm³ occurs in nearly 40% of recipients and <500/mm³ in upwards of 30% for those given induction therapy of 10 mg/kg per day for 14 days, followed by 5 mg/kg per day. Neutropenia is reversible and develops during the early treatment or maintenance phase, but may occur later. Thrombocytopenia of <20 000/mm³ and <50 000/mm³ develops in about 10% and 19% of patients, respectively. Frequent monitoring of the full blood count is recommended.

Adverse effects on the CNS, including confusion, convulsions, psychosis, hallucinations, tremor, ataxia, coma, dizziness, headaches and somnolence, occur in around 5% of patients. Liver function abnormalities, fever and rash occur in about 2%. Intraocular injection of ganciclovir is associated with intense pain, and occasionally amaurosis lasting for 1–10 min.

Animal studies indicate that inhibition of spermatogenesis and suppression of female fertility occurs. Ganciclovir is also potentially embryolethal, mutagenic and teratogenic, and is contraindicated during pregnancy or lactation. It can cause local tissue damage and should not be administered intramuscularly or subcutaneously; patients should be adequately hydrated during treatment.

CLINICAL USE

Life- or sight-threatening CMV infections in immunocompromised individuals
Prevention and treatment of CMV disease in patients receiving immunosuppressive therapy for organ transplantation

An ocular implant has been developed for the treatment of CMV retinitis.

Use in congenital CMV infections has not yet gained regulatory approval.

Preparations and dosage

Proprietary names: Cytovene, Cymevene, Vitraser (ocular implant), Valcyte (valganciclovir).

Preparations: Capsules, i.v. infusion, ophthalmic solution (ganciclovir); tablets (valganciclovir).

Dosage: Adults, i.v., treatment, 5 mg/kg every 12 h for 14–21 days. Maintenance dose, i.v., 6 mg/kg per day on 5 days per week or 5 mg/kg once every day. Oral, 1 g every 8 h or 500 mg every 4 h, following at least 3 weeks i.v. therapy.

Valganciclovir: 900 mg every 12 h.

Widely available.

PENCICLOVIR

Molecular weight (penciclovir): 253.3; (famciclovir): 321.3.

Famciclovir

Penciclovir

A synthetic acyclic purine nucleoside analog, usually administered orally as the diacetyl ester, famciclovir, which acts as a prodrug undergoing rapid first-pass metabolism to release the active compound in vivo. The parent compound has virtually no oral bioavailability, but is supplied as a topical formulation.

LAMIVUDINE

An antiretroviral agent that also exhibits activity against hepatitis B virus and duck hepatitis B virus. Its properties are described in Ch. 36 (p. 432). Use is limited by the development of resistance within 1 year in up to 25% of treated patients. It is likely to be used with other drugs in the future.

CLINICAL USE

Therapy of chronic hepatitis B

Preparations and dosage

Proprietary name: Epivir.

Preparations: 100 mg tablets, oral solution.

Dosage: Adults, oral, 150 mg every 12 h. Children, 3 months–12 years, 4 mg/kg every 12 h (maximum dose, 300 mg per day).

Widely available.

ANTIVIRAL ACTIVITY

It is active against members of the herpes virus family, with greatest activity against HSV-1 (ID_{50} 1.6 μmol), somewhat lower activity against HSV-2 (ID_{50} 6.0 μmol), and less activity against VZV (ID_{50} 12 μmol). The ID_{50} values for aciclovir in the same cells were 0.9, 2.7 and 17 μmol , respectively. CMV is relatively resistant and EBV has intermediate susceptibility. The activity of hepatitis B virus is inhibited in vitro.

In cells infected with HSV-1, HSV-2 and VZV monophosphorylation is more efficient than that of aciclovir. It has less affinity for viral DNA polymerases than aciclovir triphosphate and does not act as a DNA chain terminator; however, it has a much longer half-life.

ACQUIRED RESISTANCE

Penciclovir is inactive against thymidine kinase-deficient strains of HSV.

PHARMACOKINETICS

Oral absorption, penciclovir famciclovir	5% 77%
Cmax famciclovir 250 mg oral famciclovir 500 mg oral famciclovir 750 mg oral	1.6 mg/L after 0.5–1.5 h 3.3 mg/L after 0.5–1.5 h 5.1 mg/L after 0.5–1.5 h
Plasma half-life	2.1–2.7 h
Volume of distribution	c. 1.5 L/kg
Plasma protein binding	<20%

Following absorption famciclovir is converted rapidly by enzyme-mediated deacetylation and oxidation to penciclovir. Food does not lead to any significant change in the availability or elimination.

The pharmacokinetics in elderly subjects are similar to those seen in younger subjects, although small increases in AUC and plasma half-lives were seen, consistent with slightly decreased renal clearance.

Renal excretion is the major route of elimination, 50–60% of an oral dose being recovered in the urine. After intravenous infusion, about 70% is excreted unchanged in the urine. After oral administration of famciclovir, penciclovir accounts for 82% of urinary drug-related material. The remainder includes metabolites, of which the largest is the 6-deoxy precursor of penciclovir. Renal clearance exceeds glomerular filtration, indicating renal tubular secretion.

TOXICITY AND SIDE EFFECTS

In clinical trials the incidence of adverse events after famciclovir, aciclovir and placebo were similar, the most common adverse events being headache and nausea.

CLINICAL USE

Herpes zoster and genital herpes
Orolabial herpes (topical)

Preparations and dosage

Proprietary names: Denavir, Famvir, Vectavir.

Preparations: Tablets and topical cream.

Dosage: Adults, oral, 125–500 mg every 6–8 h for 7 days for HSV and VZV infections. Alternative 1-day treatment regimens include 1000 mg every 12 h for 1 day in the treatment of genital and labial herpes. Topical, every 6 h.

Widely available.

RIBAVIRIN

Molecular weight: 244.2.

A synthetic nucleoside. It is neither a classic pyrimidine nor a purine, but stereochemical studies indicate that it is a guanosine analog. It is usually formulated for administration by inhalation, but oral and intravenous preparations are also used.

ANTIVIRAL ACTIVITY

Laboratory tests indicate that herpes viruses are the most sensitive. Of the RNA viruses, activity has been noted with influenza types A and B; parainfluenza virus types 1, 2 and 3; mumps, measles and respiratory syncytial virus (RSV); Lassa fever and Machupo viruses; Rift Valley fever, sandfly fever, Hantaan and yellow fever viruses. RSV plaques are reduced 85–98% by 16 mg/L.

Ribavirin is phosphorylated in cells and inhibits inosine monophosphate dehydrogenase, which is involved in the synthesis of guanosine triphosphate. Decrease in intracellular thymidine triphosphate has also been noted. In most cell lines the antiviral activity is much lower than the cytostatic dose, which ranges from 200 to 1000 mg/L.

Ribavirin and interferon- α , particularly the pegylated forms, act synergistically in the treatment of chronic hepatitis C virus (HCV) infection, resulting in sustained reduction in alanine aminotransferase levels and loss of HCV RNA in 40% of patients who failed to respond to interferon previously.

ACQUIRED RESISTANCE

Development of resistant virus strains has not been demonstrated.

PHARMACOKINETICS

Oral absorption	36–46%
C_{max} 3 mg/kg oral	4.1–8.2 $\mu\text{mol/L}$ after 1–1.5 h
600 mg intravenous	43.6 $\mu\text{mol/L}$ end infusion
Plasma half-life	c. 24 h
Volume of distribution	647 L
Plasma protein binding	<10%

Absorption

It is rapidly absorbed after oral administration. Mean peak concentrations after 1 week of oral doses of 200, 400 and 800 mg every 8 h were 5.0, 11.1 and 20.9 $\mu\text{mol/L}$, respectively. Trough levels 9–12 h after the end of 2 weeks' therapy were 5.1, 13.2 and 18.4 $\mu\text{mol/L}$, respectively, indicating continued accumulation of the drug. Drug was still detectable 4 weeks later. Mean peak plasma concentrations after intravenous doses of 600, 1200 and 2400 mg were 43.6, 72.3 and 160.8 $\mu\text{mol/L}$, respectively; at 8 h the mean plasma concentrations were 2.1, 5.6 and 10.2 $\mu\text{mol/L}$.

Aerosolized doses (6 g in 300 mL distilled water) are generally administered at a rate of 12–15 mL/h using a Collision jet nebulizer, the estimated dosage being 1.8 mg/kg per h for infants and 0.9 mg/kg per h for adults. When administered by small particle aerosol for 2.5–8 h, plasma concentrations ranged from 0.44 to 8.7 $\mu\text{mol/L}$.

Metabolism and excretion

It is rapidly degraded by deribosylation or amide hydrolysis, and together with its metabolites is slowly eliminated by the kidney. About 50% of the drug or its metabolites appear in the urine within 72 h and 15% is excreted in the stools. The remainder seems to be retained in body tissues, principally in red blood cells, which concentrate the drug or metabolites to a peak at 4 days, with a half-life of around 40 days. After intravenous administration 19.4% of the dose was eliminated during the first 24 h (compared with 7.3% after an oral dose), the difference reflecting the bioavailability.

TOXICITY AND SIDE EFFECTS

It is generally well tolerated, though adverse reactions appear to be related to dose and duration of therapy. Minor adverse reactions include metallic taste, dry mouth sensation and increased thirst, flatulence, fatigue and CNS complaints, including headache, irritability and insomnia. Daily doses of 1 g may cause unconjugated bilirubin levels to double and the reticulocyte count to increase. Hemoglobin concentrations may decrease with treatment or higher dosages; with doses of 3.9–12.6 g per day, a drop in hemoglobin was noted by days 7–13 of treatment, which was generally 'rapidly'

reversible on withdrawal of the drug, but in some instances necessitated blood transfusion.

Aerosol administration of about 2 g in 36 or 39 h during 3 days is well tolerated, does not affect results of pulmonary function tests, and seems non-toxic.

It is both teratogenic and embryotoxic in laboratory animals, so precautions must be observed in women of child-bearing age.

CLINICAL USE

RSV infections in infants (by nebulizer) in emergency situations (i.e. transplant recipients)

Lassa fever

Hepatitis C (in combination with interferon- α)

Use in RSV pneumonia in infants is no longer routine. It reduces mortality from Hantaan virus, the agent responsible for hemorrhagic fever with renal syndrome.

Preparations and dosage

Proprietary names: Virazole (for inhalation); Rebotal, Copegus (oral).

Preparations: Inhalation, tablets, capsules, oral solution.

Dosage: By aerosol inhalation or nebulization (via small-particle aerosol generator) of solution containing 20 mg/mL for 12–18 h per day for at least 3 days and a maximum of 7 days. Adults, oral, <65 kg, 400 mg every 12 h; 65–85 kg, 400 mg in the morning and 600 mg at night; >85 kg, 600 mg every 12 h. Oral dosage recommendation vary according to formulations: see manufacturer's literature.

Widely available.

TELBIVUDINE

Molecular weight: 242.2.

A synthetic thymidine nucleoside analog formulated for oral use in the treatment of chronic hepatitis B infection.

ANTIVIRAL ACTIVITY

Telbivudine is active at therapeutic concentrations only against hepatitis B. After phosphorylation it competitively inhibits HBV DNA polymerase. It inhibits HBV first strand (EC_{50} 1.3 ± 1.6 μM) and second strand synthesis (EC_{50} 0.2 ± 0.2 μM). Concentrations of telbivudine 5'-triphosphate ≤100 μM did not inhibit human cellular DNA polymerases. No appreciable mitochondrial toxicity was observed in HepG2 cells at concentrations up to 10 μM.

ACQUIRED RESISTANCE

After 1 year resistance occurred in 7–20% of patients on telbivudine depending upon past exposure to other drugs used in the treatment of hepatitis B and the type of infection. Development of resistance was less frequent in those receiving telbivudine than in those receiving lamivudine.

PHARMACOKINETICS

Oral absorption	100%
C_{max} 600 mg/kg oral	3.7 μg/ml
Volume of distribution	In excess of body water
Plasma protein binding	3.3%

It is eliminated renally, necessitating dose adjustment in patients with renal insufficiency.

It should not be administered with pegylated interferon because of an increased risk of neuropathy.

TOXICITY AND SIDE EFFECTS

Adverse effects are similar to those of lamivudine and include upper respiratory tract infection, headache, fatigue and gastrointestinal upset. Myopathy and peripheral neuropathy are rare but have been observed in some patients several weeks into the course with associated rise in serum creatine kinase levels. Acute exacerbations of hepatitis have been observed on discontinuation of therapy. Lactic acidosis may occur, necessitating drug discontinuation.

CLINICAL USE

Treatment of chronic hepatitis B in patients >16 years of age

Preparations and dosage

Proprietary name: Tzeka, Sebire.

Preparations: Tablets (600 mg), oral suspension (100 mg/5 mL).

Dosage: 600 mg once daily.

Available in Europe and the USA.

OTHER NUCLEOSIDE ANALOGS

IDOXURIDINE

A halogenated pyrimidine analog originally synthesized as an anticancer agent. Formulated in dimethylsulfoxide for topical application and as a solution for ophthalmic use.

Activity is largely limited to DNA viruses, primarily HSV-1, HSV-2 and VZV. HSV-1 plaque formation in BHK 21 cells is sensitive to 6.25–25 mg/L; type 2 microplaques required 62.5–125 mg/L. RNA viruses are not affected, with the exception of oncogenic RNA viruses such as Rous sarcoma virus. Drug resistance is easily generated in vitro, and may be an obstacle to treatment. However, there is little or no cross-resistance with newer nucleoside analogs.

It is poorly soluble in water, and aqueous solutions are ineffective against infections other than those localized to the eye. In animals, therapeutic levels are achieved in the cornea within 30 min of ophthalmic application and persist for 4 h. Penetration is otherwise poor, with only the biologically inactive dehalogenated metabolite uracil entering the eye.

The drug is too toxic for systemic administration. Contact dermatitis, punctate epithelial keratopathy, follicular conjunctivitis, ptosis, stenosis and occlusion of the puncta and keratinization of the lid margins occur in up to 14% of those receiving ophthalmic preparations.

It is used in herpes keratitis, but has largely been superseded by trifluridine or aciclovir.

TRIFLURIDINE

Trifluorothymidine. A synthetic halogenated pyrimidine nucleoside, first synthesized as an antitumor agent. It inhibits

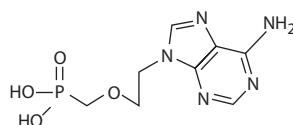

enzymes of the DNA pathway and is incorporated into both cellular and progeny viral DNA, causing faulty transcription of late messenger RNA and the production of incompetent virion protein. It does not require a viral thymidine kinase for monophosphorylation and is far less selective and more toxic than other analogs. It is active against HSV-1 and HSV-2, vaccinia virus, CMV and possibly adenovirus. When applied as a 1% ophthalmic solution, it rapidly enters the aqueous humor of HSV-infected rabbits' eyes but is cleared within 60–90 min.

It causes sister chromatid exchange – an indicator of mutagenicity – at 0.5 mg/L in human lymphocytes and fibroblasts. It is teratogenic to chick embryos when injected directly into the yolk sac. Its principal adverse effects in humans following systemic administration include leukopenia, anemia, fever and hypocalcemia. Accordingly, it is restricted to topical ophthalmic use in HSV ocular infections. The ophthalmic 1% aqueous solution produces occasional punctate lesions; other side effects are similar to those of idoxuridine but arise less frequently.

NUCLEOTIDE ANALOGS

ADEFOVIR

Molecular weight (base): 273.2; (dipivoxil): 501.5.

A nucleotide analog of adenosine monophosphate, administered orally as its prodrug, adefovir dipivoxil.

ANTIVIRAL ACTIVITY

It is phosphorylated by cellular kinases to adefovir diphosphate, which competitively inhibits HBV reverse transcriptase and terminates DNA synthesis upon incorporation into the growing chain. The inhibition constant (K_i) for adefovir diphosphate for HBV DNA polymerase was 0.1 μM . The diphosphate is a weak inhibitor of human DNA polymerases α and γ , with K_i values of 1.18 μM and 0.97 μM , respectively. It inhibits HIV in vitro, but an effective dose with a margin of safety could not be achieved in human studies.

ACQUIRED RESISTANCE

It has a lower propensity to induce drug resistance than lamivudine. Clinical trials of patients receiving 48 weeks of therapy did not identify any cases of resistance. Longer courses

yield resistant strains of HBV with mutations in the DNA polymerase gene; other rare variants of resistant strains have been identified. Lamivudine-resistant strains of HBV retain susceptibility to adefovir.

PHARMACOKINETICS

Oral absorption	c. 60%
C_{\max} 10 mg/kg oral	18.4 ng/mL
Plasma half-life	c. 7.5 h.
Volume of distribution	392 mL/kg
Plasma protein binding	Not known

The prodrug is metabolized to adefovir, which is excreted by the kidneys and therefore requires dose adjustment in patients with impaired renal function. It does not induce cytochrome P₄₅₀ at standard doses and does not influence the metabolism or plasma concentrations of the other licensed medications used in the treatment of hepatitis B.

TOXICITY AND SIDE EFFECTS

It is generally well tolerated, with headache, pharyngitis, abdominal pain and peripheral neuropathy being the most common side effects. Nephrotoxicity has been observed in some patients, with those receiving higher doses and longer courses of therapy at greater risk. Exacerbation of hepatitis has been reported in patients immediately following discontinuation of treatment. Most exacerbations occur within 12 weeks of stopping therapy, and elevations of alanine aminotransferase (ALT) up to 10 times the upper limit of normal can be observed in over 25% of patients. Lactic acidosis has been reported in a few patients and is an indication for immediate discontinuation.

CLINICAL USE

Treatment of chronic hepatitis B virus infection in patients >12 years of age

Preparations and dosage

Proprietary name: Hepsera.

Preparation: 10 mg tablet.

Dosage: 10 mg tablet.

Widely available in Europe and the USA.

CIDOFOVIR

Molecular weight: 279.

An acyclic cytosine analog administered by intravenous infusion.

ANTIVIRAL ACTIVITY

The phosphonate group enables it to mimic a nucleotide and bypass virus-dependent phosphorylation. Cellular enzymes convert it to the triphosphate, which has in-vitro and in-vivo activity against CMV and other herpesviruses, including aciclovir-resistant HSV. Oral hairy leukoplakia resolved on therapy, suggesting that it has activity against EBV. Activity against adenovirus and papillomaviruses is also reported.

RESISTANCE

Resistance can be generated in the laboratory but has not yet been encountered during treatment of patients.

PHARMACOKINETICS

Oral absorption	<5%
C_{\max} 3 mg/kg intravenous infusion	7.7 mg/L end infusion
10 mg/kg intravenous infusion	23 mg/L end infusion
Plasma half-life	c. 3–4 h
Volume of distribution	c. 0.6 L/kg
Plasma protein binding	<6%

The intracellular half-life of the diphosphate is 17–65 h. It is excreted unchanged by the kidney by glomerular filtration and tubular secretion.

TOXICITY AND SIDE EFFECTS

Nephrotoxicity, heralded by proteinuria, occurred at weekly doses of ≤ 3 mg/kg in two of five patients after 6 and 14 consecutive weeks of therapy. Two of five patients given 10 mg/kg developed nephrotoxicity, manifested as a Fanconi-like syndrome, after only two doses. Biopsy revealed proximal tubular effects. Prehydration and extended dosing intervals seem to be nephroprotective.

CLINICAL USE

Treatment of CMV retinitis

Because of nephrotoxicity it is a drug of last resort. It has been used experimentally in the treatment of adenovirus pneumonia and BK virus in transplant patients and juvenile laryngeal papillomatosis.

Preparations and dosage

Proprietary name: Vistide.

Preparation: Injection.

Dosage: Induction: adults, i.v., 5 mg/kg with hydration and probenecid once weekly for 2 weeks, then every other week.

Available in the USA and Europe, including the UK.

TENOFOVIR

A nucleotide analog structurally similar to adefovir. It is also used as an antiretroviral agent and its properties are described in Chapter 36 (pp. 434–435).

EC_{50} values for HBV, assessed in the HepG2 2.2.15 cell line, ranged from 0.14 to 1.5 μM ; the cytotoxic concentration exceeded 100 μM . A decline in HBV DNA levels below 10⁵ copies/mL at 48 weeks of therapy in 100% of patients receiving tenofovir compared with 44% on adefovir therapy has been reported. There are also case reports of patients with primary resistance to adefovir responding to tenofovir.

It is generally well tolerated in patients with chronic HBV; the most common side effects include nausea and gastrointestinal upset, headache, dizziness, fatigue and rash.

CLINICAL USE

Chronic hepatitis B infection

Preparations and dosage

Proprietary name: Viread.

Preparation: 300 mg tablets.

Dosage: 300 mg once daily.

Widely available.

OLIGONUCLEOTIDES

FOMIVIRSEN

Molecular weight: 6682.

An antisense oligonucleotide, 21 bases in length, representing the mirror image of a region of mRNA coding for a regulatory protein of CMV. It is administered as the sodium salt by intraocular injection. Experiments in monkeys suggest that it has a very long elimination half-life (*c.* 3 days). Because of its unique mode of action fomivirsen retains activity against strains of CMV resistant to other antiviral agents.

Side effects commonly include ocular inflammation, which is responsive to topical steroids, and raised intraocular pressure.

CLINICAL USE

CMV retinitis in AIDS patients intolerant of, or unresponsive to, other treatments

Preparations and dosage

Proprietary name: Vitravene.

Preparation: Injection.

Dosage: 0.33 mg intravitreal injection every 2 weeks for two doses, then every 4 weeks (half this dose for previously untreated patients).

Limited availability.

PHOSPHONIC ACIDS

FOSCARNET

Phosphonoformic acid; trisodium phosphonoformate. Molecular weight (anhydrous): 126; (trisodium salt): 300.1.

A synthetic non-nucleoside pyrophosphate analog formulated as the trisodium hexahydrate for intravenous use. The solubility in water at pH 7 is only about 5% (w/w).

ANTIVIRAL ACTIVITY

The RNA polymerase of influenza A virus, the DNA polymerases of HSV-1 and HSV-2, CMV, EBV, VZV and HBV are inhibited more efficiently than host-cell DNA polymerases. Concentrations of 6–55 μmol inhibit CMV plaque formation by 50%, but clinical isolates are generally 1.5–8 times less sensitive. In-vitro inhibition of CMV replication is reversed by withdrawal of the drug. Most strains of HSV that are resistant to aciclovir respond, but when treatment is discontinued, relapse is frequent. Foscarnet acts as a non-competitive inhibitor for substrates and templates of HIV reverse transcriptase in concentrations of 0.1–5.0 μmol , but 680 μmol was required to block replication of the virus in H9 cell cultures.

ACQUIRED RESISTANCE

Resistance can be generated in vitro, and CMV strains resistant to both ganciclovir and foscarnet have occasionally been recovered from humans.

PHARMACOKINETICS

Oral absorption	c. 17%
C_{max} 60 mg/kg intravenous 8-hourly	557 $\mu\text{mol/L}$
Plasma half-life	3.3–6.8 h
Volume of distribution	0.52–0.74 L/kg
Plasma protein binding	14–17%

Absorption and distribution

Oral bioavailability is poor. A wide range of plasma concentrations was noted (75–500 $\mu\text{mol/L}$) during 3–21 days of continuous intravenous infusion of 0.14–0.19 mg/kg per min. During continuous intravenous therapy the concentrations reached a plateau on day 3. Considerable differences in steady-state plasma concentrations exist between individuals. Drug penetrates the CSF; the mean concentration is about 40–60% of the mean plasma concentration, depending upon dose.

Metabolism and excretion

Elimination appears to be triphasic, with two initially short half-lives of 0.5–1.4 h and 3.3–6.8 h, followed by a long terminal phase of 88 h. About 88% of the cumulative intravenous dose is recovered unchanged in the urine within a week of stopping an infusion, indicating that the drug is not significantly metabolized. Non-renal clearance accounts for 14–18% of total clearance and may relate to uptake into bone. Plasma clearance decreases markedly with decreased renal function and the elimination half-life may be increased by up to 10-fold. Conventional dialysis eliminates about 25% of a dose while high-flux dialysis can remove nearly 60%.

INTERACTIONS

There is no significant pharmacokinetic interaction with zidovudine, or with ganciclovir given as concomitant or daily alternating therapy.

In view of its nephrotoxicity, co-administration with potentially nephrotoxic drugs – for example, aminoglycosides, amphotericin B, pentamidine and ciclosporin (cyclosporin) – should be avoided.

TOXICITY AND SIDE EFFECTS

Treatment is more frequently limited by toxicity than with ganciclovir. Renal toxicity is most common. A two- to three-fold increase in serum creatinine levels occurs in 20–60% (mean 45%) of patients given 130–230 mg/kg per day as a continuous intravenous infusion. Renal impairment usually develops

within the first few weeks of treatment and is generally reversible within several weeks of discontinuing therapy. Foscarnet chelates metal ions, and serum electrolyte abnormalities – predominantly hypocalcemia, hypomagnesemia, hypokalemia and hypophosphatemia – occur in about 30, 15, 16 and 8% of patients, respectively. Convulsions occur in 10–15%. Other side effects include anemia (25–50%), penile or vulval ulceration (3–9%), nausea and vomiting (20–30%), local irritation and thrombophlebitis at the infusion site, abdominal pain and occasional pancreatitis, headache (c. 25%), dizziness, involuntary muscle contractions, tremor, hypoesthesia, ataxia, neuropathy, anxiety, nervousness, depression and confusion, and skin rash. Nephrogenic diabetes insipidus has been reported.

Foscarnet is contraindicated in pregnancy. Topical application does not result in dermal toxicity similar to that produced by phosphonacetic acid.

CLINICAL USE

Treatment of CMV retinitis in patients for whom ganciclovir is contraindicated, inappropriate or ineffective

It is also potentially of value in the treatment of aciclovir-resistant HSV infection.

Preparations and dosage

Proprietary name: Foscavir.

Preparation: Injection.

Dosage: Adults, i.v., 60 mg/kg every 8 h for 2–3 weeks, then 60 mg/kg per day, increasing to 90–120 mg/kg per day if tolerated.

Widely available.

OTHER ANTIVIRAL COMPOUNDS

DOCOSANOL

A 22-carbon straight chain alcohol licensed for over-the-counter sales for the topical treatment of herpes labialis. It is thought to act by blocking viral fusion with the host cell, although definitive studies are lacking. The clinical relevance

of the antiviral activity has been debated and the place of this medication as a treatment of herpes labialis remains to be established.

IMIQUIMOD

An imidazoquinoline used for the treatment of genital and perianal warts. While the mechanism of action is not precisely known, it is thought to induce interferon. It has no direct anti-viral activity. The 5% cream applied three times a week for up to 16 weeks resulted in total wart clearance in 50% of

patients, with a better response in women than in men. Local reactions are common and include erythema, erosion, excoriation and edema.

PLECONARIL

An oxadiazole active against most enteroviruses and rhinoviruses. It binds to the hydrophobic pocket of the virus capsid protein VP1, inducing conformational changes that lead to altered receptor binding and viral uncoating. Concerns over safety and efficacy have constrained development of the drug.

CHAPTER

38 Sepsis

Anna Norrby-Teglund and Carl Johan Treutiger

In the second half of the 20th century, the use of antibiotics resulted in a sharp decline in morbidity and mortality from bacterial infectious disease. However, mortality has remained high when acute infection induces sepsis with shock, metabolic acidosis, oliguria or hypoxemia. In the USA alone, there are at least 500 000 episodes of sepsis annually; mortality rates range from 30% to 50%, despite intensive medical care, including antibiotics, intravenous fluids, nutrition, mechanical ventilation for respiratory failure and surgical eradication of the source of the infection.^{1,2} However, our understanding of sepsis and sepsis syndrome has increased markedly over the last decade. It is now well established that sepsis is an overwhelming, systemic host response to infection, resulting from complex interactions between the infecting pathogen and the host inflammatory, coagulation and fibrinolytic systems. The processes that lead to the sepsis syndrome are the result of microbial products that profoundly dysregulate mediator release and the homeostasis of several important pathways.^{3,4} One of the major advances has been the identification of mediators, both host and pathogen derived, which contribute to these pathophysiological changes and hence represent potential targets for intervention.^{4,5} Attempts to treat sepsis by blocking individual mediators or some of the common pathways have largely failed to reduce the overall mortality. This is probably due partly to the fact that where multiple cellular activation processes are involved and many humoral cascades triggered, merely blocking a single component may be insufficient to arrest the inflammatory process. However, the dysregulation that characterizes sepsis may be amenable to blockade of the bacterial components or to the intracellular pathways triggered by these products. Alternatively, intervention with pleiotropic and late-acting inflammatory mediators such as caspases, C5a, migration inhibitory factor or high mobility group box 1 may be possible.⁵

EPIDEMIOLOGY

Mortality and morbidity data from the US National Center for Health Statistics reported a 58% increase in death rates due to infectious diseases between 1980 to 1992⁶ and a rate of admission to hospital for infectious diseases that declined less steeply than for all admissions.⁷ Among the 15 leading reported causes of death in the USA since 1950, the greatest

increase in mortality has been due to septicemia. Recent data suggest that the incidence of sepsis continues to increase, but that the survival rates have gradually improved over the last 25 years.⁸

BACTEREMIA

Clinically significant bacteremia occurs with a frequency of 5–10 per 1000 hospital admissions, a figure that has been rising slowly over the last 10 years, largely due to an increasing number of nosocomial infections. Mylotte et al⁹ compared the epidemiology and outcome of community-acquired bacteremia in a teaching hospital and a non-teaching hospital and found incidences of community-acquired bacteremia to be 12.6 and 11.9 episodes per 1000 admissions, respectively. A number of sites are possible sources of bacteremia (Table 38.1). The type of pathogen and resistance pattern can vary according to the site of infection, the type of hospital and the location within the hospital in which the patient is being treated (Table 38.2). Such information may be of assistance in deciding on the most likely pathogen and most appropriate antimicrobial therapy. Mylotte et al⁹ found the proportion of episodes due to methicillin-sensitive *Staphylococcus aureus* significantly higher at the teaching hospital, in contrast to the proportion of episodes due to *Escherichia coli*, which was significantly higher at the non-teaching hospital (Table 38.2). Except for these differences, the proportion of episodes due to other organisms was similar. Community-acquired bacteremia caused by Gram-positive organisms (staphylococci, streptococci and enterococci) occurred significantly more often at the teaching hospital; conversely, community-acquired bacteremia caused by Gram-negative bacilli from a urinary tract source occurred more often at the non-teaching hospital.

The intensive care unit (ICU) is a common focus for nosocomial infections. In a 1-day point-prevalence infection surveillance performed in 1417 European ICUs, 45% of 10 038 patients were infected and 21% had ICU-acquired infections.¹⁰ Richards et al¹¹ reported on the epidemiology of nosocomial infections in adults in 112 medical ICUs in 97 hospitals in the

Table 38.1 Sources of micro-organisms isolated from blood of patients with community-acquired bacteremia⁹

Source	Site of acquisition (%)	
	Teaching hospital	Non-teaching hospital

From Mylotte JM, Kahler L, McCann C. Community-acquired bacteremia at a teaching versus a nonteaching hospital: impact of acute severity of illness on 30-day mortality. *Am J Infect Control.* 2001;29:13–19.

USA that were part of the National Nosocomial Infections Surveillance (NNIS) system of the Centers for Disease Control and Prevention between January 1992 and July 1997. The most commonly reported pathogens were coagulase-negative staphylococci (36%), enterococci (16%), *Staph. aureus* (13%) and Gram-negative aerobes (17%). The most frequent Gram-negatives were *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*. *Candida* species were found to be associated with urinary catheters, coagulase-negative staphylococci with central lines, and *Ps. aeruginosa* and *Acinetobacter* species with ventilators.

In other reports from the NNIS, trends of increasing proportions of Gram-positive infections and decreasing proportions of Gram-negative infections during the last 15 years have become apparent.

Shorr et al¹² reported on the epidemiology of 6697 patients with bloodstream infections during 2002–2003. In this study, healthcare-associated bloodstream infections accounted for 53% of all bloodstream infections, and were associated with a higher morbidity and mortality compared to community-acquired bloodstream infection. The most prevalent community-acquired pathogen was *Esch. coli* (25.2%) and *Staph. aureus* the most common hospital-acquired or healthcare-associated pathogen (25.7% and 29.7%, respectively). Of all bacterial bloodstream infections, methicillin-resistant *Staph. aureus* (MRSA) was associated with the highest mortality rate (22.5%) and the longest hospital stay.

Community-associated MRSA has recently received considerable attention due to its association with highly aggressive infections in otherwise healthy individuals outside the healthcare system.^{13,14} These infections include severe skin and soft-tissue infections, necrotizing fasciitis and necrotizing pneumonia, all associated with substantial morbidity and mortality. Several studies have highlighted the importance of *Staph. aureus* bloodstream infections, and the emergence of MRSA, as an increasing health problem.^{12,15}

SEPTICEMIA

There have been major increases in the rates of admission to hospital due to septicemia: between 1980 and 1994, the annual change in the number of admissions due to septicemia was 10.5%, second only to that for HIV AIDS infection.⁷ Simonsen et al⁷ found septicemia to be the fourth leading cause of hospital admission due to infectious diseases in the USA in 1994 (a total of 301 800, or 116 admissions per 100 000 persons). The age-adjusted death rate due to septicemia increased from 0.3 per 100 000 in 1950 to 4.2 per 100 000 in 1997, a 14-fold increase, which makes septicemia the thirteenth leading cause of death in 1997.¹⁶ The unadjusted rate in 1997 was 8 per 100 000. Among elderly people, the mortality rate was 23 per 100 000 for persons 65–74 years old, 60 per 100 000 for those 75–84 years old, and 178 per 100 000 for people of 85 years or more. Recently, Melamed and Sorvillo¹⁷ concluded that the rapid rise in sepsis mortality seen in previous decades has slowed, but population aging continues to drive the growth of sepsis-associated mortality in the USA. The age-adjusted rate of sepsis-associated mortality was 50.37 deaths per 100 000 between 1999 and 2005.

McBean and Rajamani¹⁸ examined the rates of hospital admission of elderly people due to septicemia in the period 1986–1997. The sex- and race-adjusted annual rates in 1997 were more than double the rates in 1986. For people between 65 and 74 years old, the rate in 1997 was 2.2 times the rate in 1986; for those 75–84 years it was double and 2.3 times greater for patients ≥85 years in whom rates of admission for septicemia were significantly higher ($p < 0.001$).

The overall 30-day mortality rate for persons admitted for the treatment of septicemia in 1997 was 246.5 per 1000 patients admitted and was 6.9% greater among Black Americans (262 per 1000) than among White Americans (245 per 1000). The 30-day mortality rates for patients for whom the presumed source of infection was decubitus ulcer was 372 per 1000 admissions; for pneumonia it was 336 per 1000, for urinary tract infections and cystitis 193 per 1000, for cellulitis 177 per 1000 and 66 per 1000 for kidney infections. Reasons for the increase in septicemia over the 12-year study period included an increased prevalence (due to both increased incidence and increased duration) of chronic diseases such as diabetes, cancer and end-stage renal disease in the elderly, putting them at higher risk for infectious diseases. Medical devices, either temporary or permanent, may also increase the risk of septicemia.

Drombovskiy et al¹⁹ reported on 8 402 766 patients hospitalized with sepsis in the USA from 1993 to 2003. The rate of severe sepsis hospitalization almost doubled during this 11-year period from 66.8 to 132 per 100 000 population. Age-adjusted, population-based mortality rates from severe sepsis also increased significantly from 30.3% to 49.7%.

PATHOPHYSIOLOGY

Severe sepsis is a consequence of microbial antigenemia inducing a generalized activation of numerous host defense systems, including the adaptive and the innate immune responses of which the complement, coagulation, contact-phase and fibrinolytic systems are prominent contributors.^{20,21} Activation of these proinflammatory and procoagulatory cascades results in release of proinflammatory cytokines, nitric oxide, endothelins, tissue-damaging proteinases, lipid mediators and hypotensive molecules such as kinins (see Figure 38.1). These mediators regulate cellular and humoral immune responses and are essential to an adequate and efficient host defense against infecting micro-organisms. However, excessive and dysregulated release of these mediators is the key event leading to the clinical features of sepsis and shock, namely circulatory collapse, organ failure, tissue necrosis and death. In addition to this systemic inflammatory response (SIRS), sepsis is also associated with an exacerbated release of anti-inflammatory mediators such as interleukin-10 (IL-10), IL-1 receptor antagonist (IL-1ra) and transforming growth factor-β (TGF-β). Consequently, in 1997 Bone et al coined the term 'compensatory anti-inflammatory response syndrome' (CARS) to illustrate this immunosuppressive response of SIRS patients.²² CARS is considered an adapted response to dampen the overzealous inflammatory response.²³ Multiple mechanisms, including release of anti-inflammatory cytokines, downregulation and shedding of cytokine receptors, induction of T-regulatory cells and myeloid-derived suppressor cells, as well as cell death, contribute to the immunosuppressive state in sepsis. Increased apoptosis has been observed in lymphocytes and dendritic cells in septic patients,

whereas monocytes remain unchanged and neutrophils display decreased apoptosis.²⁴ The immunosuppressive state has been suggested to contribute to the susceptibility to secondary infections and/or reactivation of otherwise dormant viruses such as cytomegalovirus.^{25,26}

Gram-positive and Gram-negative bacteria produce numerous factors capable of activating the host systems involved in sepsis. Lipopolysaccharide (LPS), a major constituent of the outer membrane of Gram-negative bacteria, has long been recognized as the principal mediator of sepsis.²⁷ The cell wall of Gram-positive bacteria also contains potent proinflammatory components, including peptidoglycan and lipoteichoic acid.²⁸ LPS, lipoteichoic acid and peptidoglycan are all examples of microbial molecules that display pathogen-associated molecular patterns (PAMPs), which are detected by pattern recognition receptors (PRRs), primarily toll-like receptors (TLRs) and nucleotide-oligomerization domain leucin-rich repeat (NOD-LRR) proteins, expressed on immune cells.^{29,30} This results in activation of the innate immune response and regulation of the adaptive immune response to infection. The PRRs are also important sensors of endogenous alarmins, i.e. intracellular proteins or mediators that are released from damaged cell and tissues. Together, endogenous alarmins and exogenous PAMPs are called damage-associated molecular patterns (DAMPs).²⁹ During sepsis, the microbial infection and damaged tissues result in high levels of DAMPs and consequently an overstimulation of immune cells resulting in the pathological cytokine storm seen in septic patients.

Streptococcus pyogenes and *Staph. aureus* express and secrete exotoxins with superantigenic activity that induce very powerful immune responses.³¹ Superantigens interact, without prior cellular processing, with the Vβ region of the T-cell receptor and the major histocompatibility complex (MHC) class II molecules on antigen-presenting cells. Cross-linking of T cells and antigen-presenting cells by superantigens results in potent activation of these cells and the excessive production of proinflammatory cytokines.³² Other virulence factors expressed by pathogenic bacteria include pili, M protein, hemolysins and proteases, which have all been shown to be important contributors to pathogenesis.^{28,33,34} In addition, synergistic or additive effects have been shown for many of these virulence factors and it is increasingly evident that the pathogenesis of sepsis involves a complex interplay between multiple microbial factors, host cells and mediators.

One of the initial events in sepsis is the induction of proinflammatory cytokines; these trigger the cytokine cascade, complement and coagulation systems, resulting in injury to endothelium and vessels, and the release of proteases, arachidonic acid metabolites and nitric oxide (Figure 38.1). The leading proinflammatory mediators are IL-1, IL-6, IL-8 and IL-12, tumor necrosis factor (TNF)-α, interferon (IFN)-γ, macrophage migration inhibitory factor (MIF) and high mobility group box 1 (HMGB1).^{35,36} IL-1 and TNF-α are commonly referred to as 'early cytokines' in the sepsis cascade. They induce potent pyrogenic and hypotensive responses, and the experimental administration of either cytokine reproduces

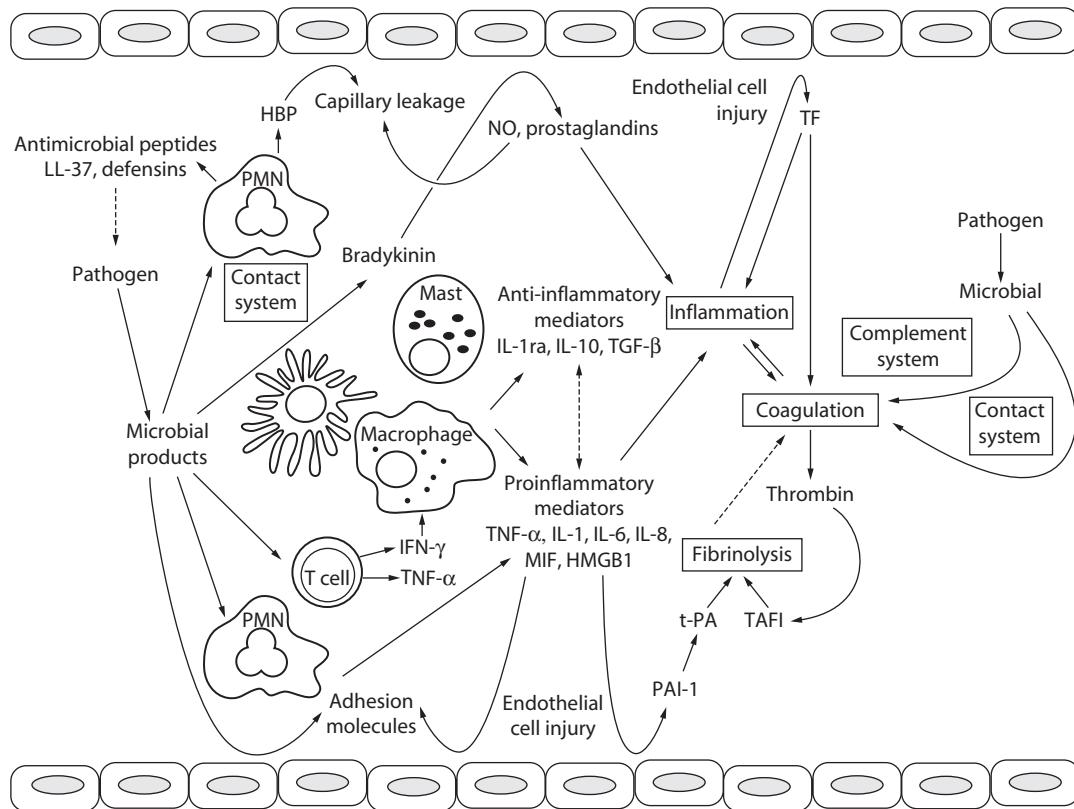

Fig. 38.1 Schematic illustration of some of the host–microbe interactions that contribute to the pathophysiology of sepsis. Microbial factors interact with specific receptors on immune cells, including macrophages, T cells, neutrophils (PMN), dendritic cells (DC) and mast cells. This results in activation of the cells and release of proinflammatory cytokines, which activate the coagulation system through induction of tissue factor (TF). TF results in production of thrombin and subsequent formation of fibrin deposition. Tissue-plasminogen activator (t-PA) triggers conversion of plasminogen to plasmin, the main effector molecule of fibrinolysis. Proinflammatory cytokines and thrombin stimulate release of plasminogen activator inhibitor-1 (PAI-1) from platelets and the endothelium. Thrombin activates thrombin-activatable fibrinolysis inhibitor (TAFI). TAFI and PAI-1 are key inhibitors of t-PA, consequently fibrinolysis is effectively suppressed during sepsis. Solid and dashed arrows indicate activation and inhibition, respectively. HBP, heparin binding protein; HMGB1, high mobility group box 1; IFN, interferon; IL, interleukin; MIF, migration inhibitory factor; NO, nitric oxide; TGF, transforming growth factor; TNF, tumor necrosis factor.

the clinical symptoms of sepsis.^{37–40} Similarly MIF, a pituitary- and macrophage-derived factor, behaves as a proinflammatory cytokine and has been shown to be a critical mediator of septic shock.⁴¹ However, in contrast to other known cytokines, MIF production is induced rather than suppressed by glucocorticoids, and MIF has been found to override the immunosuppressive effects of glucocorticoids.⁴² HMGB1 increases LPS-induced IL-1 and TNF- α , and is a late mediator of septic shock in mice.⁴³ Elevated levels of HMGB1 could be demonstrated in patient plasma up to a week after the diagnosis of severe sepsis or septic shock.⁴⁴ Although described as a proinflammatory cytokine,⁴⁵ recent studies have shown HMGB1 to enhance inflammatory responses by acting as a carrier of LPS,⁴⁶ CpG DNA⁴⁷ and proinflammatory cytokines such as IL-1 β .⁴⁸ HMGB1 acts via interaction with TLR2, TLR4 and the receptor for advanced glycation end-products (RAGE), and is considered an endogenous alarmin.

A positive correlation between the development of shock in sepsis and activation of the coagulation response was reported some 30 years ago.²¹ Microbial factors can activate

the coagulation cascade either directly or indirectly via induction of proinflammatory cytokines and subsequent expression of tissue factor on endothelial cells and monocytes, which is the main pathway for coagulation activation in sepsis (see Figure 38.1). A drastic reduction in the levels of important endogenous coagulation inhibitors, such as antithrombin III and activated protein C (APC), due to consumption, expression deficiency or proteolytic inactivation, further contributes to the procoagulatory state in sepsis. Sepsis and disseminated intravascular coagulation are associated with decreased antithrombin III and protein C, and a disruption of the balance between coagulation and fibrinolysis.²¹ Furthermore, there is a correlation between deficiency in these inhibitors and increased morbidity and mortality in sepsis.²¹ Dysregulated expression of antithrombin III and activated protein C also affects the inflammatory processes due to increased thrombin production which promotes upregulation of adhesion molecule expression and microvascular thrombosis, which further increases the inflammatory response through tissue ischemia and neutrophil/endothelium activation.

Activation of the complement and contact systems has also been linked to the sepsis process, mainly by the release of hypotensive mediators, anaphylatoxins such as C5a, and the consumption of coagulatory factors.^{49,50} Herwald et al⁵¹ demonstrated that the fibrous surface components of Gram-positive and Gram-negative bacteria bind to and trigger assembly of the components of the contact system, resulting in the release of hypotensive kinins, hypocoagulatory state, and dysregulated fibrin and clot formation. Other virulence factors, such as the streptococcal M protein and the streptococcal proteinase, also interact with components of the contact system.⁵¹

DIAGNOSTIC ISSUES

Sepsis is not a single disease. It is a syndrome that can result from diverse causes, with a spectrum of severity that ranges from fever associated with transitory hypotension through to profound shock and high mortality. The same clinical picture is seen in some non-infective conditions, which has given rise to some confusion.

Identifying and naming subgroups is worthwhile only if doing so aids design of better treatment or more accurate prediction of outcome. In 1991 the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM)⁵² published consensus definitions of sepsis. Sepsis was defined as the presence of systemic inflammatory response syndrome (SIRS; Box 38.1) with a confirmed infectious process. Sepsis associated with organ dysfunction, hypoperfusion abnormality or sepsis-induced hypotension was named severe sepsis, and septic shock was defined as severe sepsis with sepsis-induced hypotension persisting despite adequate fluid resuscitation.

The critical difference between SIRS and sepsis is the requirement for clinical or laboratory evidence of infection. The relationships between SIRS, sepsis, shock and death is well illustrated by a prospective study of nearly 4000 patients admitted to ICUs in the USA.⁵³ The incidence of SIRS on surgical ICUs was 857 episodes per 1000 patient-days, and the mortality of these patients was just 7%, emphasizing that SIRS is a very sensitive definition. However, in the small proportion (4%) that developed septic shock, mortality was 46%.

With further advances in the understanding of the pathophysiology of sepsis and identification of new biomarkers, a new consensus sepsis definition conference was held in 2001 by SCCM, the European Society of Intensive Care Medicine (ESICM), the ACCP, the American Thoracic Society (ATS) and the Surgical Infection Societies (SIS).⁵⁴

Box 38.1 Systemic inflammatory response syndrome (SIRS)

SIRS is defined as the presence of two or more of the following criteria:

- Temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$
- Heart rate >90 beats/min
- Respiratory rate >20 breaths/min or $\text{Paco}_2 <32$ mmHg
- White blood cell count $>12 \times 10^9/\text{L}$ or $<4 \times 10^9/\text{L}$

The previous definitions of sepsis, severe sepsis and septic shock, as defined in 1991, remain useful, but the diagnostic criteria for SIRS were too sensitive and non-specific. An expanded list of signs and symptoms of sepsis was proposed to better reflect the clinical response to infection (Box 38.2). The list of signs and markers should be considered as a guide to diagnosis. Not all patients with sepsis will have all the markers included on the list, and many patients without sepsis may have several. The unexplained presence of several of the listed signs in a patient, however, should be used to raise suspicion of sepsis.

There are two major reasons why an infectious etiology is not identified in a patient presenting with sepsis:

- Antibiotics are often used empirically in the outpatient and home care setting and the hospital before testing.
- Bacteremia may be intermittent, except in the patient with endovascular infection.

However, in patients with sepsis, it is more important to promptly initiate appropriate antimicrobial therapy in order to ensure optimal outcome than to wait for further blood culture sets.^{55,56} Although 75–80% of neutropenic fevers are thought to be caused by infections, a causal organism can be confirmed in only 30–50% of episodes. In a prospective study of sepsis and septic shock, at least 15% of patients had no documented infection. Even among patients with presumed infection, less than half had bacteremia.⁵⁷ Ideally two or three blood cultures should be obtained several hours apart to increase the likelihood for detection.⁵⁸ The total volume of blood cultured is one of the most important factors in the

Box 38.2 Clinical signs of sepsis¹¹⁰

General signs and symptoms

Rigor – fever (sometimes hypothermia)
Tachypnea/respiratory alkalosis
Positive fluid balance – edema

General inflammatory reaction

Altered white blood cell count
Increased C-reactive protein, interleukin-6, procalcitonin concentrations

Hemodynamic alterations

Arterial hypotension
Tachycardia
Increased cardiac output/low systemic vascular resistance/high Svo_2
Altered skin perfusion
Decreased urine output
Hyperlactatemia – increased base deficit

Signs of organ dysfunction

Hypoxemia
Coagulation abnormalities
Altered mental status
Hyperglycemia
Thrombocytopenia, disseminated intravascular coagulation
Altered liver function (hyperbilirubinemia)
Intolerance to feeding (altered gastrointestinal motility)

recovery of bacterial pathogens: in one study, increasing the volume over a 24-h period from 40 to 60 mL increased recovery by 10%.⁵⁹

TREATMENT

Studies have demonstrated that the first 6 h of management of sepsis are especially important, and that measures taken during this period have a significant impact on outcome.^{60,61}

The need for evidence-based recommendations regarding the acute management of sepsis and septic shock led to a consensus meeting in 2004. Following that, an international group of experts in the diagnosis and management of infection and sepsis, representing 11 organizations, published the first internationally accepted clinical guidelines for the practicing clinician to improve outcomes in severe sepsis and septic shock.^{62,63} A new consensus meeting held in 2008 has updated the original Surviving Sepsis Campaign recommendations.⁶⁴

TRADITIONAL THERAPEUTIC STRATEGIES

ANTIMICROBIAL THERAPY

Antimicrobial therapy remains fundamental to the treatment of sepsis; many studies have demonstrated that inadequate initial antimicrobial and/or delayed therapy is associated with marked increases in all-cause and infection-related mortality in patients admitted to the ICU with life-threatening infection.^{55,65–68} Duration of hypotension before initiation of effective antimicrobial therapy is the critical determinant of survival in human septic shock.⁵⁵ Such findings support the empirical use of broad-spectrum therapy before the results of laboratory culture are known.

The number of effective antimicrobial agents available is becoming increasingly limited because of the emergence of multidrug resistance in both Gram-negative and Gram-positive pathogens.⁶⁹ One of the consequences of drug-resistant infections is the increased likelihood of inappropriate initial therapy. Leroy et al⁷⁰ found that ineffective initial antimicrobial therapy was the best predictor for poor prognosis in community-acquired pneumonia.

Which antimicrobial or antimicrobial combination to use empirically depends on the source of the infection, whether it is community or nosocomially acquired, whether or not the patient has an underlying illness that alters the predictability of the offending pathogen, and the local antimicrobial resistance rates. A broad-spectrum empirical antibiotic should be started as soon as possible for suspected severe infections, especially in the presence of hypotension. Every effort should be made to obtain proper site-specific cultures. However, such efforts should not delay antimicrobial therapy. There are studies suggesting that, in certain circumstances, outcomes may

improve if two or more effective agents are used,^{71,72} however, whether possible pathogens should be covered by multiple antibiotics or not is still under debate. So far there are no prospective controlled studies that compare multiple versus single drug therapy in severe sepsis or septic shock. Importantly, empirical antimicrobial therapy should be adjusted and narrowed within 48–72 h if a pathogen is identified or if there is a resolution of septic shock.

VOLUME REPLACEMENT

The first goal of management of severe sepsis is to adequately monitor vital signs so that any hemodynamic changes can be promptly detected and treated. Insertion of a central venous pressure monitoring device, arterial catheter and Swan-Ganz catheters to determine the left atrial end-diastolic pressure allows for optimal monitoring and fluid replacement.

To expand intravascular fluid volume and colloid oncotic pressure, a number of solutions may be used, including normal and hypertonic saline, fresh-frozen plasma, albumin and various dextran preparations. There is general agreement that volume therapy is an essential component of early resuscitation and that the goal is to optimize systemic oxygen delivery (cardiac preload, afterload, arterial oxygen content, contractility, or stroke volume) and ultimately to balance tissue oxygen demand.⁷³

Crystallloid solutions are the first choice to correct fluid and electrolyte deficits in non-hemorrhagic shock. In the case of major hypovolemia, particularly in situations of increased capillary permeability, colloid solutions are favored to achieve sufficient tissue perfusion. However, different colloids have different molecular weights and therefore vary in the length of time they remain in the circulation. Because of this and their other characteristics, colloids may differ in their safety and efficacy. Bunn et al⁷⁴ reviewed randomized and quasi-randomized trials comparing colloid solutions in critically ill and surgical patients thought to need volume replacement. They found no evidence that one colloid solution was more effective or safer than another.

The use of colloids for the treatment of septic shock has been challenged: they are more expensive than crystalloids, some colloid solutions may be associated with adverse outcomes, and some clinical trials have found them to be no better than crystalloids. Schierhout and Roberts⁷⁵ carried out a systematic review of randomized controlled trials of resuscitation with colloids or crystalloids for volume replacement of critically ill patients. The overview concluded that the use of colloids for volume resuscitation in critically ill patients is not supported by the literature. Concern has also been raised about the use of albumin, often the colloid of choice for replacement therapy.⁷⁶ The Cochrane Group carried out a review of randomized controlled trials comparing administration of albumin or plasma protein fraction with no administration, or with administration of crystallloid solution, in critically ill patients with hypovolemia, burns or hypoalbuminemia. They concluded that use of human albumin in critically ill patients should be urgently

reviewed and that it should not be used outside the context of rigorously conducted, randomized controlled trials. However, a saline versus albumin study compared fluid resuscitation with albumin or saline on mortality in critically ill patients and found no difference between them.⁷⁷

VASOPRESSOR AGENTS

If fluid therapy alone fails to restore adequate arterial pressure and organ perfusion, vasopressor agents should be used. The goal of mean arterial pressure should be at least 65 mmHg.⁷⁸ For many years, noradrenaline (norepinephrine) and adrenaline (epinephrine) were the principal agents available. However, because of their intense peripheral vasoconstricting activity and increase in myocardial irritability, they have been replaced with isoproterenol, dopamine and dobutamine. These agents have an inotropic effect on myocardial function but because of β -adrenergic activity are capable of enhancing peripheral tissue perfusion. The recent Surviving Sepsis Campaign recommendations were published with six evidence-graded statements for vasopressor use, concluding that there is no high-quality primary evidence to recommend one catecholamine over another; consequently, neither noradrenaline

(norepinephrine) nor dopamine can be recommended over the other. Furthermore, adrenaline (epinephrine) should be limited for use in patients unresponsive to other agents.⁷³

NOVEL THERAPEUTIC STRATEGIES

During the last two decades, significant advances have been made in the field of sepsis that have allowed the development of novel therapeutic strategies, ranging from interventions with defined microbial factors to the various host systems (Table 38.3).

NEUTRALIZATION OF MICROBIAL FACTORS

Anti-endotoxin therapies, including polyclonal and monoclonal antibodies and various lipid analogs, have been extensively tested in clinical trials, but have so far failed to have a significant effect on mortality.²⁷ Other anti-endotoxin approaches under investigation include:

- Eritoran, a synthetic lipid A antagonist, now in phase III⁷⁹
- bactericidal-permeability-increasing protein⁸⁰

Table 38.3 Some novel therapeutic strategies in septic shock

Strategies*	Type of agent	References
Neutralization of microbial factors		
Anti-endotoxin	Polyclonal antiserum (J5, anti-Lipid A, IVIG)	27, 111
	Polymyxin B immobilized hemofiltration columns	83
	Monoclonal antibodies (HA-1A, E5, T88)	27, 111
	Lipid A analogs (lipid X, monophosphoryl lipid A, etc.)	28, 112
	Recombinant bactericidal/permeability-increasing protein	80, 112, 113
Anti-superantigen	IVIG	90, 114
Modulation of proinflammatory mediators		
Anti-cytokines	Corticosteroids	64
Anti-tumor necrosis factor	Monoclonal antibodies, receptor fusion proteins, cytofab	111, 115, 116
Anti-interleukin-1	Interleukin-1 receptor antagonist	111, 115
Anti-PAF	PAF antagonist	115
Anti-bradykinin	Bradykinin antagonist	115
Anti-prostaglandin	Ibuprofen (cyclo-oxygenase inhibitor)	111
Statins	3-Hydroxymethyl-3methylglutaryl coenzyme A	117, 118
Modulation of coagulation		
Antithrombin III	Inhibitor of coagulation	103–105
Activated protein C	Inhibitor of coagulation	102, 108, 109
Recombinant tissue factor pathway inhibitor	Inhibitor of coagulation	119

IVIG, intravenous polyclonal immunoglobulin; PAF, platelet-activating factor.

*Includes therapeutic agents that have been tested in controlled human sepsis trials.

- recombinant human lactoferrin⁸¹
- TAK-242, a small molecule blocking the MyD-88 pathway⁸²
- polymyxin B immobilized hemofiltration columns⁸³
- anti-endotoxin vaccines.⁸⁴

Neutralization of Gram-positive microbial factors has mainly been achieved by intravenous polyspecific immunoglobulin G (IVIG), which contains a broad spectrum of neutralizing antibodies against streptococcal and staphylococcal superantigens, as well as opsonic antibodies against a variety of micro-organisms.⁸⁵ In addition to its direct toxin-neutralizing and opsonic activities, IVIG has a general immunomodulatory effect due to its interaction with Fc receptors, complement, immune cell functions, cytokines and cytokine antagonists.⁸⁵ Recent meta-analyses have reported an overall reduction in mortality with the use of IVIG as adjunctive therapy in critically ill patients with sepsis.⁸⁶⁻⁸⁹ However, due to heterogeneity of the trials and small patient cohorts, the power is insufficient to allow solid conclusion.^{86,87}

Certain subgroups of patients may benefit more than others from IVIG-treatment, such as those with superantigen-mediated toxic shock.⁹⁰ Two studies have reported that adjunctive therapy with IVIG reduces the mortality associated with streptococcal toxic shock syndrome.^{91,92} The first is an observational cohort study, which showed significant improvement in survival among IVIG-treated cases.⁹² However, confounding factors that could have affected the outcome of the trial included the fact that the majority of the controls were historical and IVIG-treated cases were more likely to have received clindamycin therapy than the controls.

Further support for the use of IVIG in streptococcal toxic shock syndrome is provided by a multicenter placebo-controlled trial.⁹¹ Due to a low incidence of invasive streptococcal infections during the study period, the trial was prematurely terminated after enrolment of 21 patients. The results revealed a trend towards a reduced mortality rate in IVIG-treated cases as compared to those receiving placebo (10% versus 36%). Importantly, this trend in reduced mortality was supported by significantly better improvement of organ dysfunction following treatment in the IVIG group, whereas no such change could be noted in the placebo group.

INHIBITION OF PROINFLAMMATORY MEDIATORS

As principal mediators of sepsis and shock, TNF- α and IL-1 were obvious therapeutic targets. However, none of these agents succeeded in lowering the mortality of sepsis in large phase III clinical trials (Table 38.3). There are several potential reasons why these therapies failed:

- Blockage of one mediator may not suffice to arrest the whole process.
- Agents directed against early mediators have a narrow therapeutic window.
- Peak cytokine production may have passed by the time treatment started, and downstream cascades may already be triggered.

Corticosteroids have been extensively studied in sepsis, with results ranging from beneficial to harmful. Recommendations have included the use of low-dose corticosteroids in the management of septic shock.^{62,93,94} A recent European trial of corticosteroid therapy in septic shock (CORTICUS)⁹⁵ has confirmed early shock reversal, although by day 28 the overall number of patients with shock reversed was not significantly greater in the treated versus the placebo group. The updated Surviving Sepsis Campaign guidelines advise hydrocortisone only in adults with septic shock in whom there is a poor response of low blood pressure to fluid replacement and vasopressor therapy.⁷³

Another approach directed at attenuating the pathogenic proinflammatory response involves the parasympathetic anti-inflammatory pathway by which the brain modulates systemic inflammatory responses.⁹⁶ Vagus nerve stimulation inhibits proinflammatory cytokines via the alpha7 nicotinic acetylcholine receptor subunit.⁹⁷ Lethal endotoxic shock in rats can be prevented by direct electric stimulation of the peripheral vagus nerve, which decreases in-vivo levels of TNF.⁹⁸

Other potential targets for intervention include the danger protein HMGB1 and the receptor for advanced glycation end-products (RAGE). HMGB1 have been shown to be a persistent mediator of severe sepsis and its neutralization results in protection against experimental septic shock.⁴³ In contrast to the early cytokines TNF- α and IL-1, HMGB1 is a late mediator of sepsis and is produced over an extended period of time,⁴⁴ which would provide a wider therapeutic window.^{5,43,99} The RAGE recognizes several ligands, among others HMGB1. Inhibition of RAGE in experimental sepsis increases survival.^{100,101}

MODULATORS OF COAGULATION

Patients with severe sepsis are deficient in important coagulation inhibitors, suggesting that modulation of coagulation might be a potential therapeutic strategy.⁷² Several anticoagulant strategies have been proposed, among which the most promising are the natural coagulation inhibitors antithrombin III and activated protein C.^{102,103} However, the KyberSept study published in 2001¹⁰⁴ showed no significant benefit overall with high-dose antithrombin III, but rather an excess risk of bleeding in patients receiving antithrombin. However, in a prespecified subgroup of patients (i.e. patients with severe sepsis and with a predicted high risk of death) there was a modest improvement in survival.¹⁰⁵

The Recombinant Human Protein C Worldwide Evaluation in Severe Sepsis (Prowess) study was a phase III, double-blind, randomized, placebo-controlled, multicenter trial which showed a significant treatment effect on 28-day mortality rate.¹⁰² There are several reasons as to why activated protein C might be effective in patients with sepsis:

- Most patients with severe sepsis have diminished levels of activated protein C because of the reduction in the components of the coagulation system necessary for the conversion of inactive protein C to activated protein C.¹⁰⁶

- Activated protein C inhibits activated factors V and VIII, thereby decreasing the formation of thrombin and stimulating fibrinolysis by reducing the concentration of plasminogen-activator inhibitor type 1.
- In addition to its central regulatory role in coagulation, protein C has been shown to have a strong anti-inflammatory effect, some of which may be mediated by its inhibition of the proinflammatory cytokines MIF and TNF- α .¹⁰⁷

Bernard et al¹⁰² conducted a randomized, double-blind, placebo-controlled, multicenter trial, assigning patients with systemic inflammation and organ failure due to acute infection to receive an intravenous infusion of either placebo or activated protein C (APC). Patients receiving APC demonstrated a dose-dependent reduction in the plasma levels of D-dimer and serum IL-6, markers of coagulopathy and inflammation, respectively. The absolute reduction in the 28-day mortality rate was 6.1% (in the placebo group it was 30.8%, compared with 24.7% in the APC group), and the relative risk of death was reduced by nearly 20% in the treated group. The exact role of APC has been questioned. A study in which APC was given to patients defined to have mild to moderate sepsis was terminated prematurely due to lack of efficacy after a second interim analysis.¹⁰⁸ A recent Cochrane systematic review suggested that the use of APC should be suspended pending results from additional trials as they found no evidence suggesting that APC should be used for treating patients with severe sepsis or septic shock, and, additionally, APC seems to be associated with a higher risk of bleeding.¹⁰⁹

CONCLUSION

As the number of patients with chronic underlying disease and temporary or permanent implanted medical devices has increased, so has the number of episodes of sepsis. The microbial etiology of these episodes reflects the patient population and the geographical location of the healthcare facility in which they are treated. Patients with severe underlying illness or chronic disease will always be at increased risk of endotoxin-mediated Gram-negative sepsis, whereas those with intravascular catheters or prosthetic devices are at greater risk for Gram-positive infections. Complicating the management of these infections has been the emergence of multidrug resistance in such pathogens, both in the hospital and the community. In some countries and regions, multidrug-resistant strains are endemic and account for the majority of infections. This often means that first- and second-line antimicrobials are ineffective, leaving few and often less acceptable alternatives. Infections caused by multiresistant organisms are associated with increased morbidity and mortality.

However, despite the advancements in medical treatment, the outcome of patients with sepsis syndrome and septic shock has not improved greatly. This is because we treat only the cause and not the consequences of such infections. We now

recognize that these conditions reflect a generalized activation of numerous host defense systems, resulting in excessive and dysregulated release of inflammatory and coagulatory mediators.

Blockade or antagonism of the actions of individual intermediary messenger molecules has proved unsuccessful. The most promising therapies today seem to be agents that target several different microbial factors and/or host systems involved in sepsis. Furthermore, several clinical trials have shown clinical efficacy in subgroups of patients, but not in the whole study population. This indicates that by targeting more defined patient populations based on specific clinical, immunological and/or microbiological parameters, a more favorable outcome may be seen in future trials of treatment for these syndromes.

CHAPTER**39**

Abdominal and other surgical infections

Eimear Brannigan, Peng Wong and David Leaper

Surgical site infection (SSI) represents 20% of healthcare-associated infections (HCAs) in the UK.^{1,2} Superficial SSIs are the most common but the more serious and complex deep and organ/space remainder lead to abscesses, bacteremia, sepsis and death, with an associated strain on healthcare resources because of prolonged hospital, high dependency unit (HDU) and intensive care unit (ITU) stays.^{4–6} These infections mostly involve the patient's own organisms (endogenous) but others materialize later, probably relating to poor infection control practices (exogenous).

The surgically presenting community-acquired complicated skin and soft tissue, orthopedic, urological and gynecological infections are covered elsewhere (see Chs 49, 52, 54–56). Peritonitis and abdominal infections are addressed in this chapter.

ETIOLOGY OF COMMUNITY-ACQUIRED AND POSTOPERATIVE ABDOMINAL INFECTIONS

Community-acquired abdominal infections are polymicrobial and potential pathogens act in synergy. Treatment must be directed against colonic organisms that have breached the bowel lumen to cause peritonitis. These potential pathogens are typically endogenous flora, mostly anaerobes, predominantly the *Bacteroides fragilis* group, clostridial species and peptostreptococci, and aerobic Gram-negative organisms.^{7–9} Peritonitis may be generalized or focal, or be divided into primary, secondary and tertiary forms (see below).

Postoperative abdominal infections also involve enterococci, *Candida* spp. and drug-resistant organisms in addition to the enteric pathogens seen in community-acquired infection. Complex surgical procedures, undertaken on patients with increasing co-morbidity, longer hospital stays and prolonged exposure to antimicrobials and hospital flora, lead to infections with resistant organisms. This has driven the search for new antimicrobial agents with activity against organisms with these new defenses, including extended spectrum β-lactamases (ESBL) and AmpC, which render third-generation cephalosporins inactive. These include the carbapenems and drugs

such as tigecycline, although resistance to these agents has also emerged, notably among *Klebsiella* spp.¹⁰ This requires unorthodox antimicrobial combination strategies, with the guidance of infection expertise¹¹ and excellence in antimicrobial stewardship.¹²

Superficial SSIs are predominantly caused by organisms carried on the skin or anterior nares of patients or healthcare staff. These are *Staphylococcus aureus* and coagulase-negative staphylococci (CNS), but *Enterococcus* spp. and *Escherichia coli* may also be implicated. Increasing numbers are drug resistant, reflecting increased broad-spectrum use in more severely ill, debilitated surgical patients.

Deep SSIs are caused by similar organisms, and can be lessened by good surgical technique and limitation of tissue damage at operation, with prevention of hematomas and seromas. Transient bacteremia with seeding of a hematoma or devitalized tissue, and translocation of gut organisms are alternative mechanisms leading to SSIs. Superficial or deep SSIs originate from intraoperative wound contamination. Tissue invasion leads to local infection, as cellulitis or an abscess, or dissemination to cause systemic inflammatory response syndrome, sepsis, septic shock syndrome and multiorgan failure. Influential factors include the load of contamination, the extent of tissue damage at operation, and host defense.

BACTERIAL CONTAMINATION

In the pathogenesis of SSI, contamination of the site precedes tissue invasion. When there are more contaminating organisms present at the end of an operation, infection is more likely. This has been demonstrated in quantitative studies; the increased risk of infection matches the four hypothetical categories of clean, clean-contaminated, contaminated and dirty surgery.¹³ However, the source of contamination attributable to organisms of either exogenous (surgical team or instruments) or endogenous (patient skin, nasal carriage, gut flora) origins may not be identifiable in an individual case of SSI.

Bacterial contamination of an operative site is inevitable, and organisms survive on the skin despite optimal aseptic technique and sterilization procedures. Operating room ventilation, attention to preoperative preparation of the patient's general health, and the appropriate use of antimicrobial prophylaxis are additionally directed at achieving the lowest possible contaminating bacterial load, thereby minimizing infection. Despite the ultra-clean environment of the orthopedic theatre – with laminar flow, high efficiency particle air (HEPA) filtration and intensive focus on aseptic technique – organisms can still be found on surfaces¹⁴ and in wounds at the close of clean elective surgical cases.¹⁵ Air sampling shows that these are mainly Gram-positive organisms.¹⁶ As more procedures are performed involving prosthetic material, on patients who are more debilitated, and with an increased incidence of antimicrobial-resistant organisms, it is not surprising that SSIs still occur.

A combination of strategies to minimize bacterial contamination is optimal, although there may not always be robust supportive evidence. Many operating theater practices, skin preparation and draping, theatre staff apparel and the surgical team's handwashing are largely directed against exogenous sources of infection. However, there is little scientific evidence to show that the use of caps, masks, gloves or overshoes alters the infection rate after most non-implant operations. Novel strategies such as antiseptic impregnated drapes and microbial sealants for wounds have been studied, with variable outcomes.¹⁵ Incise drapes, adhesive polyethylene sheets designed to 'isolate' the incision site, increase the risk of SSI, but when impregnated with povidone-iodine the risk is lessened. Antimicrobial sealants^{17,18} and antiseptic-coated sutures^{19,20} also show promise in early evaluation.²¹ Prevention of infection from endogenous sources includes decolonization of nasal *Staph. aureus* or bowel preparation for colonic surgery. In the former case, application of mupirocin reduces nasal carriage and as most *Staph. aureus* infections result from autoinfection, SSIs should also fall, although this has not been proven.²²

Bowel preparation of patients undergoing elective colorectal surgery reduces colonic fecal content and microbial load. Dietary restriction, cathartic agents and whole gut lavage are used, and many surgeons additionally use oral and parenteral antimicrobials.²³ A number of studies suggest that this common practice may need re-evaluation as the proof they reduce infection is lacking.²⁴

TISSUE DAMAGE

The proliferation of endogenous bacteria also depends on intraoperative tissue damage, which varies between wounds, operations and surgeons. Virulence factors and pathogenicity of micro-organisms, as well as their numbers in the wound at closure, are also influential. Gram-negative bacterial cell walls, rich in lipopolysaccharide, initiate a chain of responses via toll-like receptor 4 (TLR4) mediated activation of immune defenses. These trigger stimulation of adaptive immune defenses and the systemic inflammatory response and, if inappropriate or excessive, may lead to sepsis. Gram-positive

organisms such as *Staph. aureus* can produce a similar end result.²⁵ Optimal operative technique is essential in limiting such damage. Delicate handling of tissues, together with hemostatic control to prevent seromas or hematomas, removal of devitalized tissues, avoidance of inadvertent entry into hollow viscera and use of electrocautery all positively influence the risk of infection.²⁶ Choice of suture and prosthetic material contributes to optimal wound healing and minimization of postoperative infection. In many operations prosthetic, non-absorbable materials are used which reduce the number of organisms necessary to cause infection.

Suction or open drains also increase the risk of infection by providing a portal of entry for bacteria and acting as foreign bodies.²⁷ Placement of drains distant from the operative incision, with early drain removal, is optimal, as sterile drains soon become colonized with potential pathogens.²⁸ Meta-analyses of the use of surgical drains do not encourage their use.²⁹⁻³¹

HOST RESISTANCE

Tobacco smoking, diabetes, malignancy, and renal and liver disease are recognized influences on health outcomes, but also specifically on infection after surgery. Host resistance to infection is adversely affected by malnutrition (including obesity) and perioperative hyperglycemia. These factors impair a patient's ability to overcome bacterial contamination at operation and the incidence of postoperative infection.

In obesity, for example, there is evidence that immune and inflammatory responses are diminished. This has implications for the increasing numbers of obese patients embarking upon bariatric surgery.³² Immunosuppressive drugs influence the risk of infection and include corticosteroids, cytotoxic chemotherapeutic agents and immune-targeted biologically active agents such as etanercept and monoclonal antibody therapies such as natalizumab. Although they have specific intentional immunological consequences, they may additionally result in vulnerability to infection.

Genetically influenced variations in immune defense mechanisms predict postoperative infection, and coordination of innate immune responses to, for example, secondary peritonitis is central in determining clinical outcome depending on whether responses are contained or become more generalized and systemic.³³ Individuals with TLR4 polymorphisms have aberrant responses to some Gram-negative infections with increased susceptibility and severity of infection.²⁵

INCIDENCE AND SURVEILLANCE OF SURGICAL SITE INFECTION

The intensity of post discharge surveillance (PDS) of SSI, and other surgical infections, may lead to different figures of incidence and prevalence. Audit surveillance is less accurate than research surveillance, relating as it does to the definitions used, and the rigor and extent of follow-up. Defining SSI is central to measuring incidence, but is difficult. Although no

generally accepted guidelines exist, the most widely used and accepted clinical definitions used in surveillance and research are the Centers for Disease Control (CDC) definition³ and the ASEPSIS score.³⁴

The CDC definition of SSI requires identification of a number of features within 30 days of surgery, or up to 1 year after prosthetic surgery, although the majority are usually apparent between the fifth and tenth postoperative day. These diagnostic features are:

- a purulent discharge or abscess
- organisms isolated from the wound
- at least one Celsian sign
- wound separation or need for drainage
- the attending surgeon records the presence of an SSI.

In addition there are three categories of SSI: superficial incisional which affect the skin and superficial tissues, usually with the classical Celsian signs of calor, rubor, dolor and tumor (and functio laesa); deep incisional which affect the fascial and muscle layers; and organ/space infection involving anatomical sites other than the incision, for example joint or peritoneum.

The ASEPSIS score acronym (see below) is an excellent tool for research and allows collection of continuous or interval scale data as opposed to the categorical data of other systems:

- Additional treatment
- Serous discharge
- Erythema
- Purulent exudates
- Separation of deep tissues
- Isolation of bacteria
- hospital Stay for longer than 14 days.

The ASEPSIS score allows distinction of life-threatening SSIs (needing readmission or prolonged inpatient stay) from less serious infections (such as discharge of pus that interferes minimally with postoperative recovery).

Many surgeons believe that their SSI rate after clean wound surgery is low. The often quoted Cruse and Foord data on SSI after clean surgery, using questionnaire by telephone, does indicate rates of <2%;³⁵ however, more intensive methods, employing an independent, blinded, trained and validated observer, produce higher figures. The cost and management of SSIs are transferred to primary care where instead of appropriately opening a wound to release pus, empirical antibiotics with an inappropriate spectrum of activity may be given (adding to the risk of resistance).

Audit of all surgical wounds with extensive PDS is expensive. However, an early study in this field (Study on the Efficacy of Nosocomial Infection Control, SENIC) showed that surveillance, which included collection, analysis and feedback of data to surgeons, significantly reduced SSI rates.³⁶ Many surveillance systems have been established since then and are mandatory for orthopedic SSIs in the UK.^{37,38} A drawback of these systems is that they tend to be recorded only during the increasingly short, postoperative, inpatient hospital stays.^{39,40}

Up to 75% of elective clean surgery is now undertaken on a day-case basis so that the high incidence of SSI is often

not recognized by the operating team in secondary care. To allow feedback to surgeons or for the evaluation of related research, data relating to rates and incidence of SSI must be valid. It may be possible to undertake an intensive audit of SSI in rotation between hospital-based specialties but accurate recognition after every type of surgery requires significant resources. These data cannot be easily collected by a surveillance coordinator or infection control team, with standardization and validation of definitions and approach, unless they are adequately funded.

PATIENT FACTORS WHICH INFLUENCE POSTOPERATIVE INFECTIONS (particularly SSIs)

The logic of having a risk score or recognized risk factors to predict infection in surgical patients is attractive. Healthcare resources could thereby be directed at pre-empting or avoiding risk, or at anticipating and managing infection earlier. The risk of SSI has been identified by the National Nosocomial Infections Surveillance System (NNISS) in North America to relate to the parameters of the American Society of Anesthesiologists (ASA) score, length of operation and wound class.⁴¹

Longer operations reflect severe underlying illness and greater blood loss; conversely, endoscopic surgical approaches have reduced the risk of SSI, even though they often have a longer operative time.⁴² Statistical analysis to identify independent variables is clearly important.

Concern that the NNISS system would not necessarily work for all surgical operations, particularly in predicting the more clinically significant deep and organ/space infections,^{43,44} led Haridas and Malangoni⁴⁵ to hypothesize that additional risk factors could be identified. A previous operation and hypoalbuminemia were significant risks for deep or organ/space infections. Many other patient risk factors have been suggested, including age, a history of cardiac failure, diabetes and hyperglycemia in non-diabetic patients, immunological insufficiency, high body mass index (BMI), low hemoglobin and blood transfusion, remote infection, excessive alcohol use and smoking. This is well summarized in the National Institute for Health and Clinical Excellence (NICE) guideline on prevention and treatment of SSI in which few systematic assessments of patient risk factors were found.⁴⁶ However, in the first of the American College of Surgeons Best Practices Initiative, many of these factors were addressed.⁴⁷

PRINCIPLES OF ANTIBIOTIC AND OTHER PROPHYLACTIC MEASURES IN SURGERY

ANTIBIOTIC PROPHYLAXIS

The choice of antibiotic prophylaxis prior to surgery depends on the type of surgery. There is now level I evidence that intravenous prophylactic antibiotics should be given at induction

of anesthesia for optimal tissue levels during the operation (above the minimum inhibitory concentration (MIC_{90}) of anticipated bacteria), and repeated *only* if there is excess blood loss, a long operation time or the placement of a prosthesis, as in hip replacement. Even then, three-dose prophylaxis should not be exceeded; extension beyond this is therapy with all the risks of resistance and emergence. Excessive, unanticipated fecal spillage during an elective colorectal operation serves as an example where prophylaxis should be extended to 5 days of antibiotic therapy.

Use of antibiotic prophylaxis to prevent SSI is based on the work of John Burke.⁴⁸ After staphylococci were injected into rabbit skin, a 4-hour delay in the host response was described (the ‘decisive period’). Administering an antibiotic before this period prevented abscess development. In surgical patients, this decisive period immediately follows surgery when host defenses are being mounted and the wound is most at risk of contamination and subsequent SSI; antibiotic prophylaxis is protective during this period of vulnerability. Level I evidence in Cochrane systematic reviews recommends antibiotic prophylaxis in colorectal surgery and in prosthetic hip surgery to prevent SSIs.^{49,50}

Four categories of operative wound contamination have been defined.⁵¹ Prior to antibiotic prophylaxis the corresponding SSI rates were:⁵²

- clean (5%+)
- clean-contaminated (<10%)
- contaminated (15–20%)
- dirty (>40%).

Rates of SSIs have been significantly reduced since the introduction of antibiotic prophylaxis.⁵³ The choice of a prophylactic regimen depends on availability and cost, and local guidelines which consider local resistance patterns, and microbiological and pharmaceutical advice. Guidelines adapted from the previous edition of *Antibiotics and Chemotherapy* are listed in Table 39.1.

Paradoxically, the reported rates of SSI after clean, non-prosthetic surgery are variable, and use of prophylactic antibiotics for non-prosthetic operations is controversial. The National Research Council definition⁵¹ of clean wound surgery is that no other inflammation is encountered, the respiratory, alimentary and gastrointestinal tracts are not opened, and there is no breach in aseptic technique. Cruse and Foord,⁵⁵ in a clean wound audit, estimated that the superficial SSI rate was 1.4%. While this figure is widely quoted, other papers report much higher rates of SSIs ranging from 4.5% to 18%.^{54–59} This variation in rate can be accounted for in part by the different audit techniques used. Higher rates are found in studies that incorporate surveillance by a trained unbiased observer than in studies employing telephone or postal enquiry.^{60,61} Keeling and Morgan⁵⁷ reported that the observed infection rate increased 10-fold if surgical patients were followed up after discharge.

Should perioperative antibiotic prophylaxis be given for clean wound surgery? Platt et al⁶² reported a reduced infection rate following hernia or breast surgery in patients given

antibiotic prophylaxis versus placebo. However, the analysis included chest and urinary tract infections; if these are excluded the SSI rates do not differ significantly. Taylor and colleagues⁵⁸ reported no effect of co-amoxiclav in patients undergoing open groin hernia repair (9%). High rates of SSI following breast surgery (17–19%) have been reported,⁵⁹ whether patients were given co-amoxiclav prophylaxis or placebo. A Cochrane meta-analysis of antibiotic prophylaxis in hernia repair, involving eight randomized controlled trials (RCTs) and 2907 patients, found no significant difference in infection rates after prophylaxis (2.9%) compared to placebo (4.3%). It was concluded that antibiotic prophylaxis could neither be firmly recommended nor discarded.⁶³ Thus, SSI after clean surgery is probably underestimated, the value of antibiotic prophylaxis is uncertain and the cost of infection can be high. A better picture will only develop from studies that employ a rigorous definition of SSI, accurate audit, an independent trained observer and a scoring system, such as ASEPSIS.

There is compelling evidence supporting antibiotic prophylaxis in clean-contaminated and contaminated wounds but the value in non-prosthetic clean wound surgery is less clear. There is also controversy over the true incidence of infection, and even whether these wound complications are superficial SSIs or represent a ‘failure to heal’. Adjuvant approaches which may also be effective are discussed next.

MAINTENANCE OF PERIOPERATIVE NORMOTHERMIA

Patient warming, systemic or local, is logical in preventing SSIs because of the known link between warming and tissue viability; low tissue perfusion increases the risk of infection^{64,65} and warming increases tissue oxygenation.⁶⁵ Operating theatres are designed for operating personnel comfort, not that of patients (21°C, 55% relative humidity); gases and intravenous fluids need to be warmed for patients losing heat following exposure and the vasodilatation caused by anesthesia. The pathophysiological consequences are an increased basal metabolic rate, with shivering; increased oxygen demand, acidosis, shift in the oxygen dissociation curve; relative organ ischemia and cardiac dysfunction; and prolonged drug actions. The result is an increased risk of infection and poor healing.

Warming patients systemically during elective colorectal surgery significantly reduces SSIs⁶⁶ and the value of prewarming before anesthesia and surgery has been shown.⁶⁷ A meta-analysis by Mahoney and Odom⁶⁸ combined 18 studies involving 1575 patients and identified significant reductions in the use of blood products, length of hospital stay, length of time in the intensive care unit (ICU), reduced infection and mortality by the avoidance of hypothermia, with considerable cost savings.

Local warming of patients prior to clean wound surgery at the intended surgical incision site has also been shown to reduce SSI rates.⁶⁹ Infection rates were 13.7% for standard

Table 39.1 Antibiotic prophylaxis in surgery

Type of operation	Principal pathogens	Antibiotic regimens and recommended doses ^a			
Clean operations					
<i>In hospitals without endemic MRSA</i>					
Implanted prosthesis Other clean operations for which prophylaxis is indicated	<i>Staphylococcus</i> spp. including MRSA	Amoxicillin-clavulanic acid Flucloxacillin + gentamicin Cefuroxime	1.2 g i.v. 2 g i.v. 2 mg/kg i.v. 1.5 g i.v.		
<i>In hospitals with endemic MRSA</i>		Vancomycin Teicoplanin or linezolid	1 g i.v. infusion over 60 min 600 mg i.v.		
<i>For penicillin-allergic patients</i>		(Clindamycin) (Clarithromycin + gentamicin)	(500 mg i.v.) (2 mg/kg i.v.)		
Clean-contaminated operations					
<i>Head and neck</i>					
(if sinus, nasal, oral or pharyngeal mucosa breached)	Staphylococci Streptococci Oral anaerobes	Amoxicillin-clavulanic acid Cefuroxime + metronidazole (Clindamycin)	1.2 g i.v. 1.5 g i.v. 500 mg i.v. (600 mg i.v.)		
<i>Thoracic</i>					
Bronchial	Staphylococci	Amoxicillin-clavulanic acid	1.2 g i.v.		
Esophageal	Streptococci GNAB Oral anaerobes	Cefuroxime + metronidazole (Cefuroxime + metronidazole)	1.5 g i.v. 500 mg i.v. (1.5 g i.v.) + (500 mg i.v.)		
<i>Upper gastrointestinal</i>					
Gastric	GNAB	Amoxicillin-clavulanic acid Gentamicin + metronidazole Clarithromycin Cefuroxime	1.2 g i.v. 5 mg/kg i.v. 500 mg i.v. 500 mg i.v. 1.5 g i.v.		
Biliary	GNAB	Amoxicillin-clavulanic acid	1.2 g i.v.		
ERCP	Enterococci	Piperacillin + gentamicin Cefuroxime (Vancomycin)	2 g i.v. 2 mg/kg i.v. 1.5 g i.v. (1 g i.v. infusion over 1 h)		
<i>Urology</i>					
TURP	GNAB Enterococci	Amoxicillin-clavulanic acid Gentamicin (Ciprofloxacin)	1.2 g i.v. 2 mg/kg i.v. (500 mg orally with premed)		
<i>Obstetrics and gynecology</i>					
Hysterectomy	GNAB <i>Bacteroides</i> spp.	Amoxicillin-clavulanic acid Gentamicin + metronidazole Cefotetan (Clindamycin)	1 g i.v. 2 mg/kg i.v. 500 mg/kg i.v. 1 g i.v. (600 mg i.v.)		
Cesarean section	β-Hemolytic streptococci <i>Bacteroides</i> spp Enterococci <i>Staph. aureus</i> <i>Chlamydia</i> ^b	Options as above	As above		
<i>Amputation</i>					
	<i>Clostridium</i> spp.	Benzylpenicillin + gentamicin + metronidazole (Clarithromycin + metronidazole) (Clindamycin)	1.2 g i.v. 2 mg/kg i.v. 500 mg i.v. (500 mg i.v.) + (500 mg i.v.) 600 mg i.v.

Table 39.1 Antibiotic prophylaxis in surgery—cont'd

Type of operation	Principal pathogens	Antibiotic regimens and recommended doses ^a			
Contaminated operations					
Colorectal					
Elective operations	GNAB <i>Bacteroides fragilis</i>	Amoxicillin-clavulanic acid Amoxicillin + gentamicin + metronidazole Cefotetan (Cefuroxime + metronidazole)	1.2 g i.v. 1 g i.v. 2 mg/kg i.v. 500 mg i.v. 1 g i.v. (1.5 g i.v. + 500 mg i.v.)		
Intestinal obstruction	<i>Bacteroides</i> spp. GNAB	Options as above	As above		
Compound trauma (within 4 h)	Other anaerobes <i>Staph. aureus</i> GNAB <i>Bacillus</i> spp.	Penicillin + gentamicin + metronidazole (Clarithromycin + metronidazole)	1.2–2.4 g 5 mg/kg i.v. 500 mg i.v. (500 mg i.v. + 500 mg i.v.)		

^aThe evidence indicates that single-dose prophylaxis is adequate, although some surgeons administer antibiotic prophylaxis for 24 h.

^bIs not an acute surgical infection risk, although it may be spread by surgery. If prophylaxis is considered appropriate, azithromycin 1 g is recommended.

ERCP, endoscopic retrograde cholangiopancreatogram; GNAB, Gram-negative aerobic bacilli; MRSA, methicillin-resistant *Staphylococcus aureus*; TURP, transurethral prostatectomy.

Antibiotics shown in brackets are replacements for β-lactam antibiotics in the above regimen for patients allergic to penicillin.

treatment, 3.6% for local warming ($p = 0.003$) and 5.8% for systemic warming ($p = 0.028$). Other surgical complications were also reduced in the warmed patients and significantly fewer antibiotics were prescribed for wound complications on return to primary care.

Prudent antibiotic prescribing and warming have not been widely or consistently adopted, despite directives and ‘checklists’ from the Department of Health⁷⁰ and from the World Health Organization.^{71,72}

PERIOPERATIVE SUPPLEMENTAL OXYGENATION

Another intervention that has been shown to reduce the incidence of SSIs is the use of supplemental perioperative oxygen.^{73,74} Although taken up widely in the USA, together with other factors such as tight perioperative blood glucose control,⁷⁵ this intervention has not been adopted in the UK. A fall in SSI rates from 2.3% to 1.7% was reported in the 44-hospital US collaborative. In the UK it is normal recovery-room practice to ensure that oxygenation is optimal (95% hemoglobin saturation) and that patients are routinely given an F_{IO_2} of >60%, which, after extubation, is not likely to offer any further benefit.⁴⁶ The results of further studies are anticipated.

SELECTIVE DECONTAMINATION OF THE DIGESTIVE TRACT

Selective decontamination of the digestive tract (SDD) was developed to reduce the incidence of morbidity and mortality resulting from nosocomial acquisition of infection by Gram-negative aerobic bacilli (GNAB) in patients treated in the ICU. The intention is to remove GNAB and yeasts from

the oropharynx and upper and lower gastrointestinal tract using non-absorbable antibiotics, thereby reducing the risk of ventilator-associated pneumonia (VAP) and mortality (this topic, and the use of probiotic bacteria, is discussed in more detail in Ch. 41). The challenge is related to the time it takes to eradicate GNAB from the gastrointestinal tract: in very sick patients it can take 5–10 days, by which time the organisms have already caused infection. There appears to be little to choose between SDD and selective oropharyngeal decontamination (SOD) alone.⁷⁶

Meta-analyses of trials of SDD^{77,78} have shown significant reduction in mortality in critically ill patients. Webb⁷⁹ has expressed concern about the impact on antibiotic resistance of such use. He notes that other methods of preventing VAP carry no such risks and have yet to be evaluated in comparison with SDD. Ebner and colleagues⁸⁰ share Webb’s concern. Certainly outbreaks of infection, resulting from GNAB containing plasmid-mediated ESBL genes, have been reported. This may be related to the use of third-generation cephalosporins during SDD in the ICU, and laboratory identification of multiple drug-resistant GNAB ought to guide the use of SDD.⁸¹ Nevertheless, the proponents of SDD report no clear increase in resistance in a review of RCTs.⁸² The practice has not been taken up widely in the UK and there is also controversy as to whether SDD should be part of the surviving sepsis campaign bundles.⁸³

The organisms responsible for the development of postoperative sepsis, multiple organ dysfunction syndrome (MODS) and multiple organ failure (MOF) are mainly derived from the colon, described as the ‘motor’ of sepsis, MODS and MOF.⁸⁴ Although aerobic and anaerobic colonic flora act synergistically, preoperative eradication of anaerobes from the colon may not be possible because of their large numbers, and not desirable because of their influence on colonization and resistance.⁸⁵ The aerobes in the colon can be suppressed by SDD

and it has been shown that SDD mainly targets GNAB with little increase in Gram-positive infections.⁸⁶

In health the small bowel remains relatively sterile but in disease it is colonized rapidly by GNAB which adds to the risk of bacterial translocation and sepsis. The value of SDD has been favorably assessed to prevent these infective complications after cardiopulmonary bypass,⁸⁷ esophageal surgery,⁸⁸ liver transplantation,⁸⁹ small-bowel transplantation⁹⁰ and colorectal surgery.⁹¹

SPECIFIC ANTIBIOTIC THERAPY IN ABDOMINAL AND OTHER SURGICAL AREAS

HEAD AND NECK SURGERY

Endogenous oropharyngeal organisms are the most common cause of infection. Antimicrobial prophylaxis is not required for clean surgery for benign disease, but should be considered for malignant disease. Prophylaxis for clean-contaminated or contaminated procedures is recommended, but for a maximum of 24 h. For procedures such as complex septorhinoplasty or grommet insertion, a single dose or short duration (<24 h) antimicrobial prophylaxis is recommended. The agents should have activity against both aerobic and anaerobic organisms.

Following tonsillectomy or adenoidectomy, bacteremia occurs with a frequency dependent upon the indication for the procedure. Children operated on for recurrent acute otitis media or otitis media with effusion had higher rates of bacteremia than children whose surgery was for other indications.⁹²

After tracheostomy, it is common to culture organisms from tracheal aspirates, but this most often represents bacterial colonization of the tube surface. As the length of time the tracheostomy tube is in place is extended, colonization is more likely, with *Pseudomonas* spp. or resistant GNAB. Optimal management includes attention to limiting antimicrobial exposure, and chest physiotherapy to expectorate secretions and prevent mucous stasis.

Deep space neck infections are the most severe, but have decreased since the introduction of penicillin and the appropriate use of antimicrobial prophylaxis in head and neck procedures. Community-acquired pharyngitis and tonsillitis were primarily responsible for precipitating deep neck infections, but this has decreased and has been overtaken by those related to odontogenic infection. The complex anatomy of the fascial planes and potential spaces within the neck has been reviewed by Vieira et al⁹³ and this should direct clinical examination and appropriate imaging during evaluation of a patient with such an infection.

Poor oral hygiene increases odontogenic infection, including Ludwig's angina, while altered states of immunity such as malignancy, diabetes and HIV infection result in atypical presentations of deep neck infections. Predominant organisms are viridans streptococci, staphylococci and anaerobes such as *Prevotella* and peptostreptococci.

The priority in managing a patient presenting with fever, pain and swelling in the neck, up to the parotid and mastoid, and

down to the supraclavicular fossae, is airway protection. This is followed closely by antibiotics, with a spectrum of activity sufficiently broad to treat the anticipated organisms, and surgical decompression of any collection. Surgical management, particularly of deeper space infections, requires extensive debridement, antimicrobial-impregnated dressings to permit frequent review and tracheostomy. Complications include mediastinitis, osteomyelitis, bacteremia and empyema.⁹³

THORACIC SURGERY

For non-cardiac thoracic surgery antimicrobial prophylaxis is standard, although in health the lower respiratory tract is usually sterile. In complex or recalcitrant infection requiring surgical intervention, prophylaxis is warranted. A single dose of an agent active against aerobic and anaerobic organisms common to the oropharyngeal and upper respiratory tract is adequate for esophageal surgery or resection of lung tissue. When a complex loculated infection or abscess is present, treatment should be directed by microbiological analysis of drained pus or culture of resected tissue and often needs to be prolonged for several weeks. *Staph. aureus*, *Streptococcus pneumoniae*, CNS and GNAB are the usual organisms encountered.

Complicated parapneumonic effusions or empyemas may require open surgical management if tube drainage or aspiration procedures have failed. Later indications for surgery include thoracotomy and restoration of normal chest mechanics by decortication of adherent thickened pleura. Thoracostomy allows irrigation and gradual closure over months in more complicated cases. Decortication is a procedure with significant morbidity and mortality,⁹⁴ however, in severely ill patients, the best outcomes are achievable by this approach.⁹⁵ The esophagus is normally colonized by oropharyngeal and upper respiratory tract organisms. Esophageal operations are frequently combined with gastric surgery for malignancy; in these operations, and where there is an esophageal stricture, overgrowth of both aerobic and anaerobic organisms with Enterobacteriaceae, enterococci and streptococci may occur. Single-dose prophylaxis with cefuroxime, cefotaxime or piperacillin (possibly with the addition of metronidazole) or amoxicillin-clavulanate is recommended.

STERNOTOMY WOUND INFECTIONS AND MEDIASTINITIS

The reported rate for deep sternal wound infections (DSWIs) is 1–2%.⁹⁶ Established patient risk factors include increased BMI, chronic airways disease, renal impairment, diabetes, steroid use, concurrent infection and immunosuppression. Operative factors also influence risk and include perioperative glycemic control, surgical technique including off-midline incisions, and prolonged cardiopulmonary bypass time. Preventive strategies include primary sternal plating and materials such as titanium in sternal plates, which limits mobility during chest wall movement, such as coughing, thereby decreasing the opportunity for

infection.⁹⁷ The diagnosis of deep infection is largely clinical, supported by microbiological data, but neither CT nor MRI adequately differentiates usual benign postoperative findings from abscesses and deep space infections.

DSWIs include mediastinitis, osteomyelitis, pericarditis, sepsis and wound dehiscence. Infection of prosthetic valves and of coronary grafts may occur and be fatal. The predominant pathogens are *Staph. aureus* and CNS, and hematoma formation, bone debris and suture wires in the sternotomy site are ideal substrates on which to form biofilm in which these organisms thrive.

Superficial infections should be drained, material sent for microbiological analysis and treatment initiated with an anti-staphylococcal agent, often a combination of a β-lactam and vancomycin until culture and sensitivity data are available.

Deeper infections can be catastrophic and require aggressive surgical debridement and high-dose, long-term antibiotic therapy directed by bacterial cultures from the deep tissues and local sensitivity patterns. The precise pathophysiology of mediastinitis is unclear but is related to imperfect asepsis, perioperative bleeding, sternal instability and operative time, as well as patient-related factors. Microbiological analysis of deep tissue samples directs appropriate therapy as infection often needs prolonged courses with parenteral agents. Where methicillin-resistant *Staph. aureus* (MRSA) is isolated, treatment with a glycopeptide is required, although novel agents such as linezolid, daptomycin and tigecycline may have a role.

Mediastinitis may complicate cardiac or esophageal surgery, penetrating trauma and spontaneous or instrumental perforation. Surgical management depends upon the underlying cause and may need thoracotomy with drainage of the mediastinum. The use of broad-spectrum antibiotics covering both aerobic and anaerobic organisms (e.g. cefotaxime and metronidazole, imipenem or amoxicillin-clavulanate) is required, and evidence of MRSA infection should be sought. Once the patient has stabilized and the operative management of the infection is completed, long-term antimicrobials can be chosen and managed in an outpatient antimicrobial therapy (OPAT) program.

Reoperation and rewiring may be required. Chest wall reconstruction has evolved, including omental interpositioning and the use of muscle flaps from the abdominal wall. Vacuum-assisted closure (negative pressure) devices are increasingly widely used with improved outcomes after DSWI.⁹⁸ Hyperbaric oxygen therapy over prolonged courses has been used with some success. The theory is attractive, with delivery of increased ‘antimicrobial’ oxygenation to tissues, but the supporting evidence is limited. A review of the available evidence specifically for sternal infections⁹⁹ found only a handful of papers encompassing the experience from four centers which had used hyperbaric oxygen in approximately 150 patients, and concluded that the evidence base was very weak and in need of RCT data.

With regard to SSIs at the saphenous vein harvest site, the usual pathogens are staphylococci and streptococci, but can include enterococci and *Esch. coli*. The presentation ranges

from cellulitis to wound dehiscence and necrosis requiring debridement. Low rates of infection relate to the technique of vein harvesting and the introduction of endoscopic methods. Therapy should be directed against skin organisms, and where MRSA is endemic, glycopeptides should be included.

CARDIAC SURGERY

Before the advent of antibiotics, infective endocarditis had a mortality of 100%. A more recent study of endocarditis in London reported an 18% mortality at discharge, with a 6-month mortality of 27%.¹⁰⁰

The common organisms identified in endocarditis are streptococci, *Staph. aureus*, CNS and occasionally yeasts. Appropriate antimicrobial therapy should always accompany surgery on an infected valve. Other foci of infection such as dental disease should be identified and controlled.

Surgical technique is central in preventing early postoperative infection of prosthetic valves, although accompanying interventions are also portals of entry (central venous access devices, pacing wires, intra-aortic balloon pumps and urinary catheters). Management should now follow the care bundle concept to reduce infection risk. Postoperative infection after valve surgery is usually caused by CNS, *Staph. aureus*, streptococci and occasionally GNAB. Late infection of prosthetic valves may follow subsequent bacteremia, particularly after dental procedures. MRSA has become prevalent in many cardiac units and in ICUs where these patients are managed postoperatively.

CARDIAC PACEMAKERS

Patients undergoing cardiac pacemaker insertion or open heart surgery should receive antimicrobial prophylaxis not exceeding 24 h. Typically postoperative infections are caused by CNS and *Staph. aureus* from the patient’s skin and this, together with the catastrophic consequences of such infections, has led to the use of prophylaxis, although cardiac surgery is in the clean surgery category. After coronary artery bypass grafting (CABG), the sternotomy wound and the saphenous vein harvest site wound are vulnerable to infection. Screening for MRSA and decolonization of nasal carriage in advance of elective CABG or valvular cardiac surgery can reduce infections, but CNS also play a significant role. The most dreaded complication is mediastinitis.

Over 3 million people worldwide have a permanent pacing device.¹⁰¹ Following insertion of a cardiac pacemaker or implantable cardioverter defibrillator (ICD), infection may occur in the pocket created to contain the device, on the subcutaneous electrodes or in tissues surrounding the leads. Infection originates in the external elements such as the pocket, and advances into the deeper regions along the electrodes or wires. The incidence of infection is higher for temporary external pacemakers (1–5%) than for permanent pacemakers (1%). ICD infection rates are around 1%¹⁰¹ and skin organisms predominate as pathogens,

mainly *Staph. aureus* and CNS. Local evidence of infection – such as pain and erythema, swelling, discharge of pus or exteriorization of the lead or generator – indicates a pocket abscess but deeper or invasive infection including bacteremia and endocarditis can be predicted.¹⁰² Extraction of hardware is needed and blood cultures underestimate deep infection. Optimal management requires removal of the pacemaker and leads, a significant procedure with an associated mortality risk and which may need open heart surgery with cardiopulmonary bypass.

Antibiotics are widely used prophylactically at the time of pacemaker implantation, as infection probably arises from peri-implantation contamination. However, evidence for the efficacy of this approach is lacking as the infection rate is low (around 1%) and valid trials are virtually impossible. Nevertheless, as the consequences of infection can be life-threatening, it is pragmatic to continue administration of single-dose prophylaxis with activity against the commonly implicated organisms (flucloxacillin, oxacillin or amoxicillin-clavulanate, or a glycopeptide where MRSA is endemic).

PERIPHERAL VASCULAR SURGERY

Vascular graft infection, in particular prosthetic graft infection, is uncommon (1–5%)¹⁰³ but carries a high amputation risk (10–25%) and mortality (20%).¹⁰⁴ Most graft infections originate from direct contamination at surgery or by hematogenous seeding from intravascular line, urinary tract or respiratory tract infection. Grafts to or below the groin are the most vulnerable, particularly when there is distal tissue necrosis or infection.

Prosthetic graft infection can present as local abscesses, sinuses, graft exposure, thrombosis or anastomotic hemorrhage. Infected aortic grafts can erode the fourth part of the duodenum or bowel, forming an aortoenteric fistula, and present with catastrophic gastrointestinal bleeding.

Most graft infections are due to skin organisms and the vast majority are due to *Staph. epidermidis*, *Staph. aureus* and *Esch. coli*. CNS and other organisms, when present within a biofilm bound to the prosthesis, are protected from antibiotics. MRSA infection is associated with a high morbidity and mortality. Fungal infections are rare and tend to occur in immunocompromised patients.

Prompt treatment is required to prevent catastrophic hemorrhage or graft thrombosis. Conservative measures are rarely curative. Treatment often involves explantation of the graft and revascularization via an extra-anatomical, uninfected route. The use of the sartorius muscle flap has been shown to be effective in facilitating complicated groin wound healing, while maintaining vascular graft salvage and patency. There is no evidence to guide the optimal duration of antibiotic therapy.¹⁰⁵ As *Staph. aureus* is the organism most likely to be isolated in early infection,¹⁰⁶ and as MRSA is increasingly common, empirical treatment of early-onset infection should include a glycopeptide.¹⁰⁷ The serious consequences of graft infection have led to almost universal

prescribing of perioperative antibiotic prophylaxis. Antibiotics active against *Staph. aureus* and *Staph. epidermidis*, and if the operation extends to or below the groin, activity against Enterobacteriaceae are recommended. Where MRSA is endemic, a glycopeptide may be needed. There is little evidence to indicate that prophylaxis for more than 24 h is necessary.¹⁰⁸

GASTROINTESTINAL SURGERY

PERITONITIS

Bacterial peritonitis following an ischemic, inflammatory or perforated pathology in an abdominal viscus is one of the major infective challenges in surgery. Despite advances in diagnosis, surgical and anesthetic techniques, antimicrobial agents and supportive care, mortality remains high (20–60%).

Peritonitis can be subclassified into primary, secondary or tertiary according to the underlying etiology. Primary peritonitis occurs in the absence of any loss of integrity of the gastrointestinal tract. The most characteristic syndrome of primary peritonitis is spontaneous bacterial peritonitis, in which the peritoneum is infected via the bloodstream. In contrast, secondary peritonitis is an acute infection of the peritoneal cavity, usually arising from a perforation, anastomotic disruption or transmural necrosis. Tertiary peritonitis has been described as a diffuse and persistent form of peritonitis with impaired host defenses following overwhelming infection of the peritoneal cavity, the result of which is often fatal. Understanding the classification of peritonitis is important in guiding management as the pathogenesis and the microbial nature of the different causes vary.

PRIMARY PERITONITIS

Primary peritonitis usually occurs in the presence of ascites. Primary or spontaneous bacterial peritonitis (SBP) develops in up to 25% of patients with alcoholic cirrhosis.¹⁰⁹ It is accepted that colonization of the ascitic fluid from an episode of bacteremia initiates peritoneal infection, made possible by the constant fluid exchange between the circulatory and ascitic compartments.

The diagnosis of SBP is based on the polymorphonuclear (PMN) cell count in ascitic fluid. A PMN count of more than 250/mm³ is highly suspicious of SBP and is an indication to start empirical antibiotic treatment. A bedside leukocyte esterase reagent strip with spectrophotometric analysis is available to rapidly exclude SBP.¹¹⁰ *Esch. coli* is the commonest pathogen responsible for SBP, followed by *Klebsiella pneumoniae*, *Str. pneumoniae* and other streptococcal species, including enterococci.¹⁰⁹ Anaerobes are rare; the presence of aerobes and anaerobes suggests secondary peritonitis.

Third-generation cephalosporins are the antibiotics of choice because of their safer profile, despite the lack of evidence found in a systematic review.¹¹¹ Antibiotic prophylaxis has been advocated for cirrhotic patients with ascites^{112,113} using oral fluoroquinolones.¹¹⁴

SECONDARY PERITONITIS

The microbial flora of the gastrointestinal tract increase in numbers and diversity from proximal to distal end. Gram-positive organisms predominate in the oral cavity, while the stomach and small bowel are relatively sterile. Increased numbers of Gram-negative organisms occur in the distal small bowel and anaerobes appear in large numbers in the colon.¹¹⁵ Patients with secondary peritonitis are most frequently encountered on surgical wards.

These abdominal infections are accompanied by a significant systemic inflammatory response and endotoxin production, which often leads to multiple organ failure.

The organisms isolated in secondary peritonitis vary depending on the site of the pathology. The stomach in the fasting state contains few, relatively acid-resistant species (e.g. lactobacilli or *Candida* spp.). Gastric perforation is therefore associated initially with a sterile chemical peritonitis. In contrast, perforation of the colon results in a peritoneal influx of an enormous number of organisms that constitute the normal colonic flora. *B. fragilis* is the most frequently isolated anaerobe and *Esch. coli* is the most frequently isolated facultative anaerobe.¹⁰⁹ They act in synergy.

Treatment of secondary peritonitis involves judicious fluid and oxygen resuscitation, correction of physiological derangements, administration of empirical antibiotics and source control by surgical closure, resection or excision of the diseased segment. Source control should be followed by extensive peritoneal lavage to remove fibrin (which traps bacteria), blood, bacteria, toxin and debris. If the source of infection cannot be controlled, continuous postoperative lavage, staged relaparotomy or treatment by an open abdomen (laparostomy) could be considered to prevent secondary or recurrent infection. The use of the APACHE (Acute Physiology and Chronic Health Evaluation) II scoring system of stratification provides objective discrimination between low-risk and high-risk patients with intra-abdominal infection.¹¹⁶

Antimicrobial therapy should include narrow-spectrum agents to treat community-acquired infections, and broader-spectrum agents for hospital-acquired infections,¹¹⁷ as this latter group of patients often harbors resistant pathogens. The Surgical Infection Society of North America¹¹⁸ has made recommendations for antimicrobial therapy for intra-abdominal infections (Boxes 39.1 and 39.2). Furthermore, a Cochrane review of antibiotic regimens in secondary peritonitis has shown equivocal efficacy of several regimens.¹²⁰ The choice of antibiotics must be influenced by toxicity, local nosocomial patterns of microbiological sensitivity and cost. The optimal duration of antibiotic therapy must be individualized and

Box 39.1 Surgical Infection Society recommended antimicrobial regimens for patients with intra-abdominal infections

Single agents

Ampicillin–sulbactam
Cefotetan
Cefoxitin
Ertapenem
Imipenem–cilastatin
Meropenem
Piperacillin–tazobactam
Ticarcillin–clavulanic acid

Combination therapy

Aminoglycoside (amikacin, gentamicin, netilmicin, tobramycin) plus an anti-anaerobe
Aztreonam plus clindamycin
Cefuroxime plus metronidazole
Ciprofloxacin plus metronidazole
Third/fourth generation cephalosporin (cefepime, cefotaxime, ceftazidime, ceftizoxime, ceftriaxone) plus an anti-anaerobe

With kind permission from Springer Science+Business Media: Varela JE, Wilson SE, Nguyen NT. Laparoscopic surgery significantly reduces surgical-site infections compared with open surgery. *Surgical Endoscopy*, Jan 2009.

Box 39.2 Surgical Infection Society recommended antimicrobial regimens for higher-risk patients with intra-abdominal infections

Single agents

Imipenem–cilastatin
Meropenem
Piperacillin–tazobactam

Combination therapy

Aminoglycoside (amikacin, gentamicin, netilmicin, tobramycin) plus an anti-anaerobe (clindamycin or metronidazole)
Aztreonam plus clindamycin
Ciprofloxacin plus metronidazole
Third/fourth generation cephalosporin (cefepime, cefotaxime, ceftazidime, ceftizoxime, ceftriaxone) plus an anti-anaerobe

With kind permission from Springer Science+Business Media: Varela JE, Wilson SE, Nguyen NT. Laparoscopic surgery significantly reduces surgical-site infections compared with open surgery. *Surgical Endoscopy*, Jan 2009.

depends on the underlying pathology, severity of infection, speed and effectiveness of source control, and the patient response to therapy.

A recent randomized controlled trial has shown that procalcitonin levels effectively differentiate patients with sepsis from those with the systemic inflammatory response syndrome, thereby reducing the duration of antimicrobial use.¹²¹

TERTIARY PERITONITIS

Tertiary peritonitis is a sepsis-like syndrome not induced by endotoxin and seen in patients who, despite being ‘adequately treated’, have persistent signs of sepsis. These patients exhibit

impaired host defenses and multiple organ dysfunction, and are unable to compartmentalize and clear the initial infection, or subsequently develop a superinfection of the entire peritoneal cavity. As a result of impaired host defense, low virulence pathogens (usually enterococci and fungi) can overgrow. The microbial nature of tertiary peritonitis is therefore difficult to predict when compared with primary and secondary peritonitis. *Staph. epidermidis*, *Pseudomonas* and *Candida* spp. are the predominant micro-organisms, with *Esch. coli* and *B. fragilis* only being occasionally found. The main source of these micro-organisms is thought to be the patient's own gastrointestinal tract, intestinal hypoperfusion, intestinal starvation or elimination of normal gut flora by antimicrobial agents. Adequate perfusion and enteral feeding aid preservation and restoration of the gastrointestinal tract and maintenance of barrier function.

Management of tertiary peritonitis entails correction of physiological derangements, administration of antimicrobial therapy, and surgical or other means of source control. The antibiotics commonly used are those listed in Box 39.1.¹¹⁸ Yeasts and other fungi can be major pathogens in tertiary peritonitis, particularly in patients who have received prolonged antimicrobial therapy or immunosuppression. It is critical that all patients with tertiary peritonitis have cultures of blood and infected peritoneal fluid.

GASTRODUODENAL SURGERY

The stomach is essentially sterile as a result of its high acidity and swift peristalsis. It contains mainly acid-tolerant lactobacilli and streptococci. The acidity of the stomach can be reduced or neutralized by drug therapy, proton-pump inhibitors, gastroduodenal bleeding or in the presence of obstruction. Combined failure of intestinal clearance and the gastric acid barrier results in more severe colonization with increased numbers of GNAB. Antibiotic prophylaxis in gastroduodenal surgery has been advocated and the commonly used antibiotic regimens include cephalosporins (commonly cefuroxime) plus metronidazole, and amoxicillin-clavulanate; third- or fourth-generation cephalosporins are reserved for high-risk patients.¹²² Empirical *Helicobacter pylori* eradication treatment has been proposed for perforated peptic ulcers to prevent recurrence of ulcers.¹²³

LIVER SURGERY

Patients undergoing liver surgery, specifically hepatectomy, are at increased risk of SSI and liver failure due to impaired glucose tolerance, long operation time, large blood loss and bile spillage. *Staphylococcus* and *Enterococcus* spp., *K. pneumoniae*, *Enterobacter* spp., *Esch. coli* and *B. fragilis* are the commonly encountered micro-organisms.^{124,125}

Cefazolin^{125,126} and flomoxef¹²⁷ have both proven efficacious in clinical trials as prophylactic agents in hepatectomy. *B. fragilis* is, however, resistant to cefazolin and the addition of

metronidazole can improve cover. (In view of the latter, and as cefazolin is no longer available in many countries, we would advocate the use of cefuroxime as an appropriate substitute.) Only two randomized trials have examined the effects of antibiotic prophylaxis after hepatectomy and are conflicting.^{126,127} Antibiotic prophylaxis is recommended by the Scottish Intercollegiate Guidelines Network (SIGN) based on evidence inferred from biliary surgery.¹²⁸ There is no consensus with regard to the duration of antibiotic prophylaxis, but current evidence suggests that there is no benefit in extending beyond 24 h¹²⁷ in patients undergoing hepatectomy.

LIVER ABSCESS

Liver abscesses can be classified according to their etiology:

- Pyogenic abscess, usually polymicrobial, accounts for 80% of hepatic abscesses
- Amebic abscess due to *Entamoeba histolytica* accounts for 10%
- Fungal abscess, most often due to *Candida* spp., accounts for less than 10%.

Liver abscess can be solitary or multiple and commonly affects the right lobe. Biliary tract infection is the main cause of pyogenic abscess and accounts for 21–30%. Biliary obstruction encourages bacterial proliferation and can cause multiple liver abscesses.

Infections within organs drained by the portal vein (portal pyemia) can result in localized septic thrombophlebitis, leading to liver abscess. Diverticulitis, pancreatitis and diffuse peritonitis are now some of the more frequently reported causes. Septic emboli are released into the portal circulation and are trapped by the hepatic sinusoids, each becoming the nidus for micro-abscess formation. These micro-abscesses usually coalesce into a solitary lesion. Micro-abscess formation can also follow hematogenous dissemination in association with systemic bacteremia, endocarditis, pyelonephritis, pneumonia, osteomyelitis or following intravenous drug abuse. Cases are also reported in immunocompromised children affected by diseases such as chronic granulomatous disease and leukemia. Hematogenous spread from non-gastrointestinal sources accounts for 10–20% of liver abscesses. In 15–35% of patients, the etiology of hepatic abscess remains obscure (cryptogenic abscess). The incidence of cryptogenic abscess is increased in patients with diabetes and metastatic cancer. Unusual pathogens such as *Mycobacterium avium* complex are seen in patients with AIDS and *Yersinia enterocolitica* in patients with cirrhosis, diabetes mellitus, alcoholism or malnutrition. Mortality from liver abscess has decreased steadily and ranges from 2.5% to 10.9%.^{129,130}

Most liver abscesses are polymicrobial and are commonly due to *Esch. coli*, *K. pneumonia*, *Bacteroides* and *Streptococcus* spp. and microaerophilic streptococci. The incidence of *K. pneumonia* is rising¹²⁹ in the western world, and streptococci of the *anginosus* group (formerly *Str. milleri*), which are microaerophilic commensals of the gastrointestinal tract, have emerged as important causes of hepatic abscess.

The clinical presentation of liver abscess is insidious; many patients have symptoms for weeks prior to presentation, which may include fever, malaise, anorexia, weight loss and right upper quadrant pain. Ultrasonography or CT scan are usually diagnostic.

Antibiotic therapy as a sole treatment modality is not routinely advocated. Regimens using β -lactam/ β -lactamase inhibitor combinations, carbapenems or second-generation cephalosporins with anaerobic coverage are excellent empirical choices for the coverage of enteric bacilli and anaerobes. Fluoroquinolones are an acceptable alternative in patients who are allergic to penicillin. Metronidazole or clindamycin should be added for anaerobic coverage. The optimal duration of parenteral therapy, as well as of subsequent oral therapy, remains unclear.¹²⁹ Amebic abscesses are cured by metronidazole in 90% of cases, which should be initiated before serological test results are available. This should be followed by an agent with luminal activity such as diloxanide furoate or paromomycin. Systemic antifungal agents should be initiated if a fungal abscess is suspected and after the abscess has been drained percutaneously or surgically. Initial therapy for fungal abscess is currently amphotericin. All patients should have serial radiological investigations to assess efficacy of medical treatment.

Percutaneous drainage and aspiration have become the standard of care and are advocated for abscesses larger than 5 cm.¹³¹ Laparoscopic drainage has been shown to be a safe alternative.¹³² Liver resection may be indicated in management of complicated liver abscesses.

BILIARY TRACT SURGERY

Laparoscopic cholecystectomy is the ‘gold standard’ in managing gallstone disease. It has an extremely low rate of postoperative infection (0.4–1.1%)¹³³ in comparison to open cholecystectomy, consisting mostly of superficial SSIs around the trocar site. Two meta-analyses have revealed no beneficial effects of antibiotic prophylaxis in low-risk patients (those without cholecystitis, choledocholithiasis and cholangitis) undergoing elective laparoscopic cholecystectomy in reducing postoperative infection rates.^{133,134} SIGN guidance¹²⁸ reflects this, and advocates that antibiotics are not required. However, antibiotic prophylaxis remains appropriate in complicated patients and patients requiring open cholecystectomy.

Bacterial colonization of bile occurs as a result of either obstruction of the biliary tree or biliary stasis. In the former, it is commonly due to gallstones but can be as a result of benign or malignant obstruction to the common bile duct. Biliary stasis is seen in critically ill patients as a consequence of increased bile viscosity due to fever and dehydration. Patients on long-term total parenteral nutrition (TPN), prolonged fasting, gallbladder dysmotility and occasionally diabetes are at increased risk of biliary stasis, which can lead to acalculous cholecystitis. Bacterial infection is thought to be a consequence, not a cause, of cholecystitis. In early acute cholecystitis, bile is sterile.

Bacteria can enter bile by ascending the common bile duct from the duodenum (across an incompetent sphincter of Oddi or following instrumentation); entering directly from the small bowel after choledochoenterostomy; or by translocation from the gut into the portal vein, resulting in cholangitis. Some 20–75% of bile cultures are positive, with the most common organisms being *Esch. coli*, *Klebsiella* spp., enterococci, *Enterobacter* and *Ps. aeruginosa*. Anaerobes are rare. Recurrent pyogenic cholangitis (oriental cholangiohepatitis) is common in South East Asia and is characterized by recurrent attacks of primary bacterial cholangitis. The cause is unknown, although *Clonorchis sinensis*, ascariasis and nutritional insufficiency have been suggested.

Antimicrobial treatment of biliary tract infections usually requires single-agent therapy, or combination treatment with broad-spectrum cover for more serious infections. High biliary concentration of antimicrobials is vital, but the range of antimicrobial activity is a more important factor. When there is biliary obstruction, it is doubtful whether any antibiotic is excreted effectively into the bile. Cephalosporins have the required spectrum of activity and suitable pharmacokinetics, while quinolones achieve high concentrations in the biliary tract and are active against biliary pathogens. Suitable single-agent regimens include the following:

- Mild to moderate cholecystitis: ampicillin–sulbactam, ticarcillin–clavulanate, ertapenem, quinolones, cefuroxime, ceftriaxone or cefoxitin
- Severe cholecystitis, nosocomially acquired or prior antibiotic exposure: piperacillin–tazobactam, imipenem or meropenem.

Combination regimens include penicillin (including piperacillin, ampicillin, or penicillin) and metronidazole; penicillin with an aminoglycoside (gentamicin or tobramycin); or an aminoglycoside and third-generation cephalosporin. In cholangitis or biliary obstruction, biliary secretion of antibiotics may be impaired. Treatment may therefore require decompression and drainage of the biliary system depending on the cause of the infection and the severity of illness. This could be performed via endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic biliary (PTC) drainage. The incidence of infective complications after ERCP for acute cholangitis and cholecystitis is less than 2%.¹³⁵ *Ps. aeruginosa* cholangitis has been reported in post-ERCP patients as a result of inadequate endoscope disinfection.¹³⁶

Early laparoscopic cholecystectomy for acute cholecystitis is controversial as there is a higher complication rate with conversion to open surgery. However, a meta-analysis¹³⁷ has shown that early laparoscopic cholecystectomy is safe and shortens hospital stay.

PANCREATITIS

Acute pancreatitis is a common emergency hospital admission and carries a mortality rate of 5–10%. The diagnosis is supported by a raised total serum amylase (at least three times the upper limit of normal). Pancreatic duct obstruction (e.g. by

gallstones) induces activation of proenzymes within the acinar cell by intracellular lysosomal enzymes, resulting in a cascade of enzymatic reactions. The mechanism of alcohol-induced acute pancreatitis (second commonest cause of pancreatitis) is less clear. These reactions cause release of mediators of inflammation resulting in increased pancreatic vascular permeability, leading to hemorrhage, edema and eventually pancreatic necrosis. The initial management of acute pancreatitis involves aggressive fluid resuscitation, pain control and correction of underlying physiological derangements. Uncontrolled local and systemic inflammatory responses from the initial insult can lead, apart from pancreatic necrosis, to multiorgan failure and death.

Acute necrotizing pancreatitis develops in 15% of patients with pancreatitis and is associated with mortality rates of 12–35%.¹³⁸ Pancreatic necrosis results in three potential outcomes: resolution, pseudocyst or abscess formation. Infections complicating necrotizing pancreatitis are often polymicrobial. Causative organisms most commonly originate from the gastrointestinal tract and include *Esch. coli*, *Ps. aeruginosa*, *Klebsiella*, *Enterobacter*, *Proteus*, *Bacteroides* and *Clostridium* spp. and enterococci. Why, and by what route, the necrotic pancreas becomes infected is not clear. It is most probable that passage of bacteria from the bowel lumen or from the bile into the pancreatic duct is the route of infection, although bacterial translocation from the colon into lymphatics and retroperitoneal inflammatory edema is possible.

Antibiotics are used to treat both infected pancreatic necrosis and extrapancreatic infections, and to prevent infection in patients with pancreatic necrosis. Guidelines suggest that a carbapenem should be used prophylactically and continued for 14 days, and infected necrosis should be assessed using fine-needle aspiration and culture.¹³⁹ For extrapancreatic infections, the most commonly used antibiotics are cephalosporins whereas carbapenems, glycopeptides and antifungals are used in the treatment of proven infected pancreatic necrosis.¹⁴⁰ Prophylactic antibiotic use in acute pancreatitis is controversial. A systematic review concluded that antibiotics in severe acute pancreatitis do not reduce mortality or protect against infected necrosis or the frequency of surgical intervention,¹⁴¹ contrasting with two other meta-analyses.^{142,143} There was a benefit for non-pancreatic infections. Only five of the studies reviewed were considered to be of high quality and used various antibiotic regimens.

The choice of antibiotics in preventing infection during necrotizing pancreatitis should be based on their antimicrobial activity, penetration rate, persistence and therapeutic concentrations. This is achieved by pefloxacin and metronidazole, imipenem and mezlocillin. In the absence of strong evidence, an expert group has recommended that prophylactic antibiotic therapy should be considered only for patients with CT evidence of more than 30% necrosis of the pancreas.¹⁴⁴

All patients with persistent symptoms and greater than 30% pancreatic necrosis, and those with smaller areas of necrosis and clinical suspicion of sepsis, should undergo image-guided

fine-needle aspiration to obtain material for culture 7–14 days after the onset of pancreatitis. Patients with infected necrosis require drainage of infected pseudocysts or abscess, with debridement.

COLORECTAL SURGERY

Surgery in the colon is associated with a high incidence of postoperative infection and mortality. Complication rates of 10–20% have been reported. A systematic review¹⁴⁵ found a statistically significant benefit in favor of antibiotic prophylaxis with a variety of antibiotics. The overall SSI rate was reduced from 39% to 10%. There is no advantage in extending the duration of antibiotic prophylaxis beyond the single preoperative antibiotic dose unless there is gross spillage. Additional dosing increases the risk of resistant organisms and *Clostridium difficile* infection.

Antimicrobial prophylaxis for colorectal operations can involve oral antimicrobial bowel preparation, a preoperative parenteral antimicrobial, or the combination of both. A combination of oral and parenteral prophylaxis is common practice in the USA.¹⁴⁶ The regimen should cover Gram-positive and -negative, aerobic and anaerobic enteric bacteria, particularly *Bacteroides* spp. Although a number of anaerobically active drugs such as clindamycin, cefoxitin and tinidazole have been used, metronidazole (intravenous, oral or rectal) has been the mainstay of therapy and prophylaxis.

Recommended oral prophylaxis consists of neomycin plus erythromycin or neomycin plus metronidazole, started no more than 18–24 h preoperatively. Mechanical bowel preparation is controversial, being phased out in the enhanced recovery program, as it has not been shown to confer any benefits in terms of anastomotic leak and SSI rates.²⁴ Furthermore, there is no trial examining the effects of oral antibiotic prophylaxis in uncleansed colon. Oral, non-absorbable antibiotics in bowel preparation in a retrospective case-controlled study may have an associated higher rate of *Clostridium difficile* infection.¹⁴⁷ Cefotetan or cefoxitin are recommended for parenteral prophylaxis and the combination of parenteral cefuroxime and metronidazole is recommended as a cost-effective alternative. In patients with confirmed allergy to β-lactams, one of the following regimens is recommended: clindamycin plus gentamicin, aztreonam or ciprofloxacin; or metronidazole plus gentamicin or ciprofloxacin. A single 750 mg dose of levofloxacin can be substituted for ciprofloxacin.¹⁴⁸

Two significant advances in colorectal surgery within the last decade are the enhanced recovery program and laparoscopic-assisted colorectal surgery. The enhanced recovery after surgery (ERAS) program does not recommend mechanical bowel preparation, uses carbohydrate loading preoperatively, and advocates early introduction of enteral feeding and patient mobilization. Patients so treated are less likely to develop postoperative complications.¹⁴⁹ A meta-analysis of RCTs of patients having laparoscopic colorectal surgery had a statistically significant reduction in SSI rates.¹⁵⁰

APPENDICECTOMY

Appendicitis is a common acute surgical presentation. Obstruction of the appendiceal lumen leads to ineffective lymphatic and venous drainage and bacterial invasion which progresses to perforation and peritoneal contamination.

Open or laparoscopic appendicectomy is the treatment of choice. Interval appendicectomy is occasionally performed as part of treatment of appendiceal abscess/mass following resolution. A large retrospective study has shown a statistically significant reduction in SSIs rate from 1.9% in open, to 0.7% in laparoscopic appendicectomy.¹¹⁹ The contributing factors are believed to be a shorter surgical incision, decreased tissue trauma and contamination, and elimination of mechanical retraction of the abdominal wall.

Wound infection is more common in patients with a perforated or gangrenous appendix, and antibiotic therapy, rather than prophylaxis, is indicated.

The predominant microbial flora associated with acute appendicitis include *Esch. coli*, *Klebsiella* and *Proteus* spp. Other anaerobic organisms, particularly *Bacteroides*, are common in wound infections after appendicectomy, leading to the widespread use of metronidazole. Postoperative complication rates parallel those found from a perforated viscus of any cause and rates of as high as 40% have been reported.¹⁵¹ The most common complications are intra-abdominal abscesses and superficial SSI. In a meta-analysis¹⁵² it was shown that antibiotic administration pre-, peri- or postoperatively significantly reduces SSI or intra-abdominal abscess following appendicectomy. The most common antibiotics used were cephalosporin and imidazole derivatives, followed by aminoglycosides and clindamycin. Use of piperacillin-tazobactam, tigecycline, ertapenem or doripenem is more appropriate for severe cases of intra-abdominal infection or patients with recent antibiotic exposure.

Duration of antibiotic dosing logically depends on the severity of the peritoneal contamination. In an RCT in non-perforated appendicitis,¹⁵³ single dose, three doses and 5-day doses of cefuroxime and metronidazole were compared. Postoperative infective complication rates were the same (6.5%, 6.4% and 3.6%, respectively). A single-dose prophylactic antibiotic is therefore probably adequate for uncomplicated appendicitis. The duration of therapy required for high-risk patients with perforated or gangrenous appendicitis is unclear. If source control is optimal, it is likely that 24–48 h therapy will be effective, although 5-day treatment is usually administered. Controversially, Hansson et al¹⁵⁴ reported efficacy rates of 90.8% and 89.2% for antibiotic therapy only and surgery, respectively. However, this study was flawed as a result of its methodology.

SPLENECTOMY

Overwhelming postoperative splenectomy infection (OPSI) is an uncommon condition but has a mortality rate up to 50%. This follows the loss of splenic macrophages which

filter and phagocytose bacteria and other pathogens. OPSI is usually caused by the encapsulated bacteria *Str. pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis*. Other pathogens may include *Esch. coli*, *Ps. aeruginosa*, *Capnocytophaga canimorsus*, group B streptococci, *Enterococcus* and *Ehrlichia* spp., and protozoa such as *Plasmodium* and *Babesia* spp. It is most common during the first 2 years following splenectomy but can also occur decades later.

The main risk factors are the age of the patient (young children are more prone, particularly those with sickle-cell disease), timing of the procedure (emergency splenectomy carries a higher incidence of OPSI), splenectomy for haematological malignancies and the time interval from surgery.¹⁵⁵ Most postoperative infections can be avoided by preoperative immunization, at least 2 weeks prior to elective splenectomy, or within 2 weeks after emergency splenectomy.¹⁵⁶ Vaccines should include conjugated pneumococcal and meningococcal C vaccine, in addition to the conjugated Hib vaccine. Pneumococcal and meningococcal vaccination boosters should be given every 5–10 years. Patients should also be offered influenza immunization yearly.

The role and efficacy of antibiotic prophylaxis are controversial, further compounded by problems with patient compliance. Young children should be given oral phenoxymethyl penicillin or erythromycin to at least age 5 years or for 5 years, and adults for 2 years following splenectomy.¹⁵⁶

Patients with OPSI require urgent blood culture and parenteral penicillin, ceftriaxone or similar antibiotics. A combination of antibiotics should be given to cover the wide spectrum of bacteria implicated. Where moderately or highly penicillin-resistant pneumococci are prevalent, ceftriaxone plus vancomycin or teicoplanin (plus rifampicin [rifampin] for highly resistant pneumococci) provide suitable initial cover.

TRAUMA SURGERY

Early deaths after major trauma follow brain, spinal, cardiac or vascular injury. Hypothermia, acidosis and coagulopathy which follow blood loss conspire against the patient, but 'damage control' surgery can improve survival.^{157,158} Deaths continue over subsequent weeks, resulting from trauma-related infection or indirectly related to critical care: endotracheal intubation, blood transfusion, catheterization or nasogastric suction (see Selective decontamination of the digestive tract, above). Infection after abdominal trauma is related to the mechanism of injury and organs involved. The interval between injury and treatment, and the occurrence of hypovolemic shock, are also important, particularly after vascular injury. Catastrophic injuries in the military arena have led to great advances in surgical and infection management, including early and aggressive debridement, pedicle flaps for repair of tissue defects and ABC resuscitation. Recognition of nosocomial infection, with infection control practices enforced through the leadership and command,

have had an impact on wound outcome. Resistant organisms have appeared in infections of injured extremities, particularly multidrug-resistant GNAB such as *Acinetobacter* and *Klebsiella* spp.¹⁵⁹

Traumatic injury leads to conditions favorable for infection: tissue damage, impairment of vascular supply, breach of skin defenses and exposure to contaminated environmental materials and micro-organisms. Military wounds are compounded by high-velocity injuries where the kinetic energy ($1/2 mv^2$) of a bullet or shrapnel can cause massive tissue damage with cavitation that causes suction of clothing and other foreign bodies, including soil, into the wound.

The greatest risk of infection follows trauma involving colonic injury and peritoneal contamination.¹⁶⁰ The options of stoma versus primary anastomosis must be considered in this context. Nutritional support, particularly parenteral nutrition, also influences infection after visceral injury. Empirical antimicrobial choice should anticipate polymicrobial exposure, and cover GNAB, Gram-positive cocci and anaerobes. Antimicrobials can be limited to 24 h after early surgery, but extension to 48–72 h is required if colonic contents have contaminated the peritoneum. Local microbiological data and guidelines should guide choice.¹²⁰ Broad-spectrum regimens can be narrowed according to clinical response and microbiological culture data.

In orthopedic trauma with open fractures, anticipated organisms are *Staph. aureus*, coagulase-negative staphylococci and Gram-negative rods, and perioperative antimicrobials targeting these organisms are recommended. In penetrating abdominal trauma, anaerobes are also implicated. In chest trauma, parenteral antibiotics after chest tube insertion in prevention of empyema and pneumonia are recommended when there is an associated hemopneumothorax.

Weigelt⁸ found a higher incidence of infection after shotgun injuries (20–25%) than after gunshot wounds (3.6–16%) or stab injuries (4–4.7%), and particularly after four or more intra-abdominal organs were injured. Together with thermal injury, there is widespread soft-tissue injury, which favors infection of devitalized tissues. Extensive irrigation and debridement with removal of foreign material and dead tissue is recommended with 48–72 h of intravenous antibiotics. Activity against clostridia and β -hemolytic streptococci is essential, and cephalosporins are widely used because of penicillin-resistant streptococci, with an aminoglycoside for significant soft-tissue defect. Intra-articular injuries require 24 h antimicrobial prophylaxis, with extension for significantly contaminated wounds.¹⁶¹

Factors that predicted infection in patients with intra-abdominal vascular injuries who survived beyond 48 h of hospitalization have been examined: 40% of survivors developed intra-abdominal infection when blood pressure was initially unrecordable, but was 11% in those with a blood pressure over 90 mmHg on admission. Resuscitation to restore blood pressure to a level of >70 mmHg, with early control of bleeding, resulted in a serious infection risk of 20% but failure of resuscitation resulted in a 77% risk.¹⁶²

Bacterial translocation may occur more commonly in patients with hypovolemic shock but does occur after traumatic injury. Its clinical significance in humans continues to be debated.¹⁶³ Nutrition is as important after trauma as in other patients requiring major surgery. Concepts linked to bacterial translocation have underpinned the practice of preferring enteral nutrition to parenteral nutrition. However, it is only in trauma patients that there is firm evidence that morbidity from sepsis is improved in enterally nourished patients.¹⁶³ Early introduction of nutrition (i.e. within 36 h of surgery) benefits severely injured patients who have undergone damage control surgery with open abdomens.¹⁶⁴ Specifically, the rate of pneumonia was significantly lower in patients fed early (43%) than those for whom feeding was delayed (72%).

The abdominal trauma index and the presence of a colostomy were found to be independent risk factors associated with intra-abdominal abscesses in an analysis of patients sustaining penetrating injuries of the colon.¹⁶⁵ In patients with bullet injuries of the colon, primary repair of the colon led to less abdominal sepsis.¹⁶⁶ In the civilian context, the majority of colon injuries can be managed by repair or resection with primary anastomosis;¹⁶⁷ however, in the military context, with the adversity of conditions and complexity of assessment and access to care, there may still be a role for the use of temporary stomas.¹⁶⁸

Infection following abdominal trauma involves aerobic and anaerobic bacteria. Enterobacteriaceae are the main pathogens in early peritonitis, whereas anaerobes, particularly *B. fragilis*, are predominantly responsible for the later abscess stage. Therefore, antibiotics chosen must have activity against aerobic and anaerobic organisms.

The pharmacokinetics of antibiotics in trauma patients may be important, following changes in volume of distribution and total body clearance of drugs.¹⁶⁹ Significant expansion in the apparent volume of distribution for amikacin, which correlated with fluid resuscitation, has been shown.¹⁷⁰ Similar variability in other aminoglycoside pharmacokinetics has also been shown,¹⁷¹ suggesting that higher doses of antibiotic are more effective than longer courses, provided there is adequate source control. The Surgical Infection Society of North America has endorsed this approach in patients who have traumatic enteric perforations and operated on within 12 h of injury.¹¹⁸

Infections associated with neutropenia and transplantation

Emmanuel Wey and Chris C. Kibbler

Neutropenic patients and transplant recipients are at risk of a number of life-threatening opportunistic infections. Neither patient group suffers from a single specific immunological deficit, there being a subtle blend of physical and immunological defects which evolve with time. Judgments about management need to be based upon knowledge of the balance of these defects and the timing of the infection.

The majority of hemato-oncology centers and transplant units base patient management (including that of infection) upon agreed protocols and the evidence base for these has become more robust in recent years. In addition there are now more national and international guidelines on which to base these. It is important that protocols are regularly updated and take account of local variations in risk, organisms and antimicrobial sensitivities.

INFECTIONS IN NEUTROGENIC PATIENTS

The inverse relationship between the numbers of circulating neutrophils and the risk of infection was established more than four decades ago.¹ This effect becomes apparent when the absolute neutrophil count is less than $1.0 \times 10^9/L$. The risk increases considerably as the count falls below $0.5 \times 10^9/L$ and all patients with a count of less than $0.1 \times 10^9/L$ for more than 3 weeks have been found to develop an infective episode.¹ Criteria for enrollment in a febrile neutropenia trial usually include a neutrophil count less than $0.5 \times 10^9/L$.

CAUSES OF NEUTROGENIA

Most of these patients are neutropenic following chemotherapy for leukemia while some leukemic patients will present with neutropenia before chemotherapy. In addition, the neutrophils of patients with myelodysplastic syndrome (MDS) or leukemia, particularly those with acute myeloid leukemia (AML), may have impaired microbicidal activity.^{2,3}

Patients receiving chemotherapy for high-risk or relapsed leukemia may be neutropenic for 2–3 weeks, and longer if receiving regimens containing fludarabine. Those undergoing standard chemotherapy for lymphoma or for solid tumors may also suffer a reduction in circulating neutrophils, but this is rarely less than $0.1 \times 10^9/L$ and is often not below $0.5 \times 10^9/L$ with the duration of neutropenia often less than 7 days. In patients with aplastic anemia, or bone marrow transplant (BMT) recipients who fail to engraft, neutropenia is often profound and prolonged. Normal engraftment in allogeneic BMT recipients takes place between 2 and 3 weeks after transplantation.

There has been a steady increase in the numbers of peripheral blood stem cell transplants (PBSCT) performed in Europe and autologous PBSCT has virtually replaced autologous bone marrow transplantation. Autologous PBSCT recipients have a shorter duration of neutropenia.

Patients undergoing allogeneic bone marrow transplantation behave essentially like neutropenic patients during the early post-transplant phase, but remain immunosuppressed for up to 2 years, even without complications such as graft-versus-host disease (GVHD).

Other causes of neutropenia are shown in Box 40.1.

Box 40.1 Non-malignant causes of neutropenia

Congenital

- Cyclical neutropenia
- Chronic benign neutropenia
- Severe congenital neutropenia

Acquired

- Drug-induced
 - Cytotoxic chemotherapy (the most common cause of neutropenia)
 - Antimicrobial associated: chloramphenicol; β -lactams; sulfonamides; trimethoprim; nitrofurantoin; flucytosine; ganciclovir; zidovudine
 - Other drugs (e.g. phenothiazines, tolbutamide)
- Alcohol
- Radiation
- Megaloblastic anemia
- Autoimmune neutropenia

FACTORS PREDISPOSING TO INFECTION

The pathogenesis of infection in these patients is multifactorial and is often the consequence of a breach in the skin or oral mucosa plus defects in cellular or humoral immunity.

Some defects are associated with specific infections (Table 40.1). Lymphopenia, as a consequence of lymphoid malignancy or treatment, is associated with reactivation of intracellular organisms such as mycobacteria, the herpes viruses, *Toxoplasma gondii* and *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*). Patients with chronic lymphoid malignancies and those receiving immunosuppressive chemotherapy, such as BMT recipients, have impaired antibody production which predisposes to infection with encapsulated organisms such as *Streptococcus pneumoniae*. The use of indwelling central venous catheters and mucosal damage caused by chemotherapy and herpes simplex virus (HSV) infection⁴ allows penetration by commensal flora. In recent years changes in cytotoxic chemotherapy have rendered the oropharynx a major portal of entry for α -hemolytic streptococci. Likewise, splenectomy undertaken as treatment or for diagnosis renders the patient susceptible to infection with encapsulated organisms such as *Str. pneumoniae*. Others have pre-existing sites of chronic infection such as middle-ear disease or bronchiectasis, which may act as reservoirs of infection

Table 40.1 Factors predisposing to infection in the neutropenic patient

Immune defect/risk factor	Example of opportunistic organisms
Neutropenia	<i>Streptococcus oralis</i> <i>Pseudomonas aeruginosa</i> <i>Candida</i> spp. <i>Aspergillus</i> spp.
Lymphoid cell defect	<i>Mycobacterium</i> spp. <i>Toxoplasma gondii</i> Herpes viruses <i>Pneumocystis jirovecii</i>
Humoral	<i>Str. pneumoniae</i>
Mucosal barrier (e.g. HSV/chemotherapy-induced mucositis)	<i>Str. oralis</i> Enterobacteriaceae Fungi
Vascular access	Coagulase-negative staphylococci Fungi Non-tuberculous and environmental mycobacteria
Foreign travel/ethnic origin	<i>Mycobacterium</i> spp. <i>Strongyloides stercoralis</i> <i>Blastomyces dermatitidis</i> <i>Coccidioides immitis</i> <i>Histoplasma capsulatum</i>
Anatomical defect/reservoir (e.g. chronic sinusitis)	<i>Pseudomonas</i> spp.
Splenectomy	<i>Str. pneumoniae</i> Other encapsulated bacteria

with organisms such as *Pseudomonas aeruginosa*. Ethnic origin and foreign travel may increase exposure to infections such as tuberculosis, malaria or strongyloidiasis.

CAUSATIVE ORGANISMS

Between 30% and 50% of febrile episodes in neutropenic patients can be confirmed microbiologically, and of these, most are due to bacteremia. Infections with Gram-positive bacteria, especially the coagulase-negative staphylococci and α -hemolytic streptococci, have increased in frequency over the past two decades. In the EORTC (European Organisation for Research and Treatment of Cancer) participatory centers the incidence of bacteremia due to Gram-positive organisms increased from 29%⁵ to 67% during the 1970s and 1980s.⁶ This increase correlates with the escalating use of central venous catheters, the development of alternative high-dose chemotherapy with attendant mucositis, and better prevention of Gram-negative infections. However, subsequent trials have shown a fall again, possibly associated with the decline in quinolone prophylaxis usage associated with emerging resistance. Of recent interest is the finding that cell-wall deficient (mostly Gram-positive) bacteria may be responsible for up to 25% of episodes of neutropenic fever in BMT recipients.⁷

Gram-negative bacteria continue to cause some of the most serious episodes of sepsis. Infections caused by the Enterobacteriaceae and *Ps. aeruginosa* carry a mortality of 40–60%.^{8,9} Oropharyngeal candidosis is extremely common in patients not receiving prophylaxis, while invasive candidosis and aspergillosis account for 20–30% of fatal infections when treating acute leukemia.^{10,11} Invasive aspergillosis is the most important infective cause of death in childhood acute myeloid leukemia¹² and in adult allogeneic bone marrow transplant/hematopoietic stem cell transplant patients. Other important infectious agents are listed in Box 40.2.

CHEMOPROPHYLAXIS

Allogeneic hematopoietic stem cell transplant (HSCT) recipients are at risk of a wide range of infections based upon extent of exposure and degree of immunosuppression. Autologous HSCT recipients are also at risk of infection although to a lesser degree due to shorter periods of neutropenia and time to engraftment. However, patients receiving CD34-enriched autografts appear to be at a similar level of risk as allogeneic HSCT recipients for cytomegalovirus (CMV) and other opportunistic infections.¹³ These risks are summarized in Box 40.3.

Prevention of these serious infections has been the goal of clinicians for many years. Strategies for preventing acquisition of organisms, such as the provision of a low microbial diet, or the use of high-efficiency particulate air (HEPA) filtration, appear important in some profoundly neutropenic patients at risk from aspergillosis and have been increasingly emphasized in recent years.¹⁴

Box 40.2 Important infectious agents in neutropenic and hematopoietic stem cell transplant patients

Bacteria	Viruses
Staphylococci	Herpes simplex virus
Streptococci	Varicella zoster virus
Enterobacteriaceae	Cytomegalovirus
Pseudomonads	Epstein–Barr virus
<i>Mycobacterium</i> spp.	Hepatitis A, B, C viruses
<i>Legionella</i> spp.	Parvovirus
<i>Clostridium septicum</i>	Adenovirus
<i>Clostridium difficile</i>	Polyomavirus
<i>Rothia</i> spp.	Measles virus
Fungi	Human herpesvirus-6
<i>Candida</i> spp.	
<i>Aspergillus</i> spp.	Protozoa/helminths
Zygomycetes	<i>Toxoplasma gondii</i>
<i>Cryptococcus neoformans</i>	<i>Strongyloides stercoralis</i>
<i>Pneumocystis jirovecii</i>	

Box 40.3 Summary of overall infection risk

Overall infection risk	Disease/chemotherapy regimen/duration of neutropenia
Low	Standard solid tumor chemotherapy regimens Duration of neutropenia <7 days
Intermediate	Autologous HSCT Lymphoma Multiple myeloma Chronic lymphocytic leukemia Purine analog therapy (fludarabine, 2-CdA) Duration of neutropenia 7–10 days
High	Allogenic HSCT Acute leukemia, induction and consolidation phases Campath (alemtuzumab) therapy Graft-versus-host disease treated with high-dose steroids Duration of neutropenia >10 days

HSCT, hematopoietic stem cell transplant.

The infections to which these HSCT recipients are most vulnerable can be temporally categorized into three periods following transplantation:

- Pre-engraftment – less than 3 weeks
- Immediate postengraftment – 3 weeks to 3 months
- Late postengraftment – more than 3 months.

These periods, pathogens, immune defects and associated host factors in HSCT recipients are illustrated in Figure 40.1.

BACTERIAL CHEMOPROPHYLAXIS

Various trials have examined the efficacy of oral non-absorbable antibiotics. Although a number of these were flawed, several controlled trials showed a benefit only when they were combined with a protective environment.^{15–23}

Although trimethoprim–sulfamethoxazole was first used in patients with acute leukemia to prevent *Pn. jirovecii* pneumonia, it also reduced the incidence of bacterial infection.²⁴ Further studies demonstrated the greatest benefit in patients with prolonged neutropenia, where a reduction in Gram-negative bacterial infections was seen.^{25–28} However, the incidence of side effects (including bone marrow suppression) and the selection of multiresistant organisms led to a decline in its use for this indication.

Oral quinolones are currently the most commonly used prophylactic antibacterial agents in adult patients with chemotherapy-induced neutropenia. Initially oral quinolones (ciprofloxacin, ofloxacin and norfloxacin) were compared in a number of studies with placebo, trimethoprim–sulfamethoxazole and non-absorbable antibiotics. In the majority of these the 4-quinolone treated patients had significantly fewer Gram-negative bacterial infections, a delayed onset of fever and a reduction in the number of days of fever. Importantly, a reduction in mortality was not demonstrated.²⁹ There has been concern that quinolone resistance is increasing in some units³⁰ and this has led to the discontinuation of quinolone prophylaxis. However, initial meta-analysis did not show this to be a significant problem, and recent EORTC and Health Protection Agency (HPA) data further support these findings. A sequential study has shown that combining ciprofloxacin with colistin was associated with no significant change in quinolone resistance over a 12-year period.³¹

However, a more recent meta-analysis³² that evaluated 95 randomized trials in afebrile neutropenic patients (the majority of whom had hematological malignancies) comparing antibiotic prophylaxis with placebo, no intervention or with another antibiotic class has shown a significant reduction in the risk for death when compared with placebo or no treatment (relative risk [RR], 0.67). The survival benefit was more substantial when the analysis was limited to fluoroquinolones. Fluoroquinolone prophylaxis reduced the risk for all-cause mortality (RR 0.52, 95% CI, 0.35–0.77), as well as infection-related mortality, fever, clinically documented infections and microbiologically documented infections. Although there was no significant increase in resistant bacteria with fluoroquinolone prophylaxis, the length of observation may have been insufficient to detect the emergence of resistant bacteria. All prophylactic antibiotics were associated with an increased risk for adverse events.

Following on from this meta-analysis, two randomized, double-blind, placebo-controlled trials of levofloxacin prophylaxis in neutropenic patients undergoing chemotherapy were performed.^{33,34} Levofloxacin has similar activity against Gram-negative bacteria in comparison with ciprofloxacin, with the exception of pseudomonads; however, it has improved activity against certain Gram-positive pathogens, including streptococci. The first trial evaluated levofloxacin prophylaxis from the initiation of chemotherapy until neutrophil recovery, in higher-risk, mainly inpatient adult leukaemic or stem cell transplant patients in whom chemotherapy-induced neutropenia was expected to last for more than 7 days. The second

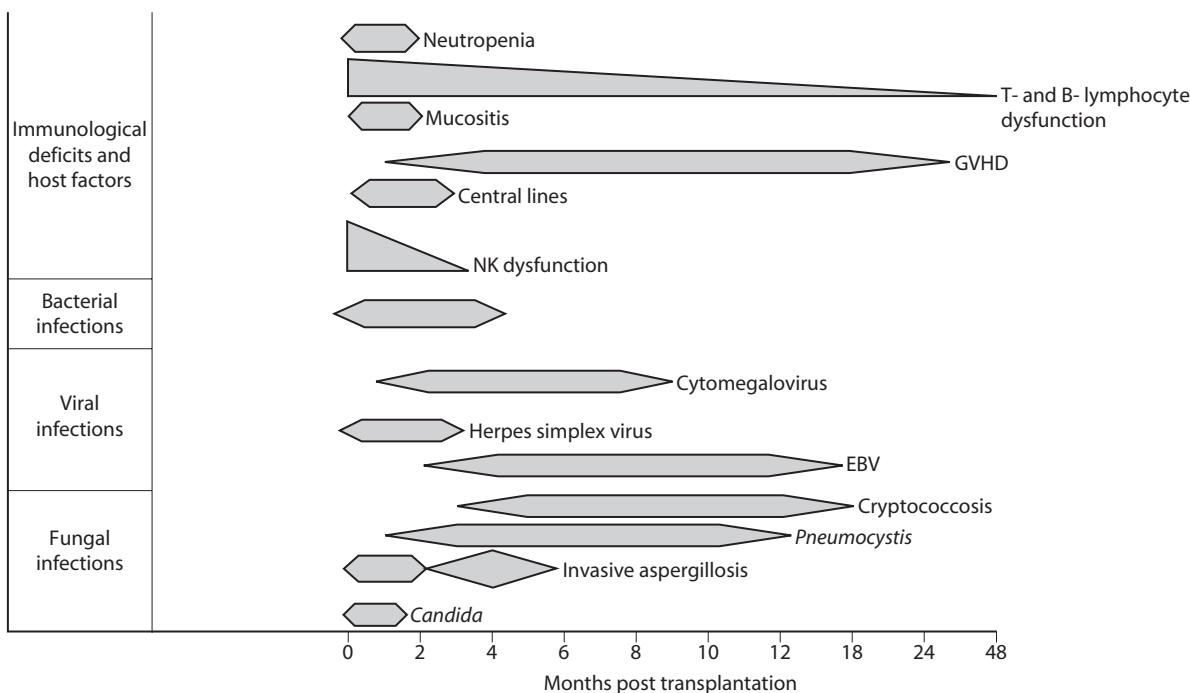

Fig. 40.1 The time course of infections after HSCT. EBV, Epstein–Barr virus; GVHD, graft-versus-host disease; LRTI, lower respiratory tract infection; NK, natural killer [cell]; UTI, urinary tract infection.

trial was in the outpatient setting and evaluated levofloxacin prophylaxis after chemotherapy for solid tumors and lymphomas for patients anticipated to have periods of neutropenia of 7 days or less. The effects of prophylaxis were similar between both patient groups in the two trials, as were mortality and tolerability. Both trials failed to demonstrate a significant survival benefit with prophylaxis. The results reflected previous meta-analyses and a review of both trials demonstrated that the numbers needed to treat to prevent one death by any cause was 24 in all patients and 43 in patients with an expected duration of neutropenia of >7 days.

The decision whether to use antibiotic prophylaxis and the selection of agent is a fine balance between calculated risk and expected benefit. Risks to consider include associations between fluoroquinolone use and severe *Clostridium difficile* and methicillin-resistant *Staphylococcus aureus* (MRSA), adverse drug reactions, antibiotic resistance, and whether prophylaxis will preclude the use of quinolones in empirical therapy of neutropenic fever in those patients stratified as low risk. The benefit of prophylactic antibiotics in other patient subsets with chemotherapy-induced neutropenia remains controversial.

With regard to timing and length of prophylaxis, guidelines from the European Conference on Infections in Leukemia (ECIL) suggest it should start with chemotherapy and continue until resolution of neutropenia or initiation of empirical antibacterial therapy for febrile neutropenia.

The problem of Gram-positive infections, particularly those due to α -hemolytic streptococci, has been addressed by a number of studies using different agents, including oral

penicillins,³⁵ macrolides^{36,37} and rifampicin (rifampin).³⁸ However, these have given mixed results and have been associated with the emergence of resistance. It is difficult, therefore, to make recommendations for prophylaxis of Gram-positive pathogens other than to use levofloxacin which has been shown to be of benefit. Some centers advocate prophylaxis against pneumococcal infection in allogeneic HSCT recipients, functionally asplenic patients and in patients receiving immunosuppressive therapy for GVHD. Where pneumococcal isolates have intermediate to high-level resistance rates to penicillin approaching 35%, alternative agents should be considered based on local susceptibility patterns. Trimethoprim-sulfamethoxazole prophylaxis for *Pn. jirovecii* is likely to be protective against pneumococcal disease.

FUNGAL CHEMOPROPHYLAXIS

Attempts at antifungal prophylaxis have met with variable success. Initial studies examined oral polyenes. Nystatin, in doses up to 12×10^6 units per day, had little effect on the incidence of invasive candidosis in neutropenic patients,¹¹ whereas amphotericin B was superior to placebo in preventing the disease.³⁹

While most invasive candidal infections are thought to gain entry via the gut,³⁹ non-absorbable antifungal agents do not protect against fungal infections at other sites, namely the skin, intravenous catheter sites and the respiratory tract. The oral, systemically active azoles have the potential to control colonization as well as prevent dissemination.

Ketoconazole reduces yeast carriage and the incidence of both local and systemic candidosis compared with placebo or non-absorbable agents.³⁹ Absorption is impaired in neutropenic patients, particularly in BMT recipients,⁴⁰ and breakthrough infections have occurred.⁴¹ Ketoconazole also causes elevated cyclosporin A levels as a result of activity on hepatic P₄₅₀ enzymes and serious idiosyncratic hepatotoxicity.

Fluconazole reduces colonization, mucosal thrush and the number of disseminated yeast infections.^{42,43} Two placebo-controlled studies in HSCT recipients showed a significant reduction in invasive fungal infections (IFI).^{44,45} Fluconazole was associated with a reduced mortality,⁴⁵ and fluconazole prophylaxis reduced the incidence of IFI, overall mortality and empirical antifungal therapy in allogeneic HSCT recipients but not autologous HSCT recipients. Unfortunately, its use in some centers has been associated with an increase in colonization and infection with *Candida krusei*, which is intrinsically resistant to fluconazole.⁴⁶ Fluconazole is also inactive against the important invasive molds that affect this population, especially *Aspergillus* spp. and the zygomycetes.

In contrast, itraconazole has activity against the molds, particularly *Aspergillus* spp. (see Ch. 32). However, in its original capsule formulation it was poorly absorbed in HSCT patients. This has been overcome by the introduction of an itraconazole–cyclodextrin complex in solution. Meta-analysis has shown this formulation to be associated with a lower overall incidence of fungal infection, lower mortality from fungal infection and a reduction in the use of intravenous amphotericin for suspected invasive fungal infection than fluconazole, oral amphotericin and placebo.^{47–49} There was also a reduction in the incidence of invasive aspergillosis.

In a randomized trial involving neutropenic patients with AML or MDS, prophylaxis with posaconazole led to a decrease in IFI due to aspergillosis and reduced overall mortality compared with the comparator group receiving fluconazole or itraconazole prophylaxis.⁵⁰ A similar effect was shown in allogeneic HSCT patients with GVHD.⁵¹ However, posaconazole prophylaxis has not been evaluated to date in allogeneic HSCT recipients in the neutropenic period post conditioning. Voriconazole has been used in prophylaxis, although large trial data of its use in this setting are still awaited. Extended-spectrum triazole prophylaxis should be avoided in patients receiving vinca alkaloid-based chemotherapy regimens such as vincristine in acute lymphoblastic leukemia. In these cases amphotericin regimens or an echinocandin could be considered.

Micafungin, an echinocandin, is approved for prophylaxis of candidal infections in patients undergoing HSCT. In a randomized, double-blind trial of neutropenic autologous and allogeneic HSCT recipients, comparing 50 mg per day of micafungin with 400 mg per day of fluconazole for antifungal prophylaxis, micafungin was superior to fluconazole based on the absence of breakthrough fungal infection.⁵²

In the absence of trial data it would be appropriate to recommend that prophylaxis continue until absolute neutrophil counts are above $0.5 \times 10^9/L$ in chemotherapy patients. In allogeneic HSCT there is an argument for continuing

prophylaxis until at least day +75 or until the end of immunosuppression (in the case of supervening GVHD).

Amphotericin administered as a nasal spray has produced conflicting results in preventing invasive aspergillosis,^{53,54} although some studies have shown greater benefit when it is aerosolized.^{55,56} One study showed no significant difference in proven, probable or possible invasive aspergillosis between aerosolized amphotericin and no inhalation (4% vs 7%).⁵⁷

Prophylaxis against *Pn. jirovecii* infection has proved remarkably effective in those undergoing treatment for acute lymphoblastic leukaemia²⁴ and for the first 6 months post-BMT. Trimethoprim–sulfamethoxazole three times weekly has been most studied, although some units are now using a 2-day regimen. Nebulized pentamidine is often used during marrow engraftment to avoid the myelosuppressive effects of trimethoprim–sulfamethoxazole, although data suggest that it may be inferior when used prophylactically in allogeneic transplant recipients. Other alternatives include dapsone and atovaquone.

VIRAL CHEMOPROPHYLAXIS

Most virus infections in the neutropenic patient are due to reactivation of the human herpes viruses. Up to 80% of adult patients with leukemia are herpes simplex virus (HSV) seropositive and the incidence of HSV infection among HSV-seropositive HSCT recipients is about 80%. HSV infection in patients with leukemia is subsequent to reactivation of latent virus in most cases.

Aciclovir (acyclovir), 200 mg every 8 h to 800 mg every 12 h, is effective as prophylaxis against HSV infection in HSV-seropositive patients with leukemia undergoing chemotherapy or in BMT recipients.^{58,59} An alternative regimen is valaciclovir 500 mg every 12 h.

Chemoprophylaxis against CMV infection, defined as the use of antiviral agents to prevent a primary CMV infection or a CMV reactivation, has been investigated in detail only in HSCT recipients, although CMV disease also occurs in patients with acute leukemia receiving chemotherapy. Allogeneic HSCT recipients comprise the group at highest risk of CMV reactivation and disease.

High-dose aciclovir has been shown to be partially effective in preventing CMV infection and disease post-BMT. A multicenter randomized trial compared 500 mg/m² intravenously every 8 h for 1 month followed by 800 mg every 6 h by mouth for 6 months with 200 or 400 mg every 6 h orally for 1 month followed by placebo.⁶⁰ The incidence of CMV infection reduced and survival increased by day 210 post-BMT, although the rates of CMV pneumonia were similar in the two groups. Valaciclovir is also being used in this setting.

The use of ganciclovir as prophylaxis against CMV infection has shown some benefit in reducing the incidence of CMV disease but has no effect on survival during the first 4 months post-BMT.^{42,61}

Pre-emptive therapy, defined as the use of antiviral agents in an asymptomatic patient with CMV detected by a screening assay, includes ganciclovir, valganciclovir and foscarnet. The choice depends on the risk of toxicity and which antiviral drugs have been used previously. Weekly monitoring in allogeneic HSCT recipients using a CMV antigenemia assay or a technique for detection of either CMV DNA or RNA is of use for the pre-emptive management of CMV infection.^{62,63} Centers vary with regard to the cut-off value used after which therapy is commenced and studies are in progress to better define this. When ganciclovir has been used as pre-emptive therapy following detection of CMV infection, survival was improved at 100 and 180 days post-transplant.⁶⁴ Foscarnet may be considered for second-line pre-emptive therapy, or in combination. Cidofovir can be considered for second-line pre-emptive therapy (3–5 mg/kg) but careful monitoring of renal function is required. Other therapeutic options in patients with multiresistant CMV disease are leflunomide and artesunate; however, experience with these agents is very limited.

To date there is no evidence to support the use of prophylaxis for other human herpesvirus (HHV) infections such as HHV-6 following HSCT.

A summary of prophylactic regimens is shown in Table 40.2.

EMPIRICAL THERAPY

The use of empirical antibiotic therapy in febrile neutropenic patients is almost universally practiced, because to await microbiological diagnosis is associated with a high mortality, particularly in patients with Gram-negative bacteremia. The

trigger for this is usually a single oral temperature of 38.3°C or two separate temperatures of 38.0°C at least 1 h apart.

The regimen chosen should be active against the common organisms likely to result in overwhelming sepsis or death, and influenced by local antibiotic sensitivity patterns, the incidence of particular infections, the specific needs of the patient and the prophylactic regimen used. Traditionally the significant organisms have been the Enterobacteriaceae and *Ps. aeruginosa*, which carry a mortality of 40–60%.^{8,9} Earlier regimens included an aminoglycoside in combination with a β-lactam antibiotic in an attempt to achieve broad-spectrum and synergistic activity against organisms such as *Ps. aeruginosa*. Aminoglycoside use carries the inherent risk of renal and ototoxicity, and data for its combination with β-lactams in empirical therapy have been conflicting. National Comprehensive Cancer Network (NCCN) guidelines recommend aminoglycosides in patients at high risk of pseudomonas infections (history of previous pseudomonas infections or the presence of ecthyma gangrenosum) whereas Infectious Diseases Society of America (IDSA) guidelines suggest they may be added in cases of progressive infection or documented resistant Gram-negative infection. A Cochrane review of 68 randomized controlled trials⁶⁵ concluded that for the primary outcome measure of all-cause mortality, there was no significant difference between monotherapy and combination (RR = 0.85). For the second outcome measure of treatment failure there was an advantage to monotherapy in 37 trials comparing different β-lactams (this was for patients with documented infection or hematological malignancy) (RR = 0.86). There was no difference between the two comparator arms in the number of superinfections but significantly more adverse events in the combination group for nephrotoxicity. Another meta-analysis also concluded that monotherapy is as

Table 40.2 Current antimicrobial prophylactic regimens for patients with prolonged neutropenia

Prophylaxis	Agent	Dosage	Duration
Antibacterial	Ciprofloxacin Levofloxacin	500 mg 12-hourly 500 mg daily	During period of neutropenia During period of neutropenia
Antifungal (high-risk patients)	Itraconazole suspension Posaconazole Voriconazole	See Chapter 60 for recommended regimens	During period of neutropenia 6 months post-BMT
Anti- <i>Pn. jirovecii</i>	Trimethoprim-sulfamethoxazole (Nebulized pentamidine in adults)	960 mg 12-hourly (150 mg fortnightly)	1 week pre- and 6 months post-BMT 3 times/week throughout treatment in acute lymphoblastic leukemia During period of neutropenia
Antituberculosis ^a	Isoniazid	5 mg/kg daily	During period of neutropenia 6 months post-BMT
Herpes simplex virus ^b	Aciclovir	400–800 mg 4–5 times per day	During period of neutropenia
Cytomegalovirus ^c	Seronegative blood products Aciclovir Ganciclovir	High dose	Not yet established Not yet established

^aAt-risk patients only.

^bSeropositive patients only.

^cHSCT recipients only.

effective as aminoglycoside–β-lactam combinations.⁶⁶ Data from patients in non-neutropenic studies have shown that once-daily dosing aminoglycoside regimens are as efficacious as multiple-dose regimens.

The first studies of double β-lactam therapy gave results inferior to aminoglycoside-containing regimens,^{5,67,68} but later studies using ceftazidime, latamoxef and cefoperazone in combination with a ureidopenicillin^{69–71} concluded that such combinations were of equal efficacy and less nephrotoxic than aminoglycoside-containing regimens. However, it was unclear whether they were any better than β-lactam monotherapy. A number of antibiotic regimens have subsequently been evaluated for empirical therapy in febrile neutropenic patients^{70–77} and are listed in Box 40.4.

There have been reports that *Stenotrophomonas maltophilia* is selected out by the carbapenems, to which it is intrinsically resistant.⁷⁸ In addition, there have been concerns over central nervous system (CNS) toxicity with high-dose imipenem⁷¹ or in patients receiving ciprofloxacin prophylaxis.⁷⁹

One advantage of the carbapenems is their activity against the α-hemolytic streptococci,⁸⁰ allowing them to be used alone without the need for early glycopeptide therapy. Similar streptococcal activity can be provided by piperacillin–tazobactam.⁸¹

A recent meta-analysis of randomized trials examining the choice of β-lactam agent as empirical therapy for the treatment of febrile neutropenia reported that cefepime was associated with an increase in all-cause mortality but not with an increase in infection-related mortality.⁸² The authors have concluded that ceftazidime, imipenem, meropenem and piperacillin–tazobactam are suitable monotherapy agents.

The high incidence of Gram-positive infections suggests that empirical therapy should contain a broad-spectrum anti-Gram-positive agent. Clinical trials of glycopeptides have provided conflicting evidence as to whether and when to add such an agent.

Early studies in centers in which there were significant numbers of Gram-positive infections showed that initial vancomycin or teicoplanin increased response rates and reduced morbidity,^{83,84} although no study showed a reduction in mortality. In addition, vancomycin is associated with increased toxicity.^{84,85} A large joint study conducted by the EORTC and the National Cancer Institute of Canada showed that including vancomycin in the initial therapy conferred no additional benefit,⁸⁶ and this has been reinforced by a meta-analysis showing no benefit of empirical Gram-positive therapy either initially or for persistent fever.⁸⁷

The increasing isolation of vancomycin-resistant enterococci (VRE)^{88,89} prompted the Centers for Disease Control and Prevention (CDC) to issue guidelines on the use of vancomycin that specifically excluded its use as empirical therapy in the neutropenic patient. This seemed prudent, although the IDSA suggests that vancomycin may be used in initial regimens in institutions where fulminant Gram-positive infections are common, particularly where MRSA may be a problem, and discontinued 3–4 days later if such an infection is not identified.⁹⁰

Box 40.4 Representative antibiotic regimens that have been evaluated for empirical therapy in febrile neutropenic patients⁷³

Penicillin and aminoglycoside combinations

Carbenicillin and gentamicin/amikacin/sisomicin
Ticarcillin and gentamicin/tobramycin/amikacin/netilmicin
Mezlocillin and tobramycin
Piperacillin and gentamicin/amikacin/netilmicin/tobramycin
Azlocillin and amikacin/netilmicin
Piperacillin–tazobactam and amikacin

Penicillin/β-lactam allergy

Vancomycin–teicoplanin + ciprofloxacin + gentamicin/amikacin

Cephalosporin and aminoglycoside combinations

Cefalotin and gentamicin
Latamoxef and gentamicin/amikacin
Cefotaxime and amikacin
Ceftazidime and tobramycin/amikacin
Cefoperazone and amikacin
Ceftriaxone and amikacin/netilmicin

Double β-lactam combinations

Carbenicillin and cefalotin
Carbenicillin and cefamandole
Ceftazidime and flucloxacillin
Ticarcillin and latamoxef
Piperacillin and latamoxef
Ceftazidime and azlocillin
Ceftazidime and piperacillin

Triple agent combinations

Carbenicillin, cefalotin and gentamicin
Carbenicillin, cefazolin and amikacin
Cefotaxime, piperacillin and netilmicin

Monotherapy regimens

Latamoxef
Ceftazidime
Cefoperazone
Ceftriaxone
Imipenem
Meropenem
Ciprofloxacin
Cefpirome
Cefepime
Piperacillin–tazobactam

Outpatient empirical regimens

Co-amoxiclav and ciprofloxacin p.o. (clindamycin and ciprofloxacin in penicillin allergy)
Ceftriaxone ± aminoglycoside

Other agents and combinations

Aztreonam and vancomycin
Imipenem and vancomycin
Trimethoprim–sulfamethoxazole and amikacin
Ticarcillin–clavulanate

From Liang R, Yung R, Chiu E, et al. Ceftazidime versus imipenem–cilastatin as initial monotherapy for febrile neutropenic patients. *Antimicrob Agents Chemother*. 1990;34:1336–1341.

Table 40.3 Options for initial empirical therapy

Regimen	Advantages	Disadvantages
Aminoglycoside + β -lactam	Broad spectrum Proven efficacy Synergy vs Gram-negative bacteria and streptococci	Poor activity vs coagulase-negative staphylococci Nephrotoxic and ototoxic Serum assays required
Double β -lactam therapy	Broad spectrum Avoids aminoglycoside toxicity No monitoring required	No more effective than single-agent therapy Possible prolongation of neutropenia Electrolyte imbalance Possible antagonism
Monotherapy	Broad spectrum Avoids aminoglycoside toxicity Avoids antagonism No monitoring required Cheaper	Lack of synergy (? less effective vs <i>Ps. aeruginosa</i>) Less active versus Gram-positive bacteria (with ceftazidime) Risk of resistance Potential central nervous system toxicity (with imipenem)
Single agent + glycopeptide	Broad spectrum including coagulase-negative staphylococci and α -hemolytic streptococci No monitoring required (with teicoplanin)	Expensive Unnecessary in some units Nephro- and ototoxicity (with vancomycin) Monitoring required (with vancomycin) Risk of glycopeptide resistance

There is also evidence that the choice of broad-spectrum agent for empirical therapy can influence the emergence of glycopeptide-resistant enterococci (GRE).⁹¹ At present glycopeptide-intermediate *Staph. aureus* (GISA) infections are not a significant problem in the UK, but provide another reason for selective use of glycopeptides in institutions where they do occur.

The oxazolidinone linezolid, the streptogramin quinupristin-dalfopristin and daptomycin are alternatives in patients intolerant of vancomycin and teicoplanin and for treatment of GRE and GISA infections. A multicenter, randomized study of febrile neutropenic patients comparing the safety of linezolid and vancomycin showed that clinical success rates 7 days after completion of therapy were equivalent, as was mortality at 16 days after completion of therapy. Drug adverse events were more frequent in the vancomycin arm and time to defervescence was shorter in the linezolid arm in patients with documented Gram-positive infections. Slower times to neutrophil recovery seen in the linezolid arm may have been secondary to the myelosuppressive effects of linezolid but were not statistically significant.

The duration of treatment has not been studied independently, but since the first EORTC trial the evidence has suggested that prolonged treatment is associated with more superinfections, often fungal, but no improvement in outcome. Current EORTC trials are conducted on the basis of discontinuing antibiotics after 7 days minimum treatment and four consecutive afebrile days, and this is similar to the IDSA and NCCN guidelines where 5–7 days without fever is recommended.⁹⁰ Options are summarized in Table 40.3.

With health services moving towards earlier discharge of all groups of patients, attempts have been made to achieve this in the neutropenic population. Talcott and colleagues derived a risk assessment model in which patients were divided into four groups.⁹² The fourth group was found to be at low risk and was studied in subsequent trials, which showed that amoxicillin-clavulanate plus ciprofloxacin was as effective as

intravenous ceftazidime or ceftriaxone plus amikacin in treating these patients.^{93,94}

Examples of outpatient oral/intravenous regimens are included in Box 40.4.

MANAGEMENT OF THE PATIENT WITH PERSISTENT PYREXIA

Approximately 20–30% of febrile patients who remain persistently neutropenic fail to respond to apparently appropriate antibiotic therapy. Some remain febrile until recovery of their neutrophil counts, irrespective of the antimicrobial therapy administered. Many patients with persistent fever will have an occult fungal infection. Patients with acute leukemia and allogeneic HSCT recipients are at highest risk due to prolonged neutropenia and immunosuppression for GVHD. Autopsy studies have shown that up to 25% of those neutropenic patients who die have an undiagnosed fungal infection.¹⁰

In view of the difficulties in diagnosis, the use of empirical antifungal therapy has been advocated. Recent ECIL 2009 guidelines are consistent with this viewpoint and current British Committee for Standards in Haematology (BCSH) guidelines advocate empirical antifungal therapy where IFI is suspected in conjunction with high-resolution computed tomography (HRCT) scanning and mycological tests (see Ch. 60). The main randomized study on which empirical antifungal therapy is based compared the effect of amphotericin (0.6 mg/kg per day or equivalent) with no treatment in patients remaining febrile 4 days after empirical therapy.⁹⁵ Although more responded in the amphotericin-treated group, the effect was only significant in patients not given antifungal prophylaxis (78% vs 45%; $p = 0.04$). Following this a number of other agents have been shown to be at least as effective as conventional amphotericin. Liposomal amphotericin B (AmBisome) is less nephrotoxic than conventional amphotericin, at least

as effective in rendering patients afebrile and is associated with significantly fewer breakthrough fungal infections.^{96,97} Subsequently, caspofungin has been shown to be at least as effective as AmBisome in this setting.⁹⁷

Patients who deteriorate during the first 48 h of empirical therapy pose a particularly difficult therapeutic challenge. It is important that there are no gaps in the spectrum of the selected regimen. Deterioration may be due to Gram-negative or Gram-positive organisms, such as α -hemolytic streptococci, which may cause features similar to those of sepsis syndrome (including acute respiratory distress syndrome and septic shock), or enterococci. Gram-negative activity (including antipseudomonal activity) is essential. Consequently, the addition of an aminoglycoside to initial β -lactam monotherapy is recommended, and this is also supported by the ECIL guidelines for patients with septic shock. A glycopeptide should also be considered. The above approach is summarized in Figure 40.2.

ASPECTS OF THERAPY FOR SPECIFIC ORGANISMS AND INFECTIONS

INTRAVENOUS CATHETER-ASSOCIATED INFECTIONS

Most neutropenic patients undergoing chemotherapy have an indwelling central line, which commonly becomes infected. The predominant pathogens are coagulase-negative staphylococci and *Staph. aureus*.⁹⁸ Others include *Candida* spp., coryneforms, *Acinetobacter*, *Stenotrophomonas* and *Pseudomonas* spp.⁹⁹ Ideally, infected catheters should be removed, but coagulase-negative staphylococcal infections may be effectively suppressed or eliminated by administering antibiotics via the catheter until neutropenia has resolved.⁹⁸ A high percentage of coagulase-negative staphylococci isolated on hematology units are resistant to methicillin and other β -lactams.

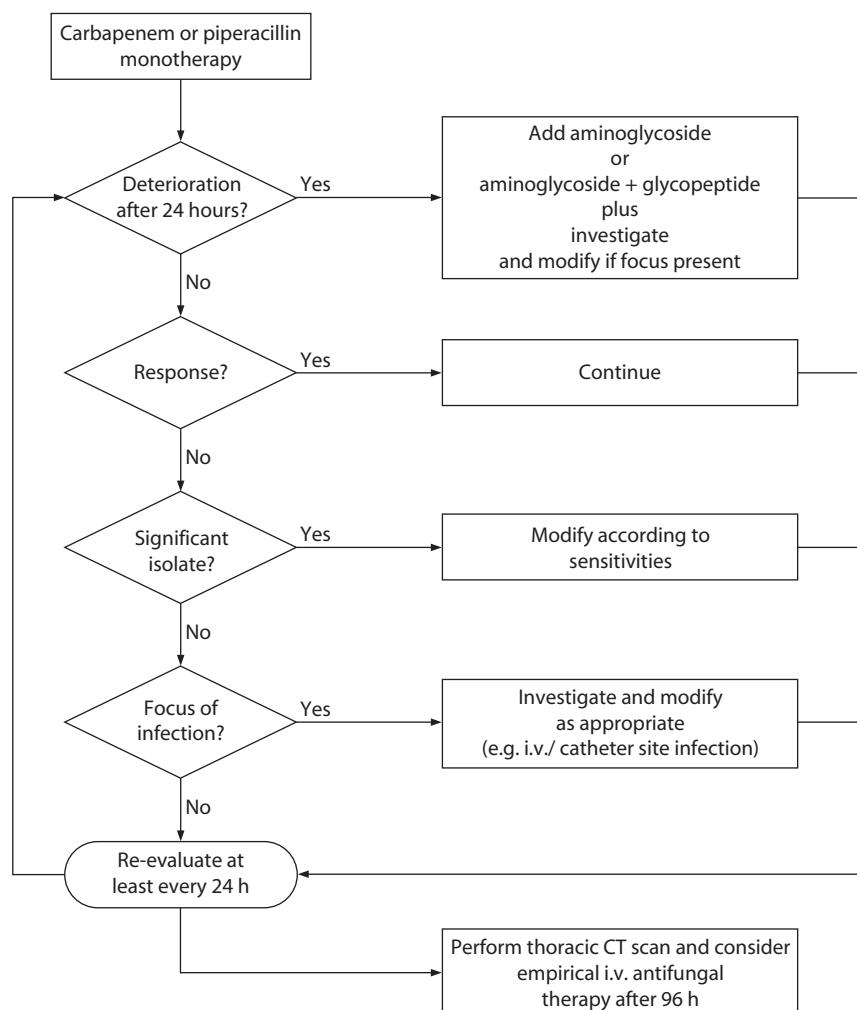

Fig. 40.2 An algorithm for the initial management of febrile neutropenic patients receiving prophylaxis.

A glycopeptide (most frequently vancomycin) is given for these, with the chance of successful resolution of bacteraemia and fever being more than 50%. Similar response rates can be obtained with coryneform infections but those due to *Candida* spp., Enterobacteriaceae, *Staph. aureus*, *Ps. aeruginosa*, *Acinetobacter*, *Sten. maltophilia*, non-tuberculous mycobacteria, and any form of tunnel infection, require the catheter to be removed and appropriate antimicrobial therapy administered.¹⁰⁰ The presence of port infection or septic phlebitis in association with long-term indwelling catheters are also indications for catheter removal and antimicrobial therapy.

PULMONARY INFECTIONS OF UNKNOWN CAUSE

Pulmonary infiltrates commonly occur in the febrile neutropenic patient and have a number of causes, especially in the BMT recipient. These include non-infective conditions such as pulmonary edema, alveolar hemorrhage, adverse drug reactions, radiation injury and the idiopathic pneumonitis syndrome. Focal lesions are more indicative of fungal infection, and HRCT or MRI scanning may reveal characteristic features of these.¹⁰¹ If clinical status permits, the causative organism(s) may be obtained by bronchoalveolar lavage. However, in many cases treatment has to be given empirically.

Initial therapy should certainly include agents effective against common respiratory pathogens such as *Str. pneumoniae* and *Haemophilus influenzae*, as well as Gram-negative organisms including *Ps. aeruginosa*, and hence a carbapenem, piperacillin–tazobactam or ceftazidime, with or without an aminoglycoside, is recommended.

Atypical pneumonias are extremely uncommon in this population and, unless there are particular clinical or epidemiological reasons to suggest Legionnaires' disease, erythromycin can be omitted from the initial therapy unless the infection appears to be community related. Mycobacterial infections may occasionally complicate hematological malignancies. Patients with lymphoid malignancy and BMT recipients who have not been receiving trimethoprim–sulfamethoxazole prophylaxis are at risk of *Pn. jirovecii* pneumonitis; empirical high-dose trimethoprim–sulfamethoxazole therapy (120 mg/kg per day in divided doses) is warranted in such patients. BMT recipients are particularly at risk of CMV pneumonitis post-transplant. However, CMV or *Pn. jirovecii* pneumonitis usually presents a month or so post-transplant, when the patient is no longer neutropenic, and the timing of the presentation should be taken into account when decisions are being made regarding empirical therapy. CMV pneumonitis is treated with intravenous ganciclovir (5 mg/kg every 12 h) plus intravenous immunoglobulin (200–400 mg/kg on alternate days for 14–21 days).^{102–104} Despite this, mortality from CMV pneumonitis is still in excess of 50% in BMT recipients. Furthermore, the myelosuppressive effect of ganciclovir can present a particular problem in these patients.

Patients discharged into the community are at risk of respiratory viral infections with agents such as respiratory syncytial

virus, influenza and paramyxoviruses, which occasionally cause outbreaks on hematology units.¹⁰⁵

INVASIVE FUNGAL INFECTIONS

Despite recent advances in the diagnosis and treatment of invasive fungal infections (IFI), failure rates approach 50% in invasive aspergillosis. Case fatality rates of 87% for HSCT and 50% for leukemia patients are quoted,¹⁰⁶ with 30-day mortality rates of 45% for candidemia in hematological malignancy.¹⁰⁷ Current BCSH guidelines advocate the use of caspofungin and liposomal amphotericin for empirical therapy of suspected IFI as they have the lowest rates of toxicity and are of equal efficacy. This is also in keeping with the current ECIL guidelines. Other options include voriconazole and posaconazole. The therapy of fungal infection is considered in detail in Chapter 60.

INVASIVE CANDIDAL INFECTIONS

A trend towards non-*albicans* species such as *C. glabrata* and *C. krusei* displaying a decreased susceptibility or resistance to azoles has been documented in both Europe and North America. These species are responsible for more than 60% of invasive candidal infections in patients with hematological malignancy.¹⁰⁸

Recent trials of the three licensed echinocandins – caspofungin, micafungin and anidulafungin – have demonstrated response rates in excess of 70% and these are now considered to be among the first-line agents for invasive candidal infections, especially where the species is not known, where the patient has received azole prophylaxis or in severe sepsis. This is supported by the ECIL-2 guideline update and IDSA candida guidelines, together with the use of AmBisome and other lipid formulations of amphotericin. Voriconazole is an alternative agent but should be used with care in patients where previous azole prophylaxis has been used. Recommendations for duration of therapy consist of 14 days following the last positive blood culture, together with extensive investigation for dissemination of infection. Further trials regarding the use of efungumab (Mycograb), a human recombinant antibody consisting of an Fv fragment that binds to the domain structure HSP90 of *Candida* spp., are needed before recommendations regarding its use in combination with antifungals can be made, and it is currently not licensed.

INVASIVE ASPERGILLOYSIS

Mortality due to invasive aspergillosis remains high in neutropenic patients; the infection is now the most important cause of death in childhood AML and adult BMT recipients. In BMT recipients case fatality rates are as high as 87%.¹⁰⁶ Successful outcome is dependent upon early treatment and, to a considerable extent, on bone marrow recovery. Agents active against *Aspergillus* spp. include amphotericin deoxycholate and its

lipid-associated preparations, the extended-spectrum triazoles and echinocandins. High-dose conventional amphotericin is also associated with a high incidence of nephrotoxicity. Lipid-associated formulations of the drug have been licensed for use in patients failing treatment or experiencing unacceptable toxicity with conventional amphotericin. Liposomal amphotericin (AmBisome) has been studied in a randomized prospective trial comparing two doses (1 mg/kg per day and 4 mg/kg per day) for the treatment of invasive aspergillosis in neutropenic patients.¹⁰⁹ 6-month mortality was approximately 60% with attributable mortality of around 20% in the two arms. A double-blind comparison of AmBisome 3 mg/kg and AmBisome 10 mg/kg in primary therapy by Cornely and colleagues demonstrated no additional benefit of 10 mg/kg dosing over 3 mg/kg dosing of liposomal amphotericin B.¹¹⁰

Voriconazole has been assessed by Denning and colleagues in two open-labeled studies in which response rates of 44% and 48% were reported, respectively.^{111,112} Superiority of voriconazole over amphotericin deoxycholate in terms of efficacy, safety and survival has been demonstrated by Herbrecht and colleagues in a randomized trial.¹¹² Superiority was irrespective of the host group, site of lesion or neutropenic status. Voriconazole has been given the highest graded recommendation in the recent ECIL-2 guideline update, followed by AmBisome. In North America the NCCN currently recommends voriconazole as the agent of choice for first-line therapy of invasive pulmonary aspergillosis. There are insufficient data to recommend the use of caspofungin, itraconazole and posaconazole as agents in first-line therapy of invasive aspergillosis, but these have all been used in salvage therapy with similar efficacy. There are also currently insufficient data to recommend combination therapy in first-line therapy. One retrospective study¹¹³ comparing the combination of voriconazole and caspofungin given as salvage therapy after failure of amphotericin formulations in allogeneic HSCT recipients with voriconazole monotherapy in a historical control group demonstrated substantially improved 3-month survival.

The development of mycotic lung sequestra (which have been mistakenly termed mycetomas) may require additional therapy. These lesions appear once the bone marrow is regenerating. Patients are at risk of life-threatening hemoptysis.¹¹⁴ In addition, patients who require further chemotherapy or bone marrow transplantation are at considerable risk of relapse of the original infection. Resection of these lesions has been shown to be effective, preventing relapse following bone marrow transplantation, and is associated with a lower mortality than antifungal therapy alone in some studies,¹¹⁵ although there are no large randomized studies in this setting.

ADDITIONAL THERAPIES

GROWTH FACTORS

Hematopoietic growth factors have been extensively used to treat neutropenic patients. Studies have consistently shown that granulocyte-colony-stimulating factor (G-CSF) reduces

the duration of neutropenia. However, the reduction in infectious complications has been modest and most trials have been unable to demonstrate a reduction in infectious morbidity and mortality.^{116–118} This is probably because the major effect of G-CSF is to accelerate the recovery of neutrophils, whereas it has no impact on the critical lag period of profound neutropenia.¹¹⁹ The American Society of Oncology and the NCCN have published guidelines for the use of these agents in the setting of anti-cancer chemotherapy.

Granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage colony-stimulating factor (M-CSF) may be beneficial in the treatment of invasive fungal infections,¹²⁰ although large-scale trials demonstrating this are regrettably still lacking.

GRANULOCYTE TRANSFUSIONS

Renewed interest is now being shown in this modality, coupled with improved methods of harvesting and increased yield following the use of growth factors.^{121,122}

IMMUNOGLOBULIN THERAPY

Routine prophylactic use of intravenous immunoglobulin does not reduce viral infections; however, the addition of intravenous immunoglobulin to ganciclovir may improve survival in CMV pneumonitis and post-exposure immunoglobulin is indicated for the prevention of hepatitis A, measles and varicella-zoster infection.

INFECTIONS IN TRANSPLANT RECIPIENTS

IMMUNOSUPPRESSIVE THERAPY

Since the first successful human cadaveric kidney transplant in 1954, solid organ transplantation has proceeded to become a viable option in the management of end-organ failure worldwide. Current 1- and 5-year graft survival for cadaveric (non-extended criteria donor) renal transplants in the USA is 95% and 82%, respectively.¹²³ The results are similar for Europe. Developments in surgery and better control of rejection and infective complications have allowed a steady improvement in the survival of other organ grafts.

Most transplant units use a triple regimen of azathioprine or mycophenolate, a calcineurin inhibitor such as cyclosporin A, and corticosteroids for immunosuppression. Azathioprine is a purine analog which inhibits both B- and T-cell proliferation; as a consequence, both cell-mediated immunity (CMI) and humoral immunity are inhibited. The drug may take weeks or months to exert its full effect. Cyclosporin, a calcineurin inhibitor, arrests the lymphocyte cell cycle in the resting

phase, having most effect on CD4-positive T cells and a minimal effect on B cells. This results in effective suppression of CMI, has little effect on humoral immunity and no effect on phagocytosis. The inflammatory response is preserved.

Corticosteroids in high dose have a very broad immunosuppressive action, producing a reduction in antigen-stimulated lymphocyte proliferation and a blunting of the primary antibody response. They also inhibit neutrophil chemotaxis and monocyte phagocytosis, dramatically reducing inflammatory responses at high dosage and disguising the presence of infection.

The aim of these regimens is to achieve a balance between graft rejection and risk of infection. Episodes of subsequent acute rejection require considerable immunosuppression and are accompanied by an increased risk of opportunistic infections. The phase of acute rejection varies in length for different transplants. Most episodes occur in the first 3 months of liver transplantation, whereas the phase of acute rejection lasts for 6 months for renal transplants.¹²⁴ Rejection episodes are usually treated with high-dose methylprednisolone or various antibody preparations such as polyclonal antithymocyte globulin (ATG), anti-lymphocyte globulin (ALG) or the pan-T-cell monoclonal antibody OKT3. Patients requiring a second or third graft are usually even more immunosuppressed and at increased risk of opportunistic infection.

Tacrolimus (FK506), another calcineurin antagonist, has been substituted for cyclosporin for certain indications; several studies have demonstrated it to have fewer infective complications,^{125–128} which may be a consequence of the need for less episodic antirejection therapy. Mycophenolate mofetil, an inhibitor of inosine monophosphate dehydrogenase which inhibits purine synthesis, has been used as a substitute for calcineurin inhibitors. Although it has no associated renal toxicity (and allows improvement in renal function), some studies have shown it to result in increased risk of rejection.¹²⁴ A recent review comparing the use of azathioprine with mycophenolate in liver transplantation concluded that, to date, little if any clinical benefit could be observed of mycophenolate mofetil over azathioprine.¹²⁹ There is still considerable scope for refining immunosuppression with these and other new agents, hopefully enabling a further reduction in infective complications.

THE SEQUENCE OF INFECTIONS FOLLOWING TRANSPLANTATION

The risk of infection in the organ transplant patient is influenced by previous epidemiological exposures and the degree of immunosuppression. Epidemiological exposures can be divided into donor-derived infections, recipient-derived infections, nosocomial infections and community infections. The extent of immunosuppression is determined by the type of immunosuppressive therapy, its dose and duration (see Box 40.5), underlying diseases and co-morbid conditions, the presence of devitalized tissues or fluid collections in the transplanted organ, and the presence of invasive devices. Other important factors include concomitant infection with immunomodulating

viruses such as CMV and other human herpes viruses, HIV-1, and hepatitis B and C viruses. Infectious complications follow a relatively predictable chronological order after any transplantation procedure. Knowledge of this is helpful in guiding the use and duration of prophylaxis, establishing a diagnosis through appropriate investigations and administering empirical treatment if necessary. This is summarized in Figure 40.3.

In the first month after transplant, infections are largely associated with the transplant surgical procedure, particularly those complicating the anastomoses associated with the specific procedure. Some infections are transmitted with the allograft or are present in the recipient before transplantation. An important component of the pretransplant evaluation is to recognize and treat such infections. Nosocomial infections such as those due to VRE or MRSA, and *Clostridium difficile* colitis are also important at this time.

Between the first and the sixth month following transplantation the most important infections are caused by the herpes group viruses (especially CMV), *Nocardia* species, *Listeria monocytogenes*, *Toxoplasma gondii*, *Pn. jirovecii* and other fungi. In addition, latent infections such as tuberculosis or histoplasmosis may reactivate at this time. The risk of infection correlates with the severity of immunosuppression required to treat rejection episodes.

Subsequent infections are usually the result of community-acquired organisms. A few patients will suffer chronic viral infections affecting the graft, while others who have been intensively immunosuppressed remain at risk of opportunistic infections. Other rare infections in the late post-transplant period have been described, including chronic infection with hepatitis E virus causing cirrhosis as a late complication.¹³⁰

BACTERIAL INFECTIONS

Bacterial infections occur in approximately 50% of renal transplant recipients and in up to 70% of liver transplant patients. In some series patients have suffered at least one bacterial infection in the post-transplant period.¹³¹ The common infections are intra-abdominal abscess, cholangitis, bacteremia, wound infection, lower respiratory tract infection and urinary tract infection, with intra-abdominal infection responsible for approximately 30% in liver transplantation.^{131–134} The overall mortality is less than 5%, but varies according to site and organ.

Subsequently resistant organisms have become established as endemic pathogens in many transplant units. MRSA was found to be the leading cause of bacteremia in liver transplant recipients in one center, responsible for 37% of all episodes.¹³⁵ VRE and extended-spectrum β-lactamase-producing Gram-negative organisms are also increasingly causing infections in these patients.

Representative organisms isolated from infected patients in the postoperative period are shown in Box 40.6. Bacteria isolated from the graft perfusion fluid differ in their propensity to cause post-transplantation infection. Positive

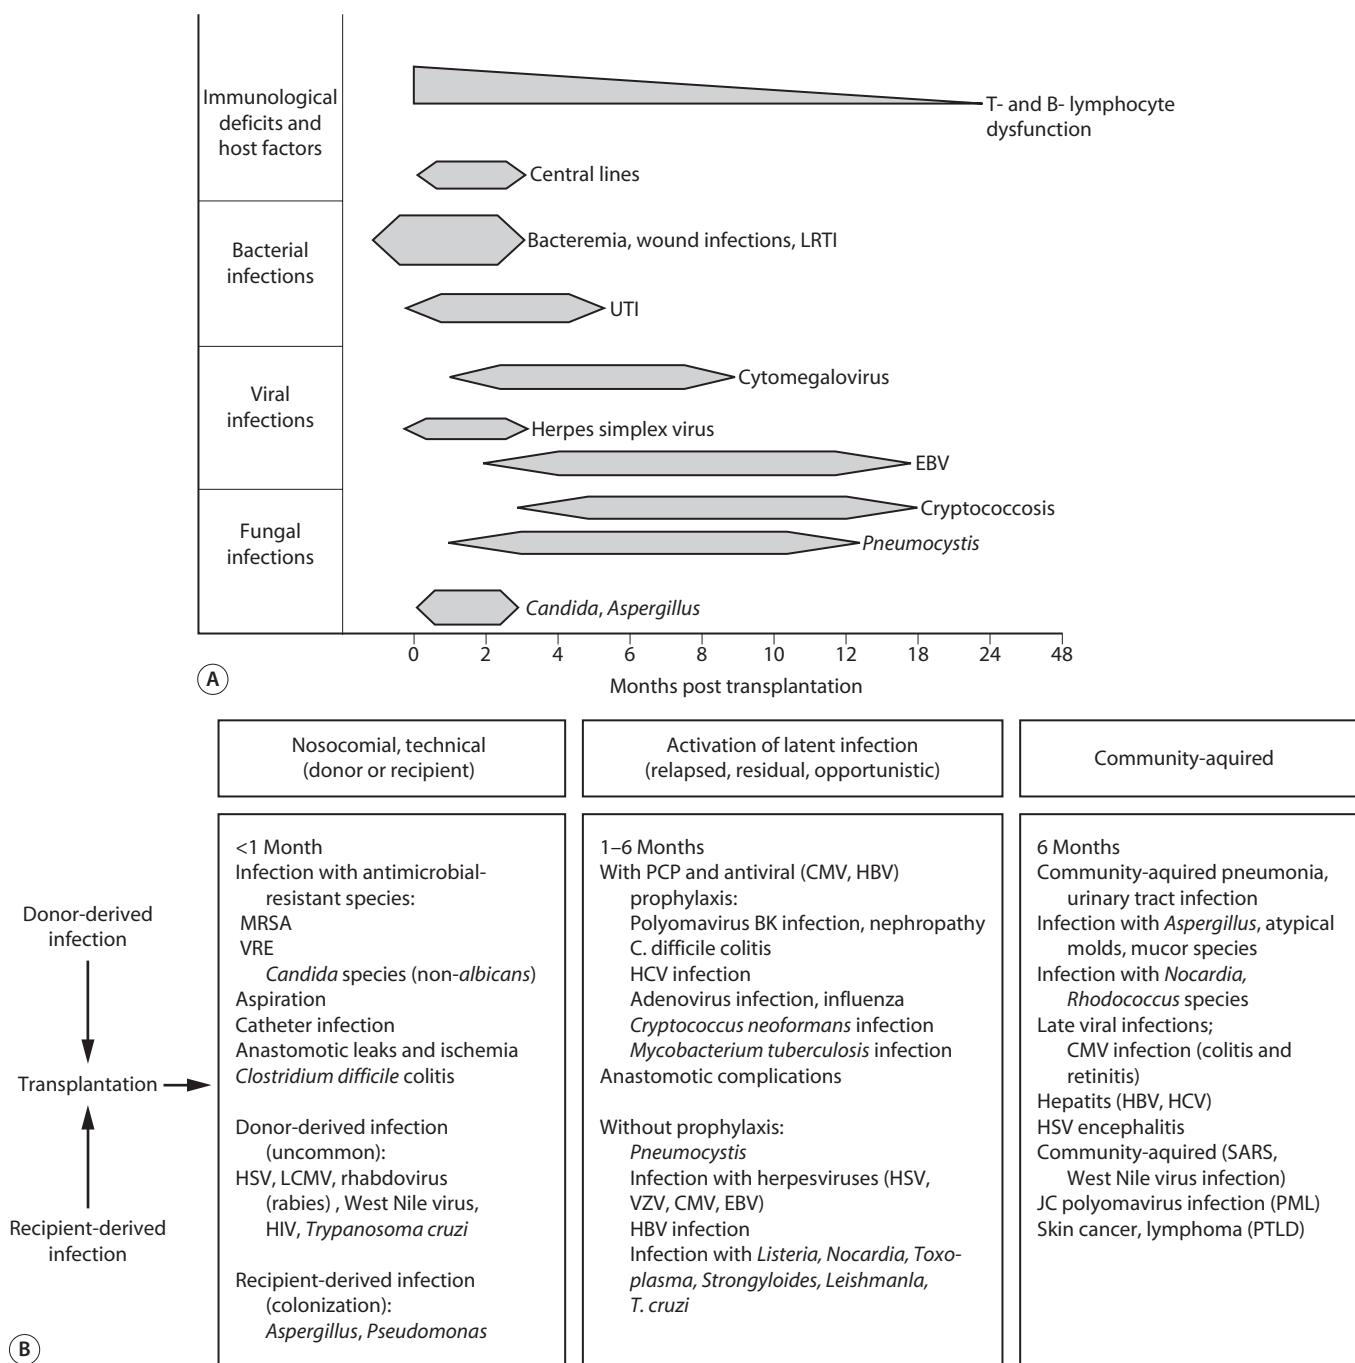

Fig. 40.3 (A) The time course of infections after solid organ transplantation. (B) Changing timeline of infection after transplantation. Infections occur in a generally predictable pattern. The development of infection is delayed by prophylaxis and accelerated by intensified immunosuppression, drug toxic effects that may cause leukopenia, or immunomodulatory viral infections such as infection with cytomegalovirus (CMV), hepatitis C virus (HCV) or Epstein–Barr virus (EBV). At the time of transplantation, a patient's short-term and long-term risk of infection can be stratified according to donor and recipient screening, the technical outcome of surgery, and the intensity of immunosuppression required to prevent graft rejection. Subsequently, an ongoing assessment of the risk of infection is used to adjust both prophylaxis and immunosuppressive therapy. HBV, hepatitis B virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; LCMV, lymphocytic choriomeningitis virus; MRSA, methicillin-resistant *Staphylococcus aureus*; PCP, *Pneumocystis jirovecii* pneumonia; PML, progressive multifocal leukoencephalopathy; PTLD, post-transplantation lymphoproliferative disorder; SARS, severe acute respiratory syndrome; VRE, vancomycin-resistant *Enterococcus* spp.; VZV, varicella-zoster virus. (Adapted from Fishman, JA. Infection in solid organ transplant recipients. *New England Journal of Medicine* 2007; 357:2601. Copyright ©2007 Massachusetts Medical Society.)

Box 40.5 Infections associated with specific immunosuppressive regimens

- *Antilymphocyte globulins*: T-cell depleting antibodies mimic the alloimmune response with activation of latent (herpes) virus, fever, cytokine release
- *Corticosteroids*: Bacteria, *Pneumocystis pneumonia*, activation of hepatitis C and hepatitis B
- *Azathioprine*: Neutropenia, uncertain role in human papillomavirus infection
- *Mycophenolate mofetil*: Early bacterial infection, B-cell depression, late cytomegalovirus infection
- *Ciclosporin/tacrolimus*: Increased viral replication, B-cell depression, gingival infection, intracellular pathogens
- *Rapamycin*: Excess infections in combination with current agents (requires monitoring), idiosyncratic pulmonary syndrome, often with other respiratory pathogens
- *Plasmapheresis*: Encapsulated bacteria
- *Co-stimulatory blockade*: Unknown so far
- *Rituximab*: B-cell depletion, bacterial and viral infections
- *Alemtuzumab*: Cytomegalovirus infection, viral infection, fungal infections

Box 40.6 Organisms causing post-transplant infections

Gram-positive bacteria	
Coagulase-negative staphylococci	<i>Pneumocystis jirovecii</i>
<i>Staphylococcus aureus</i>	<i>Cryptococcus neoformans</i>
Enterococci	<i>Blastomyces dermatitidis</i>
Streptococci	<i>Coccidioides immitis</i>
<i>Listeria monocytogenes</i>	<i>Histoplasma capsulatum</i>
<i>Nocardia</i> spp.	
Gram-negative bacteria	
Enterobacteriaceae	Herpes simplex virus
<i>Pseudomonas</i> spp.	Cytomegalovirus
<i>Stenotrophomonas maltophilia</i>	Hepatitis B virus
<i>Legionella</i> spp.	Hepatitis C virus
Anaerobic bacteria	Varicella zoster virus
<i>Bacteroides</i> spp.	Polyoma viruses
<i>Clostridium</i> spp.	Adenovirus
Fungi	Human herpesvirus-6
<i>Candida</i> spp.	Human herpesvirus-8
<i>Aspergillus</i> spp.	
Others	
	<i>Mycobacterium</i> spp.
	<i>Toxoplasma gondii</i>

cultures have been found in up to 40% of cases in renal transplantation, but most of these have been due to Gram-positive skin bacteria and do not seem to have serious consequences. However, the isolation of the Enterobacteriaceae and *Ps. aeruginosa* correlate with vascular infection and postoperative sepsis,^{136–138} and warrant systemic antibiotic therapy following transplantation.

Infections due to *Nocardia* spp. are important late complications following transplantation, usually occurring after the first month, and which correlate with the degree of immunosuppression. Outbreaks in renal transplant units have been described¹³⁹ and the incidence is up to 4% in this group.

Tuberculosis tends to occur several months after transplantation. The onset is significantly later in renal transplants than

in other groups of organ transplant recipients.¹⁴⁰ Approximately one-third have disseminated infection and the overall mortality is 29%. The overall incidence of mycobacterial infection in the transplant population is 1%, more than 50-fold greater than the incidence in the general population.¹⁴¹

Transplant recipients are at increased risk of Legionnaires' disease by virtue of their immunosuppression. In addition, a UK study demonstrated that *Legionella* spp. could be isolated from the water in approximately 50% of transplant units¹⁴² and *Legionella* control is now an important component of water and air conditioning management in hospitals.

FUNGAL INFECTIONS

Colonization with yeasts is common in this population, although the incidence varies according to the number and frequency of sites sampled and the use of antifungal prophylaxis. Infection rates vary, with the lowest in renal transplant recipients (approximately 5%).¹⁴³ The incidence of fungal infections is falling, possibly as a consequence of reduced immunosuppression and improvement in surgical technique.¹⁴⁴ Most infections are caused by *Candida* spp. (approximately 80%), with *Aspergillus* spp. accounting for the majority of invasive mold infections.^{143,145} *Pn. jirovecii* pneumonitis occurred in 4–10% of kidney, 10–11% of liver, 5–41% of heart, and 16–43% of heart-lung and lung transplant recipients before routine prophylaxis was implemented.¹⁴⁶ It is closely linked with CMV disease.

Candidal infections are associated with death in more than 50% and invasive aspergillosis is almost universally fatal in this group.¹⁴³ The site of infection is transplant dependent. Thus urinary tract candidosis is mostly confined to the renal transplant group and lung transplant recipients have a much increased risk of pulmonary infections. Although occurring very infrequently, focal brain infection in solid organ transplant patients is almost exclusively due to fungi, usually *Aspergillus* spp.;^{147–149} *Cryptococcus neoformans* is the most frequent cause of meningitis.

Most fungal infections occur in the first 2 months after transplant,¹⁴³ although *Pn. jirovecii* infection tends to be delayed and cryptococcosis usually affects patients in the late transplant period. Infections due to the endemic fungi, including *Coccidioides immitis* (most often following exposure in the southwestern United States), *Histoplasma capsulatum* (most often following exposure in the Ohio River Valley, but also elsewhere in the world) and *Blastomyces dermatitidis*, may also be seen in the late post-transplant period. In one series, the median time to symptoms from histoplasmosis was 11 months after transplantation.¹⁵⁰ The management of these infections is discussed further in Chapter 60.

VIRAL INFECTIONS

Since the earliest days of transplantation, virus infections have caused problems in transplant recipients. Members of the Herpesviridae are the most commonly implicated.

Cytomegalovirus is responsible for the greatest number of all types of infection in these patients. The incidence varies from 45% to 100%,¹⁵¹ reflecting the incidence of seropositivity among the recipient population and the numbers of seropositive to seronegative transplantations. However, the incidence of disease is transplant dependent, being lowest in renal transplant recipients, in whom it is symptomatic in less than 10%.¹⁵²

Overall, 25–30% of infected patients develop disease,^{151–153} although of those at highest risk (seropositive to seronegative transplants) 50–60% will develop clinical disease.¹⁴¹ The site of disease is transplant dependent, being focused on the graft. About 3% of all transplant recipients affected will develop CMV pneumonitis.¹⁵³

Post-transplant hepatitis occurs in more than 10% of solid organ transplant recipients overall. The most common cause is hepatitis C virus (HCV). In liver transplant patients most of these infections occur as a result of reinfection in patients who have been transplanted for HCV-related cirrhosis. Polymerase chain reaction (PCR) techniques have shown that virtually all infected patients suffer reinfection post-transplant. Before universal screening of blood donors and awareness of donor status, primary HCV infections occurred in more than 35%;¹⁵⁴ the incidence is now much lower. In one study, 95% of patients with pretransplant infection developed post-transplant hepatitis, mostly due to HCV.

Reinfection with hepatitis B virus (HBV) following liver transplantation is almost inevitable unless long-term prophylaxis is used. The highest recurrence is seen in those who are HBV-DNA positive before transplant.¹⁵⁵

Epstein–Barr virus (EBV) infection following transplant is probably underdiagnosed. Most clinical disease is due to reactivation, although primary infection does occur, usually after the patient is discharged, and is responsible for more severe disease. The most important complication of EBV infection is post-transplant lymphoproliferative disorder (PTLD). The overall incidence of this condition is approximately 1%.¹⁵⁶ In a large series of various solid organ graft recipients, viremia was found in 3.9%, and 75% of those with primary viremia developed PTLD compared with 11% of secondary viremia cases.¹⁵⁶ The risk of this disease is also increased by the use of antirejection therapy such as OKT3 anti-T-cell antibodies.

Before the advent of aciclovir, HSV infections (almost exclusively the consequence of reactivation) were responsible for clinical disease in approximately 50% of seropositive patients.¹⁴¹ HSV infections are now much less clinically significant than other herpes group infections.

Human herpesvirus-6 (HHV-6) may be responsible for central nervous system disease post transplantation. CNS symptoms occurred in 25% of liver transplant recipients with HHV-6 viremia compared with 12% of those without.¹⁵⁷ Infection with HHV-6 may also have an immunomodulatory role, being associated with an increased risk of CMV infection and fungal infection.¹⁵⁸

Human herpesvirus-8 (HHV-8) is transmitted from donor to recipient, resulting in Kaposi's sarcoma in up to 8% of cases who seroconvert.¹⁵⁹

Polyomavirus causes latent infection in the kidney in the immunocompetent subject, and in renal transplant recipients may be responsible for tubulointerstitial nephritis and graft dysfunction.¹⁶⁰

INFECTIONS DUE TO OTHER ORGANISMS

The incidence of toxoplasmosis varies according to the type of transplant and is most common in heart transplant recipients, of whom more than 50% of seronegative patients receiving a heart from a seropositive donor will seroconvert.¹⁶¹ In addition, toxoplasmosis is governed by the seroprevalence of the infection (20% in the UK and higher in other countries such as France) and the serological status of donor and recipient: the highest rate and most severe infections occur when transplanting a seropositive donor to a seronegative recipient. In renal transplant recipients less than 1% develop primary toxoplasmosis. Most such cases occur within 2 months of transplant and are characterized by encephalitis, brain abscess, retinitis, pneumonitis, cardiac involvement and hepatitis.^{162–164}

CHEMOPROPHYLAXIS

Antimicrobial prophylaxis, along with vaccination and pre-emptive therapy, form the mainstay of preventive strategies against infection. Until recently, most prophylactic regimens used in transplant recipients have been based on the risk of infection and likely organisms. Regimens shown to be effective in the neutropenic patient or in surgical prophylaxis have been adopted, yet few have been subject to randomized comparative trials. A short course of prophylactic antibiotics is probably appropriate to prevent wound infection related to the procedure itself. Selective decontamination of the digestive tract may be of benefit in some transplant groups, although there is conflicting evidence. Gram-negative infections are reduced in liver transplant recipients¹⁶⁵ but an increase in Gram-positive infections, including MRSA and VRE, has been seen in several heart transplant centers.¹⁶⁶

A number of studies have demonstrated the benefit of long-term prophylaxis for urinary tract infections in renal transplant recipients. Both trimethoprim–sulfamethoxazole (960 mg nightly) and ciprofloxacin have been effective, although the former has the additional benefit of preventing *Pn. jirovecii* infection.^{167,168}

The issue of mycobacterial prophylaxis remains controversial and policies vary internationally. As there is a significant risk of isoniazid hepatic toxicity, this drug should be used selectively. However, this risk varies according to the transplant, from 2.5% in renal transplant recipients to 41% in liver transplant recipients.¹⁴⁰ Patients in whom such prophylaxis is justified are those of Asian or other high-risk ethnic origin, those with a history of tuberculosis and those with radiographic changes suggesting past chest infection.

The high risk of fungal infection in liver transplant recipients has led to the administration of antifungal agents in the post-transplant period. Non-absorbable agents such as amphotericin or nystatin, sometimes in combination with oral antibiotics such as gentamicin and polymyxin B, have been widely used. Fluconazole and itraconazole have been studied in randomized comparative trials in liver transplantation and both are better than placebo in preventing superficial and invasive candidosis.^{169,170}

Prophylaxis against *Pn. jirovecii* pneumonia with trimethoprim-sulfamethoxazole is probably only necessary during the first year post-transplant, except in lung transplant recipients when there is a significant persisting risk of the disease.¹⁷¹

The current American Society of Transplantation guidelines recommend antiviral prophylaxis in all CMV donor-positive, recipient-negative solid organ transplant recipients.¹⁷² Several randomized comparative studies have demonstrated that early (first 14 days or until discharge) post-transplant ganciclovir, with¹⁷³ or without¹⁷⁴ gammaglobulin, is more effective than aciclovir (various doses) in preventing CMV symptomatic infection in liver transplants. Symptomatic infection was reduced to 5–9%.

Pre-emptive prophylaxis targets patients at highest risk of disease and limits duration of drug administration, reducing toxicity and cost. Hence, kidney–pancreas transplant patients receiving OKT3 pan-T-cell monoclonal antibody therapy and CMV-shedding liver transplant recipients both appear to benefit from pre-emptive prophylaxis with ganciclovir or foscarnet.^{175,176} CMV antigenemia or PCR-guided pre-emptive therapy based on attainment of a pre-defined viral load is as effective as, but less expensive than, universal oral ganciclovir prophylaxis for 90 days or intravenous ganciclovir for 14 days.¹⁷⁷ The duration of this pre-emptive therapy is not fixed and is determined by viral load and varies in length between centers.

Trials of prophylaxis with lamivudine to prevent recurrence of HBV following liver transplantation have shown that, although HBV-DNA levels become undetectable in virtually all patients, this effect is not sustained because of the emergence of resistant mutants.¹⁷⁸ As a consequence, alternative strategies involving a combination of adefovir, lamivudine and hepatitis B immune globulin are being employed.

TREATMENT

Although transplant recipients are severely immunocompromised, they do not have the same paucity of signs as neutropenic patients in the face of serious sepsis and, in the immediate postoperative period, behave more like non-transplant patients with surgical sepsis.¹⁷⁹ Consequently, the concept of early empirical therapy in response to fever alone has not been applied to these patients.

All attempts should be made to identify a focus of sepsis or the non-infective cause for fever in a transplant patient. Antimicrobial therapy may reasonably be withheld if the patient is otherwise well and there is no identifiable infective cause, but this should be kept under review. If empirical

treatment is considered necessary, the choice of antimicrobials should be governed by the timing of the infection (and hence the probable organisms), the type of transplant, the site of sepsis, knowledge of colonization with resistant organisms (such as MRSA and VRE), and local antimicrobial resistance patterns, as discussed previously.

ASPECTS OF THERAPY FOR SPECIFIC INFECTIONS

FUNGAL INFECTIONS

Fungal infections should be managed using the same agents as used in the neutropenic patient. No antifungal is contraindicated but care is required in their use because of toxicity (especially in renal and liver transplant recipients) and drug interaction (especially flucytosine with antimetabolites and triazoles with ciclosporin and tacrolimus – see below).

It is probably appropriate to reduce immunosuppression in the face of a progressive life-threatening fungal infection such as invasive aspergillosis, especially in the setting of a non-essential organ graft such as a kidney transplant, although the evidence for benefit is anecdotal. Other attempts at immunomodulation have included the use of colony-stimulating factors. G-CSF antagonizes the effect of triazoles in an immunocompromised mouse model of invasive aspergillosis.¹⁸⁰ GM-CSF has been used with some success in the neutropenic patient and might prove of more use than G-CSF in the transplant setting.

PULMONARY INFECTIONS OF UNKNOWN CAUSE

Patients presenting with pulmonary infiltrates and fever 1 month or more post-transplant are most likely to have CMV or *Pn. jirovecii* infection (unless they are receiving trimethoprim-sulfamethoxazole prophylaxis). These infections should be managed as in the HSCT recipient. The possibility of other community-acquired respiratory tract infections, including those due to influenza and respiratory syncytial viruses, should always be borne in mind.

POST-TRANSPLANT LYMPHOPROLIFERATIVE DISORDER

The incidence of this occurring in renal transplant recipients is 1–2%,^{181,182} is related to the degree of immunosuppression (it is seen particularly in patients receiving OKT3) and is more likely in primary EBV infection.¹⁸³ At present, the mainstay of therapy is the reduction of immunosuppression together with intravenous aciclovir (10 mg/kg every 8 h). However, many patients will require local resection or radiotherapy of affected

tissue and/or antilymphoma chemotherapy. Developments in this field include the possibility of immunotherapy by means of donor leukocyte infusions.¹⁸⁴ Most recently the efficacy of rituximab, an anti-CD20 monoclonal antibody in the treatment of EBV-driven PTLD, has been described.¹⁸⁵

DRUG INTERACTIONS DURING TREATMENT OF INFECTION

Ciclosporin and tacrolimus are metabolized by the cytochrome P₄₅₀ enzyme system and therefore interact with a number of important antimicrobial agents likely to be prescribed in transplant recipients (Table 40.4). Levels of these drugs may be altered by the induction or inhibition of this system and it is essential that these are measured to prevent toxicity, as well as to avoid inadequate or excessive immunosuppression with the consequences of rejection or infection. Rifampicin is a potent inducer of these cytochrome isoenzymes and causes increased metabolism of ciclosporin and tacrolimus, as well as reducing the bioavailability of corticosteroids. Erythromycin, some of the newer macrolides (particularly clarithromycin), and the azole antifungal agents, especially ketoconazole, itraconazole and voriconazole (and fluconazole at high doses), competitively inhibit this pathway, thus increasing levels of ciclosporin and tacrolimus.

Renal function is often impaired in the transplantation setting and there may be a complex interaction between ciclosporin (itself potentially nephrotoxic, particularly during initial therapy) and nephrotoxic antimicrobial agents such as the aminoglycosides, high-dose trimethoprim-sulfamethoxazole, vancomycin and amphotericin. Therapeutic drug monitoring is mandatory (with the exception of amphotericin) to prevent additional toxicity and alternative agents should be chosen whenever possible (Table 40.4).

CONCLUSION

Prevention should always be the goal in the management of infective complications in neutropenia and organ transplantation. This has become increasingly important over the past decade with the advent of MRSA, VRE and other resistant organisms. Despite the development of antimicrobials with good activity against the infecting agents, the mortality from many of these infections remains high. The spectrum of immunocompromised patients is changing with the evolution of chemotherapy, stem-cell transplantation, immunosuppression regimens, and tissue and organ transplantation techniques – thus we can expect to see the pattern of opportunistic infections shift as well.

Table 40.4 Potential drug interactions during management of infections in organ transplant recipients

Antimicrobial agent	Immunosuppressive agent	Effect
Aminoglycosides	Ciclosporin	Exacerbation of nephrotoxicity
Amphotericin	Ciclosporin	Exacerbation of nephrotoxicity
Trimethoprim–sulfamethoxazole	Ciclosporin	Possible exacerbation of nephrotoxicity Reduced levels of ciclosporin
Doxycycline	Ciclosporin	Increased ciclosporin levels
Erythromycin ^a	Ciclosporin	Increased ciclosporin levels
Fluconazole	Ciclosporin	Increased ciclosporin levels
Flucytosine	Azathioprine	Possible exacerbation of myelosuppression
Ganciclovir	Azathioprine	Possible exacerbation of myelosuppression
Itraconazole	Ciclosporin Vincristine	Increased ciclosporin levels Increased neurotoxicity
Ketoconazole	Ciclosporin	Increased ciclosporin levels
Pentamidine (i.v.)	Ciclosporin	Possible exacerbation of nephrotoxicity
Rifampicin (rifampin)	Ciclosporin Prednisone	Reduced levels of ciclosporin Reduced levels of prednisone
Sulfonamides	Azathioprine	Possible exacerbation of myelosuppression
Trimethoprim	Azathioprine	Possible exacerbation of myelosuppression
Vancomycin	Ciclosporin	Exacerbation of nephrotoxicity

^aAnd other macrolides.

41 Infections in intensive care patients

Mark G. Thomas and Stephen J. Streat

Infection is a common reason for admission to an intensive care unit (ICU) and a common complication of stay in such units. Approximately one in three patients in the ICU will have an infection. Approximately half of these are acquired before admission to the ICU, usually before admission to hospital.^{1,2} Community-acquired infection is common in pediatric and adult medical and surgical ICUs but infrequent in neonatal and cardiac surgical ICUs.¹ Between 2000 and 2008, 1131 patients with sepsis were admitted to the adult ICU in our hospital in Auckland, New Zealand. These patients comprised 14.8% of the 7640 ICU admissions but used 22.8% of ICU hours and accounted for 19.3% of the 866 ICU deaths over the 9-year period. Most received ventilatory (61%) or inotropic (84%) support; only 10% received neither form of support. Renal replacement therapy was given to 8.7%. Their overall mortality within the ICU was 14.8%. Table 41.1 shows the number of ICU admissions for all septic sites or sources together with the mean age, length of ICU stay and ICU survival for each site. The most common sites of infection were intraperitoneal from a gastrointestinal source (35.5% of admissions), respiratory tract (22%), urinary tract (13.9%), soft-tissue infections (8.1%), bacteremia with an unknown source (6.1%) and meninges (4.6%). ICU survival varied by septic site, being excellent for brain abscess (100%), meningitis (96%), genital tract infection (96%) and endovascular infection (94%), and good for urinary tract infection (90%), soft-tissue infection (90%), gastrointestinal-source infection (89%) and infections in joints and bone (86%). Survival was poorer for respiratory infection (75%), bacteremia (74%) and for infections in other less common sites (73%). ICU admissions for sepsis continue to rise while their survival is improving very slowly (at 1% per year). The reasons for the improvement in ICU mortality for sepsis are not clear and are likely to be multifactorial – including perhaps earlier attention to shock resuscitation,³ surgical source control⁴ and appropriate empirical antibiotic therapy. Currently, the total cost per ICU survivor of treating all patients with sepsis is approximately NZ\$21 333 (£8750).

Approximately half the infections present in patients in an ICU are acquired following admission to the unit. Richards et al⁵ found six nosocomial infections per 100 patients in medical–surgical ICUs in the USA, while 21% of patients in European ICUs had nosocomial infections. The most important sites of nosocomial infection in these patients are the respiratory tract, the urinary tract and the bloodstream

(Table 41.2). The spectrum of organisms responsible for infections acquired in the ICU differs from that causing community-acquired infections: *Neisseria meningitidis* and *Streptococcus pneumoniae* are important causes of community-acquired infection in adults⁶ but are unusual causes of ICU-acquired infection; enteric Gram-negative

Table 41.1 Admissions with infection to the Department of Critical Care Medicine, Auckland City Hospital, during the period 2000–2008

bacilli, *Staphylococcus aureus* and *Staphylococcus epidermidis* are responsible for most nosocomial ICU infections.^{2,7}

The presence of infection in patients in the ICU is an important risk factor for increased mortality and morbidity.⁸ Infection on admission to the ICU and nosocomial intra-abdominal infection have been shown to be independently predictive of fatality, after allowing for other variables such as acute physiology (APACHE score) or the use of steroids or chemotherapy.⁹ Commonly death is due to inadequate treatment of a nosocomial infection (often caused by an unusually resistant organism) following successful treatment of a community-acquired infection.¹⁰

In recent decades the incidence of infection due to multidrug-resistant organisms (MROs) has begun to outstrip the pharmaceutical industry's ability to develop effective new antimicrobial agents. This has led to increased interest in practices that can limit the spread of infection within the ICU. Routine screening, on admission and then weekly, to detect colonization with MROs such as methicillin-resistant *Staph. aureus* (MRSA), extended spectrum β-lactamase (ESBL)-positive Enterobacteriaceae, *Acinetobacter* spp. and vancomycin-resistant enterococci (VRE), linked to enhanced infection control precautions, can reduce the incidence of infection due to these MROs within the ICU. The dramatic reduction in central venous-line-associated infection that follows consistent application of infection control procedures is an excellent illustration of the opportunities to reduce nosocomial infection within the ICU. Prescribing practices within the ICU inevitably contribute to the selection of resistant organisms in ICU patients and provide an influential exemplar for the rest of the hospital. ICU prescribing guidelines should contribute to a hospital-wide policy of prudent antimicrobial stewardship.

PNEUMONIA

Pneumonia (Ch. 45) is a common reason for admission to the ICU and among the most common nosocomial infections in patients in these units. Both community-acquired and nosocomial pneumonia have a high mortality and management is complicated by the need to cover a wide range of pathogens.

COMMUNITY-ACQUIRED PNEUMONIA

The presence of clinical features such as tachypnea (>30/min), hypotension (systolic BP <90 and/or diastolic BP <60 mmHg), confusion, multilobar involvement, hypoxemia ($\text{PaO}_2/\text{FiO}_2 <250$) and renal impairment (serum creatinine >180 µmol/L) can help identify patients with severe community-acquired pneumonia.^{11,12} *Str. pneumoniae*, *Staph. aureus*, *Haemophilus influenzae*, enteric Gram-negative bacilli and *Legionella pneumophila* are the most commonly identified bacterial causes of community-acquired pneumonia in patients admitted to the ICU (Table 41.3). It seems likely that *Str. pneumoniae* is the etiological agent for many patients in whom no microbial cause can be proven. Enteric Gram-negative bacilli, particularly *Pseudomonas aeruginosa* and *Klebsiella pneumoniae*, are uncommon causes of community-acquired pneumonia in patients admitted to the ICU, but are associated with a mortality of 50–75%, in contrast to an overall mortality of 20–50%.^{17,18}

The clinical presentation is usually an unreliable guide to the etiology of community-acquired pneumonia,^{18–20} and initial treatment will often need to cover the most common pathogens. Occasionally the clinical features on admission may provide useful clues to the etiology. For example, a history of chronic respiratory disease, alcoholism, immunosuppression or bronchiectasis should alert the doctor to the possibility that the pneumonia is due to an enteric Gram-negative bacillus. Other clues to a specific diagnosis include admission during an epidemic due to mycoplasma or influenza. During an influenza epidemic, secondary infection with *Staph. aureus* should be suspected. The admission radiographic findings in patients admitted with pneumonia usually do not allow a reliable discrimination between the various possible etiologies. Sputum Gram stain suggests the etiology in approximately 10% of patients, while sputum culture and blood culture are diagnostic in 12–44% and 10–35%, respectively.^{13,17,19} Urinary antigen tests for *Str. pneumoniae* and *L. pneumophila* serogroup 1 should be performed on all patients with community-acquired pneumonia admitted to the ICU. Although a variety of methods (including fiberoptic

bronchoscopy with protected brush sampling or bronchoalveolar lavage; percutaneous lung aspiration with ultra-thin needles) have been proposed to increase the rate of microbiological diagnosis, none has entered routine clinical practice. Bronchoscopy with bronchoalveolar lavage should at present be reserved for selected patients, such as those in whom infection with *Mycobacterium tuberculosis*, *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) or cytomegalovirus is thought likely.

TREATMENT

An essential goal of treatment of severe community-acquired pneumonia is to ensure adequate activity against *Str. pneumoniae*, the most common cause of death in such patients. The rapid dissemination of penicillin-non-susceptible *Str. pneumoniae* has raised concern about the role of penicillins and cephalosporins in the treatment of disease due to this organism. However, high-dose intravenous therapy with many β-lactams provides serum levels well in excess of the minimum inhibitory concentrations (MICs) of non-susceptible strains of *Str. pneumoniae*, and (with the exception of rare strains for which the MIC of penicillin is greater than 4 mg/L) cure rates for non-susceptible strains are comparable to those seen with susceptible strains. At present, therefore, it does not appear necessary to include vancomycin in empirical regimens for the treatment of severe community-acquired pneumonia.

Because *L. pneumophila* may cause severe community-acquired pneumonia, treatment with a macrolide (e.g. erythromycin, clarithromycin or azithromycin) or a 'respiratory' fluoroquinolone (e.g. levofloxacin, gatifloxacin or moxifloxacin) is widely considered an essential component of the initial antimicrobial regimen.^{20,21} Both of these classes of antimicrobial agent possess the advantages of providing activity against other common respiratory pathogens. Macrolides have useful activity against *Str. pneumoniae*, *Mycoplasma pneumoniae*, *Chlamydophila (Chlamydia) pneumoniae* and, to a variable degree, *H. influenzae*, while the 'respiratory' quinolones are active against *Str. pneumoniae* (including penicillin non-susceptible strains), *M. pneumoniae*, *C. pneumoniae* and enteric Gram-negative bacilli. Two recent North American guidelines have recommended a combination of a group 4 (third-generation) cephalosporin (e.g. ceftriaxone or cefotaxime) or a penicillin with a penicillinase inhibitor (e.g. amoxicillin-clavulanate or ampicillin-sulbactam), together with a macrolide or a 'respiratory' quinolone for most patients in the ICU with community-acquired pneumonia.^{20,21} It seems likely that a group 3 (second-generation) cephalosporin (such as cefuroxime), given in high doses, would provide comparable efficacy for pneumococcal pneumonia and only marginally less efficacy against enteric Gram-negative bacilli. Units that wish to limit their use of group 4 cephalosporins may consider replacing this component of the regimen with high-dose cefuroxime. Patients whose initial sputum (or tracheal aspirate)

Gram stain suggests infection due to enteric Gram-negative bacilli should be treated with a regimen with enhanced anti-pseudomonal activity (e.g. ceftazidime or gentamicin, combined with a fluoroquinolone). Patients with suspected or proven anaerobic infection should be treated with clindamycin or a penicillin with a penicillinase inhibitor.

NOSOCOMIAL PNEUMONIA

Ventilator-associated pneumonia (VAP) is a common nosocomial infection in the ICU:^{1–5} in patients ventilated for more than 48 h the incidence of pneumonia is approximately 20% with an associated mortality of 40–60%.^{22–24} Ventilator-associated pneumonia remains a diagnostic and therapeutic dilemma, pneumonia can be diagnosed with certainty in a minority of patients in whom it is suspected, the pathogen(s) responsible for pneumonia are often uncertain, and the outcome is poor despite aggressive investigation and antibiotic treatment.²² Furthermore, ventilator-associated pneumonia is frequently a marker of terminal illness rather than an independently important cause of death, and most of the deaths associated with this condition cannot be attributed to it.^{25,26}

Aspiration of oropharyngeal secretions is the usual route of acquiring lung infection. Impaired consciousness, immobility, the presence of endotracheal and nasogastric tubes, and tracheostomies all increase the risk of aspiration and the incidence of pneumonia. The organisms aspirated into the lungs reflect those present in the oropharynx and stomach. Following admission to the ICU, the oropharynx and stomach become increasingly colonized with enteric Gram-negative bacilli. Thus, aspiration of oropharyngeal secretions at the onset of the illness or injury which leads to ICU admission commonly result in pneumonia due to methicillin-sensitive *Staph. aureus*, *Str. pneumoniae* or *H. influenzae*, while aspiration occurring 3 or more days after admission to the unit is more likely to be due to enteric Gram-negative bacilli or MRSA.^{27,28}

DIAGNOSIS

Diagnosis of pneumonia in patients in the ICU, particularly those who are being ventilated, may be difficult. Although fever, leukocytosis, hypoxemia, purulent sputum and the presence of pathogenic bacteria in the tracheobronchial secretions will raise concerns about the possibility of pneumonia, these clinical features are more commonly present in the absence of pneumonia. A simple assessment based on these clinical features can effectively identify patients with a low risk of pneumonia who do not require intensive or prolonged antimicrobial therapy.²⁹

Because the organisms responsible for causing nosocomial pneumonia in ICU patients are commonly derived from those colonizing the oropharynx, the use of sputum or tracheal aspirates to identify the causative organism(s) is hampered by the

problem of distinguishing between contaminants and true pathogens. A variety of techniques, including transthoracic aspiration and bronchoscopy with sampling by bronchoalveolar lavage or protected specimen brush, have been evaluated, but none has been shown consistently to lower mortality rates.^{24,27,30}

Gram-negative enteric bacilli, *Staph. aureus*, *Str. pneumoniae* and *H. influenzae* are the pathogens most commonly responsible for ventilator-associated pneumonia. In one study of 168 patients with bacteremic nosocomial pneumonia, the organisms isolated from blood cultures were members of the *Klebsiella–Enterobacter–Serratia* family (26%), *Ps. aeruginosa* (13%), *Escherichia coli* (8%), other aerobic Gram-negative organisms (8%), *Staph. aureus* (23%), *Str. pneumoniae* (11%) and other Gram-positive organisms (10%).³¹ Polymicrobial bacteremia, most commonly with *Staph. aureus*, *K. pneumoniae* or *Ps. aeruginosa*, occurred in 10% of episodes.

TREATMENT

Nosocomial pneumonia should be treated with an agent or combination of agents that covers this spectrum of pathogens. Occasionally, previous consistent isolation of a pathogen from surveillance cultures of the patient's sputum will assist with selection of an antibiotic regimen. Similarly, the knowledge that *H. influenzae* and *Staph. aureus* are much more likely to cause pneumonia in a patient who has not recently received antibiotic therapy, and that *Ps. aeruginosa* is a particularly common cause in patients who have received prior antibiotic therapy,³² can assist with antibiotic selection. Finally, the occurrence of endemic or epidemic transmission of a nosocomial pathogen within the ICU may need to be considered.

The combination of an aminoglycoside plus a third-generation cephalosporin or a broad-spectrum penicillin have been most commonly recommended for initial treatment of nosocomial pneumonia in the ICU.^{33,34} These regimens have been selected on the basis of having adequate activity against the usual spectrum of pathogens plus *Ps. aeruginosa* because of the especially high mortality associated with pneumonia due to this organism. In ICUs where *Ps. aeruginosa* and other multiresistant organisms are unusual causes of ventilator-associated pneumonia, a less broad-spectrum regimen may be used (e.g. a combination of an aminoglycoside with cefuroxime or amoxicillin-clavulanic acid). Concern about the nephrotoxicity and ototoxicity associated with aminoglycoside therapy has led to the use of regimens in which ciprofloxacin or aztreonam is substituted for the aminoglycoside. However, aztreonam lacks activity against Gram-positive organisms and generally should be used in combination with another agent with Gram-positive activity such as clindamycin, vancomycin or flucloxacillin.

Ceftazidime, imipenem-cilastatin, ciprofloxacin and a number of other agents have been evaluated as monotherapy for nosocomial pneumonia. Ceftazidime, imipenem-cilastatin and ticarcillin-clavulanic acid have all given high cure rates in

patients with ventilator-associated pneumonia.^{33–39} In contrast, monotherapy with ciprofloxacin or pefloxacin has been associated with unacceptably high failure rates.^{40,41} None of the monotherapy regimens evaluated was adequate treatment for pneumonia due to *Pseudomonas* spp. Persistent infection during treatment, development of resistance to the agent used, and clinical failure of monotherapy, occasionally with an improved response when a second agent was added to the regimen, were common problems when *Pseudomonas* pneumonia was treated with any of the monotherapy regimens. Although the overall outcome of monotherapy is similar to that of combination therapy,⁴² pneumonia known or suspected to be caused by *Ps. aeruginosa* (or by *Enterobacter* or *Serratia* spp.) should be treated with a combination regimen.

The patient in the ICU with a nosocomial pneumonia should usually be treated initially with a broad-spectrum cephalosporin (e.g. cefuroxime, ceftriaxone or cefotaxime) or penicillin (e.g. amoxicillin-clavulanate) plus an aminoglycoside. In patients in whom infection with *Pseudomonas* is more likely (e.g. those who have had a prolonged ICU stay plus prior antibiotic therapy), an aminoglycoside plus a β-lactam with activity against *Pseudomonas* (e.g. ceftazidime) should be used. A macrolide or quinolone should be a component of the regimen in hospitals experiencing epidemic or endemic infection with *Legionella* spp. Treatment should be modified on the basis of the microbiology results, for example to flucloxacillin or vancomycin in patients with staphylococcal infection, or to amoxicillin or cefuroxime alone in patients with infection due to a sensitive *Esch. coli*. Treatment can often be discontinued after 5–7 days but ventilator-associated pneumonia due to *Ps. aeruginosa* should be treated for at least 14 days.

INTRA-ABDOMINAL INFECTION

Intra-abdominal infection (Ch. 39) is a common important cause of sepsis in the ICU, especially in those units with surgical patients. Although the overall mortality of patients with severe generalized peritonitis or abdominal abscess(es), the most common intra-abdominal infections in the ICU, has variously been reported as being between 30% and 60%,^{43,44} our recent experience (see Table 41.1) suggests that this is now overly pessimistic.

MICROBIOLOGY

The organisms responsible for intra-abdominal sepsis vary with the source of infection. Peritonitis secondary to contamination by intestinal contents usually results in a polymicrobial mixed aerobic and anaerobic infection, with *Bacteroides fragilis* and *Esch. coli* the most commonly isolated species.⁴⁵ Spontaneous bacterial peritonitis is usually a monomicrobial infection. *Esch. coli*, *K. pneumoniae* and Gram-positive cocci are the usual pathogens. Anaerobes are rarely

present.⁴⁶ Tertiary peritonitis, which occurs in severely ill patients following laparotomy, and which is not usually associated with peritoneal contamination by intestinal contents, is often monomicrobial and commonly due to *Staph. epidermidis*, *Enterococcus* spp., *Enterobacter* spp., *Pseudomonas* spp. or *Candida albicans*.⁴⁷

TREATMENT

Antimicrobial therapy, other than brief perioperative prophylaxis, is not necessary either in patients with peritoneal contamination without infection (e.g. gastroduodenal ulcer perforation operated on within 24 h of onset) or in patients in whom a localized infectious process is treated by excision (e.g. acute suppurative appendicitis, simple acute cholecystitis and ischemic bowel without perforation). Peritonitis following contamination of the peritoneal cavity usually should be treated with a regimen active against enteric Gram-negative bacilli and anaerobes. An agent active against *Staph. aureus* should be used in patients with peritonitis following gastric perforation. A combination of an aminoglycoside (e.g. gentamicin or tobramycin) with an anti-anaerobic agent (e.g. metronidazole or clindamycin) are established regimens for patients with intra-abdominal sepsis. Aztreonam is widely used as an alternative to an aminoglycoside for those patients at significant risk from the nephrotoxicity of aminoglycosides. Aztreonam plus clindamycin was found to have similar efficacy to tobramycin (or gentamicin) plus clindamycin in five clinical trials reviewed by DiPiro and Fortson.⁴⁸ Monotherapy with imipenem–cilastatin, piperacillin–tazobactam, cefotetan or cefoxitin is as effective as combination treatment with an aminoglycoside plus an anti-anaerobic drug,^{49–51} and is associated with significantly less nephrotoxicity. These data have led Gorbach to suggest that aminoglycoside-containing regimens should not be used routinely for the initial treatment of uncomplicated intra-abdominal infection.⁴⁵ Enterococci are frequently present in polymicrobial intra-abdominal infections but are seldom found alone. Treatment with an agent active against enterococci (e.g. amoxicillin) is not routinely required.^{45,52} Monotherapy with cefoxitin, combination therapy with cefuroxime plus metronidazole or gentamicin plus metronidazole (or clindamycin) are cheap, widely used alternatives for treatment of intra-abdominal infection. More expensive alternatives such as imipenem–cilastatin or piperacillin–tazobactam should be reserved for patients with complicated infections. Patients with generalized peritonitis or localized abdominal abscess should ordinarily be treated for 5–7 days.⁵³ Runyon et al⁵⁴ treated spontaneous bacterial peritonitis with cefotaxime 2 g every 8 h for 5 days, with no deaths due to infection and a 93% microbiological cure rate. As spontaneous bacterial peritonitis is usually due to community-acquired infection with relatively sensitive organisms, it seems likely that very similar results could be achieved with cefuroxime or amoxicillin–clavulanate.

Tertiary peritonitis should initially be treated with amoxicillin, gentamicin and metronidazole, but treatment should be modified when appropriate microbiology results are available. When infection is due to *Candida* spp. other antimicrobial agents should be discontinued, foreign bodies removed if possible, and treatment with amphotericin given for at least 4 weeks.⁵⁵

Infection is a common complication of severe acute pancreatic necrosis. It usually occurs 2 or 3 weeks after the onset of acute pancreatitis and is commonly due to enteric Gram-negative bacilli, *Staph. aureus*, streptococci or *B. fragilis*. Antimicrobial prophylaxis (e.g. monotherapy with imipenem–cilastatin or cefuroxime, or combination therapy with ceftazidime, metronidazole and amikacin) appears to be useful in preventing infection in high-risk patients, i.e. those with necrosis of more than one-third of the pancreas. However, no trial has shown a significant benefit in mortality. It seems reasonable to treat patients with severe acute pancreatic necrosis with cefuroxime for 14 days in the expectation that preventing infection will reduce morbidity, if not mortality.⁵⁶

URINARY TRACT INFECTION

Urinary tract infections are the third most common cause of admissions to ICUs for sepsis and are present in approximately 10% of such patients.^{57,58} Mortality from urinary tract sepsis is lower than for the two more common sources (intra-abdominal infections and pneumonia) and has been reported as around 30%,^{59,60} but is less in our recent experience (see Table 41.1). Most patients with urinary tract sepsis who are admitted to an ICU have infections that are complicated, i.e. they are associated with obstruction in association with structural abnormalities of the urinary tract (usually urolithiasis, less commonly malignancy or congenital abnormalities). Rarely, and most often in patients with diabetes, there may be an associated perinephric abscess⁶¹ or emphysematous pyelonephritis.⁶²

MICROBIOLOGY

The organisms most commonly responsible for complicated urinary infections are *Esch. coli*, *Proteus* and *Klebsiella* spp., other enteric Gram-negative bacilli, and less commonly enterococci. *Staph. aureus*, *Candida* spp. and other fungi are sometimes responsible, particularly in patients with a renal abscess. Azotemia should not be assumed to be acute as underlying chronic renal impairment is often present. Initial empirical antibiotic therapy should include amoxicillin and either an aminoglycoside or aztreonam. Immediate investigation should include imaging of the urinary tract with ultrasonography or CT scan to define the site and nature of any obstruction and detect the presence of an abscess or free gas in the tissues. Initial diagnostic radiology

should be combined with either percutaneous nephrostomy or ureteric stenting (performed following the first dose of antibiotics). Treatment of perinephric abscess(es) should include an anti-staphylococcal antibiotic (e.g. (flucl)oxacillin or vancomycin)⁶³ and consideration of operative drainage. Nephrectomy is usually recommended in emphysematous pyelonephritis.⁶²

Colonization and infection of the urinary tract occur in 6–18% of ICU patients.^{1,2} In most of these patients urinary tract infection is a relatively insignificant complication of urinary catheterization, which usually resolves on removal of the catheter; however, in a minority it is the cause of systemic illness and in a few it may contribute to mortality. Antimicrobial treatment is not indicated in the majority of patients and should be reserved for those with evidence of systemic sepsis.

TREATMENT

A variety of different antimicrobials have been evaluated in the treatment of hospital patients with serious urinary tract infection. The most important requirement of a regimen is adequate activity against aerobic Gram-negative bacilli, including *Pseudomonas* spp. Gentamicin, or another aminoglycoside, has long been considered the standard parenteral treatment for pyelonephritis, but concerns about nephrotoxicity and ototoxicity have prompted the assessment of other agents.

Aztreonam, ceftazidime, imipenem–cilastatin, ciprofloxacin and a host of other agents have demonstrated generally similar efficacy to the aminoglycosides.^{64–66} The selection of initial empirical therapy is influenced more by the relative costs of these agents than by any differences in clinical efficacy. Once the urinary pathogen has been identified, treatment can often be modified to use a cheaper narrow-spectrum agent. Pyelonephritis should be treated for 7–10 days but colonized patients can usually be managed by observation until removal of the catheter. The management of urinary tract infection is discussed in Chapter 54.

INTRAVASCULAR CATHETER-ASSOCIATED INFECTIONS

Infections of intravascular cannulas may range in severity from asymptomatic colonization of the cannula hub or skin insertion site to suppurative thrombophlebitis. Bacteremia is a common complication of severe catheter-associated infection, and in ICU patients is associated with a significantly increased mortality.⁶⁷ The incidence of intravascular catheter-associated sepsis is particularly affected by the spectrum and density of bacterial colonization of the skin at the insertion site, the duration of catheterization and the type of catheter used. The rate of cannula-related bacteremia is approximately 0.2% for peripheral intravenous cannulas, 1% for arterial

catheters used for hemodynamic monitoring and 3–5% for short-term non-cuffed central venous catheters.⁶⁸ Infection rates in patients with burns are commonly much higher.⁶⁹ The organisms most commonly responsible for cannula-related sepsis in ICU patients are *Staph. epidermidis*, enteric Gram-negative bacilli, *Staph. aureus*, *Enterococcus* spp. and *Candida* spp.^{70–72} (Table 41.4).

Catheter-associated infection should be suspected in all febrile patients who lack an identified source of sepsis. Infection of central venous catheters is not usually associated with any signs of sepsis at the insertion site. In contrast, insertion-site inflammation may be a useful sign of infection associated with peripheral venous and arterial catheters. However, most patients with peripheral catheter insertion-site inflammation do not have significant infection. Furthermore, sepsis may occur in the absence of local inflammation. In one study of 130 arterial catheters, bacteraemia occurred in 3 of 14 patients with inflammation at the site of catheter insertion and 2 of 116 patients without local inflammation.⁷³

The management of catheter-associated infection is discussed in detail in Chapter 42.

All patients with intravascular catheter-associated sepsis, especially those with infection due to *Staph. aureus*, should be carefully evaluated for the development of distant foci of infection (e.g. endocarditis, epidural abscess, septic arthritis). While these complications most commonly occur during the first 14 days after onset of the catheter-associated infection,⁷⁴ they may present as late as 2 months after the completion of antibiotic treatment.⁷⁵ Patients who have clinical evidence of suppurative thrombophlebitis or perivascular abscess may need adjunctive treatment with heparin, surgical removal of the infected vein or drainage of a perivascular abscess.⁷⁶

The optimal duration of treatment for apparently uncomplicated intravascular catheter-associated sepsis is uncertain. Jernigan and Farr⁷⁵ reviewed 11 studies of short-course therapy of catheter-related *Staph. aureus* bacteraemia and concluded that treatment should be for more than 2 weeks. Fowler et al⁷⁷ have suggested that patients with cannula-related *Staph. aureus* bacteraemia who have no indwelling prosthetic devices, clinical resolution within 3 days of removal of the infected cannula, sterile blood cultures at 2–4 days after

Table 41.4 Etiology of primary bacteremia in patients in intensive care units

	Richards et al ⁵	Richards et al ⁷
Total no. of isolates	2971	4394
Organisms (%)		
<i>Staphylococcus aureus</i>	13	12
<i>Staph. epidermidis</i>	36	39
<i>Enterococci</i>	16	11
Enteric Gram-negative bacilli	17	20
<i>Candida</i> spp.	11	12

starting appropriate therapy and a normal transesophageal echocardiogram after 5–7 days of therapy should be treated for only 7 days. The duration of treatment for patients with cannula-related bacteremia due to other organisms is even less certain.

Use of central venous cannulas, coated with either chlorhexidine and silver sulfadiazine or rifampicin (rifampin) and minocycline has a significant benefit in the prevention of cannula-associated bacteremia.⁷⁸ Dramatic reductions in cannula-associated bacteremia can be achieved by consistent application of a bundle of infection-prevention procedures: handwashing and using full barrier precautions during the insertion of central venous catheters, cleaning the insertion site with chlorhexidine, avoiding the femoral site if possible and removal of unnecessary catheters.^{79,80}

SINUSITIS

Sinusitis (Ch. 44), particularly affecting the maxillary sinuses, is an occasional cause of fever in ICU patients.^{81,82} Complications of sinusitis include bronchopneumonia, septicemia and subdural empyema.

Sinusitis should be suspected in febrile patients who have endotracheal and gastric tubes inserted through the nares. Purulent rhinorrhea and middle ear effusion(s) (detected by pneumatic otoscopy) are useful clinical associations with sinusitis.⁸³ Partial or complete opacification of the sinuses has been demonstrated in 30–60% of patients admitted to an ICU for at least 7 days.^{81,82} However, in approximately half of these patients the maxillary sinus fluid does not grow significant numbers ($>10^3$ cfu/mL) of organisms. The demonstration of fluid in the sinuses (by CT, radiography or ultrasonography) should not therefore be regarded as proof of the presence of purulent sinusitis. In patients who do have purulent sinusitis the infection is commonly polymicrobial, with Gram-negative bacilli present in most. *Candida* spp. and anaerobes are occasional causes of sinusitis.

The initial treatment of sinusitis should include removal of any nasal tubes and treatment with a broad-spectrum antibiotic such as cefoxitin. In patients with persistent fever, radiological evidence of significant sinus opacification and no other focus of infection, the affected sinuses should be surgically drained and lavaged, and treatment modified on the basis of culture results.

SOLID ORGAN TRANSPLANTATION

Solid organ transplant recipients are admitted to an ICU under two circumstances – immediately postoperatively or at some later time following transplantation. Infection is the most common reason for such admission.

Prophylactic perioperative antimicrobial therapy in solid organ transplant recipients should be effective against the

common bacterial and fungal pathogens responsible for infection during this period of maximal immunosuppression. The regimen should represent the consensus views of transplant clinicians, intensivists and infectious disease physicians and should be in the form of a written protocol. Prophylaxis should begin immediately preoperatively so as to provide high blood levels during surgery. The agents used should be appropriate to the (site and organ-specific) infective risks and should be given for short periods only (<24 h). Finally, account should be taken of co-morbidity such as renal impairment so as to minimize iatrogenic complications. These recommendations are consistent with the general principles for the prevention of surgical site infections.⁸⁴

Common regimens in abdominal organ transplantation include either a group 3 cephalosporin (cefuroxime or cefoxitin) or a combination of an anti-staphylococcal penicillin (or vancomycin) and either an aminoglycoside or aztreonam. A short course of prophylactic systemic antifungal therapy is recommended in high-risk patients undergoing liver transplantation.⁸⁵

Perioperative regimens in heart transplantation should be similar to those used in non-transplant cardiac surgery (e.g. cefuroxime). Lung transplant recipients with cystic fibrosis or bronchiectasis are frequently colonized with multiresistant enteric Gram-negative bacilli and should receive prophylaxis with a dual antipseudomonal regimen (e.g. ceftazidime and an aminoglycoside). Other lung transplant patients, for example those with pulmonary hypertension, should have similar prophylaxis to heart transplant recipients.

Bacterial infections in critically ill transplant recipients early after transplantation should be treated according to protocols designed for other critically ill patients, bearing in mind the local microbial flora, the nature of the putative septic site and the state of immunosuppression. Empirical treatment may consist of a group 3 cephalosporin (perhaps in combination with an aminoglycoside) in pneumonia or urinary tract infection; an anti-staphylococcal penicillin (or vancomycin) with an aminoglycoside and perhaps amphotericin^{86,87} in clinical sepsis without an identified site; and either triple combination therapy (aminoglycoside, metronidazole and amoxicillin or vancomycin) or monotherapy with a carbapenem in intra-abdominal infection. *Enterococcus faecium*, including vancomycin-resistant strains, is a particular problem in biliary and intra-abdominal infection after liver transplantation, as are multiresistant organisms after lung transplantation.⁸⁸

Serious fungal infections are particularly problematic^{89–91} and constitute the most common unsuspected finding at autopsy in transplant recipients who die in the ICU.⁹² Early recourse to liposomal amphotericin is recommended in life-threatening fungal infections in transplant recipients, although successful use of caspofungin or voriconazole has been reported for invasive aspergillosis (Ch. 60).^{93,94}

Infections occurring more than a month after transplantation are more likely to be due to opportunistic organisms⁹⁵ and invasive means should be used if necessary to establish the nature of the causative organisms.

The prophylaxis and therapy of viral and other opportunistic infections in transplant patients is covered in Chapter 40.

SEPSIS MODULATORS

Sepsis (i.e. the clinical syndrome usually associated with severe life-threatening infections) has a complex pathophysiology that has proved difficult to elucidate.⁹⁶ Although understanding of many of the underlying mediators and mechanisms of disease (e.g. the inflammatory and coagulation cascades) is increasing,^{97,98} attempts to convert this understanding into effective therapeutic strategies have so far been largely unsuccessful.^{57,99,100} In large part this is because of the extreme heterogeneity of clinical sepsis with respect to patient factors (e.g. co-morbidity), quality of clinical care (e.g. the appropriateness of surgical and antimicrobial therapy),^{101,102} the nature of the septic process (e.g. abscess or bacteremia), the timing of intervention with respect to the stage of evolution of the underlying pathophysiology, and the redundancy of disease mechanisms which limit the possible efficacy of a ‘single magic bullet’ intervention strategy.

The lack of specific clinical correlates of underlying disease mechanisms has prompted calls for a reappraisal of the utility of the clinical definition of sepsis and for a classification of septic patients in ways that ensure more homogeneity with respect to these mechanisms.¹⁰³ However, despite these formidable methodological difficulties, a meta-analysis¹⁰⁴ of 18 trials of a variety of anti-inflammatory therapies showed a small but statistically significant reduction in absolute mortality (from around 39% to 36%) in the ‘active’ arm. This suggests that such therapies may indeed have therapeutic benefit. It seems likely that some of these agents may be less effective than others and that the size of the ‘benefit’ in the meta-analysis may be an underestimate of the efficacy of a few ‘strong performers’. Nevertheless, very large trial sizes (*c.* 6000 patients) would be required to detect such small (3%) benefits, unless trial design improved. After initial trials of antithrombin III suggested that this agent might be beneficial,¹⁰⁵ a large multicenter study was unfortunately confounded by the adverse effects in the antithrombin III arm of simultaneous heparin administration and the future of this agent is unclear.¹⁰⁶ Another agent with both anti-inflammatory and anti-thrombotic activity, recombinant human activated protein C or drotrecogin-alfa, was shown to reduce all-cause 28-day mortality from 30.8% to 24.7% in another large trial (PROWESS).⁵⁸ However, two subsequent trials with different protocols – one in adults (ADDRESS),¹⁰⁷ the other in children (RESOLVE)¹⁰⁸ – did not show benefit and

a fourth trial (PROWESS-SHOCK)¹⁰⁹ is currently recruiting, while the place of this expensive agent continues to be debated (*see* Ch. 38).¹¹⁰

PREVENTION OF INFECTION IN THE ICU

SELECTIVE DECONTAMINATION OF THE DIGESTIVE TRACT

The use of selective decontamination of the digestive tract (SDD) to reduce the incidence of infection in multiple trauma patients was first reported by Stoutenbeek et al.¹¹¹ The regimen used for SDD is commonly a mixture of polymyxin, tobramycin (or gentamicin) and amphotericin. This mixture is applied as a paste to the oral mucosa, and a liquid suspension is swallowed or administered via a nasogastric tube four times daily. The regimen is intended to eliminate fungi and aerobic Gram-negative bacteria from the gastrointestinal tract but to have little effect on the predominant anaerobic flora, thus maintaining ‘colonization resistance’ due to their continued growth. The purpose of SDD is to reduce the rate of pneumonia and other serious infections caused by pathogenic organisms originating from the gastrointestinal tract. In a modification of SDD the topical oral and enteric regimen used throughout a patient’s stay in the ICU has been supplemented by the addition of a systemic broad-spectrum antibiotic (usually cefotaxime) for the first 4 days of the stay. This selective parenteral and enteral antisepsis regimen (SPEAR) is intended to improve upon the efficacy of SDD by treating occult or incubating infections present at admission to the ICU. Whether or not regimens have included an initial period of systemic antimicrobial therapy, the acronym SDD is most frequently used to describe this form of chemoprophylaxis.

Colonization of the oropharynx, stomach and rectum is dramatically affected by SDD regimens. Aerobic Gram-negative bacilli are eliminated from the oropharynx and stomach within 3–4 days of starting SDD. In contrast, they continue to be isolated from these sites in 20–50% of control patients not given SDD. The proportion of patients with aerobic Gram-negative bacilli present in rectal swabs also declines from approximately 60–90% to 10–20% over a period of 10–14 days.^{102–114}

A meta-analysis of the results from 51 randomized controlled trials (including 8065 patients) of SDD regimens showed a 61% reduction in the incidence of bacteremia due to aerobic Gram-negative bacilli, no effect on bacteremia due to Gram-positive bacteria, and a 20% reduction in mortality.¹¹⁵ The analysis suggested that approximately 22 patients would need to be treated to prevent one death. The adverse effects of SDD regimens include the significantly increased expenditure on antibiotics, the potential for increased antibiotic resistance in the endemic bacterial flora of the ICU due to the selective pressure exerted by the SDD regimen, and

the toxicity of the agents used. Opinion is divided between those who consider SDD of proven benefit and those who consider that further study is required to determine whether it is cost-effective in selected subgroups (e.g. trauma and burn patients).^{27,28}

OTHER STRATEGIES TO PREVENT VENTILATOR-ASSOCIATED PNEUMONIA

Semirecumbent positioning, enteral rather than gastric feeding, use of sucralfate rather than antacids, H₂ antagonists or proton pump inhibitors as prophylaxis against stress-induced gastric ulceration, continuous subglottic aspiration and removal of nasogastric and endotracheal tubes at the earliest opportunity have all been shown to reduce the incidence of ventilator-associated pneumonia.²⁸

HAND HYGIENE

Despite clear evidence that micro-organisms are disseminated within the ICU on the hands of staff,¹¹⁶ and increasing concern about nosocomial infection with ever more resistant organisms, ICU staff wash their hands on approximately only one-third of the occasions when they should do so. The level of compliance with handwashing guidelines in ICUs tends to be lower than it is in other parts of the hospital, perhaps because of heavier staff workloads in the ICU. Placing labels on ICU equipment that remind staff to wash their hands, provision of easily accessible handbasins and dispensers, and use of an antiseptic handrub rather than handwashing, have all been found to improve hand hygiene in the ICU.¹¹⁷ Maintaining high levels of hand hygiene requires adequate staffing and continuous education and motivation of staff. While these actions may appear mundane, improvements in hand hygiene are likely to dramatically reduce nosocomial infection.

POLICIES TO MAXIMIZE THE EFFECTIVENESS OF ANTIMICROBIAL USE IN THE ICU

The prevalence of infection with antibiotic-resistant organisms is rising in ICUs,¹¹⁸ as it is in hospitals generally. Such infections are difficult and costly to treat.¹¹⁹ ICUs are often accused of indiscriminate use of antibiotics and of creating antibiotic-resistant organisms, which then spread to the rest of the hospital. While it is evident that the patients with the most severe infections in the hospital are often admitted to the ICU as a result of their infection, there is much that can be done in the ICU to limit the inappropriate use of antibiotics and the selection of resistant microbial strains.¹²⁰

Crucial to the success of these endeavors, however, is the creation of a conservative culture with respect to the use of antibiotics, both prophylactically and therapeutically. This requires

the cooperation of all clinicians practicing within the ICU. This culture should be expressed in an antibiotic management program. Infectious disease physicians and clinical microbiologists have a detailed knowledge of the local microbiological flora, both in hospital and in the surrounding community, and can provide evidence-based advice and facilitate consensus among other clinicians on appropriate antibiotic use.¹²⁰

Antibiotic management programs should be specific and applicable to the clinical situation, where decisions often need to be made without supporting microbiological information. They should specifically cover 'surgical prophylaxis' and should specify the indications, agent, dose and duration of therapy.¹²¹ They should also explicitly prohibit the use of antibiotic prophylaxis in situations where it is not indicated and should specify initial empirical therapy based on presenting clinical syndromes (i.e. before microbiological information comes to hand). Once again, the agents, dose and duration should be specified. Certain agents (e.g. perhaps expanded-spectrum cephalosporins, amphotericin, carbapenems, amikacin, streptogramins, linezolid) could be designated as mandating either prior approval or early review by an infectious disease physician. A policy commitment by the treating clinicians to reserve empirical antibiotic therapy for 'clinical sepsis' and not to treat 'colonization' is crucial to the success of an antibiotic management program in reducing unnecessary and probably harmful antibiotic use. Finally, these policies should also stipulate a commitment to rationalize antibiotics (narrower spectrum, less 'reserved', cheaper) in the light of appropriate definitive microbiological information.

Specifying the most appropriate investigation strategy for common syndromes of clinical infection²² may reduce mortality, improve the quality of microbiological information and reduce unnecessary investigation, antibiotic use and cost.

INFECTIONS DUE TO UNUSUALLY RESISTANT BACTERIA

Colonization and infection with bacteria resistant to commonly used antibiotics is a rapidly growing problem in ICUs. Recent reports have described resistance to methicillin in 65% of infections due to *Staph. aureus*, gentamicin resistance in 46% of infection due to *Ps. aeruginosa* in European ICUs,¹²² resistance to cefotaxime, ceftriaxone and aztreonam in 20–30% of isolates of *K. pneumoniae* from ICUs in France,¹²³ and resistance to vancomycin in 17% of enterococcal isolates from ICUs in the USA.¹²⁴ Potential adverse consequences of colonization or infection with multiresistant strains include failure of antimicrobial therapy, increased expense of antimicrobial therapy, spread of infection to other patients and transfer of resistance to other bacterial species. Epidemics of multiresistant bacteria in ICU patients are often followed by spread to patients in other parts of the hospital and then to the community, or back to the ICU. When formulating policies for antibiotic use in the ICU, doctors should be influenced by the distant effects of their antibiotic choices and avoid unnecessary prescription

of those agents most likely to facilitate the selection of multiresistant strains (see Ch. 3).

Colonization and infection with multiresistant bacteria is usually the result of acquisition of endemic or epidemic strains following admission to the ICU.¹²⁵ A variety of factors (including greater severity of the underlying illness, prolonged stay in the ICU, the use of invasive devices and prolonged use of broad-spectrum antimicrobial therapy) increase the rate of infection with these organisms.¹²⁶ Resistance of a bacterial isolate to commonly tested antibiotics (e.g. methicillin resistance in *Staph. aureus*, vancomycin resistance in enterococci, aminoglycoside and group 4 cephalosporin resistance in Gram-negative bacilli) frequently serves as a marker of an epidemic of nosocomial infection, which might otherwise remain unsuspected. Such epidemics are not only of importance in themselves, but should also be regarded as the visible tip of an iceberg of undetected nosocomially transmitted infection.

Pseudomonas, Klebsiella, Enterobacter, Serratia and *Acinetobacter* spp., MRSA and enterococci are the most commonly reported causes of epidemics of nosocomial bacteremia in ICU patients.¹²⁷ Such epidemics usually last less than 3 months, affect an average of 10 patients per outbreak, commonly arise from contaminated medical equipment, and often depend on transmission of infection by the hands of ICU staff. Similar factors no doubt contribute to the much larger problem of endemic nosocomial infection, but are less easily identified because the organisms responsible often lack unusual antibiotic resistance patterns.

METHICILLIN-RESISTANT *STAPH. AUREUS*

Methicillin-resistant *Staph. aureus* (MRSA) is a common cause of epidemics of infection in ICUs. Burns, surgical wounds, prolonged stay in the unit and prolonged courses of multiple antibiotics all increase the risk of MRSA infection. Although persistent colonization of hospital staff has been suspected as the source of infection in some MRSA outbreaks, this is not found in most outbreaks. However, transient contamination of the hands is common in staff directly involved in the care of patients with MRSA infection, and is presumed to be the most common mode of transmission of infection between patients. Control and, not infrequently, termination of epidemics of MRSA can be achieved by surveillance of patients for MRSA colonization or infection, strict isolation of colonized or infected patients, consistent use of hand hygiene between each patient contact and appropriate treatment to minimize colonization or eradicate infection in affected patients and staff.

MRSA colonization may be reduced or eliminated by stopping antibiotic treatment whenever possible, effective treatment of underlying skin disorders, application of mupirocin ointment to colonized sites, and washing with an antiseptic.¹²⁸ Infection with MRSA is usually treated with intravenous vancomycin or linezolid, or oral clindamycin or fusidic acid supplemented by oral rifampicin.

RESISTANT ENTEROCOCCI

Enterococci (especially *E. faecalis* and *E. faecium*) resistant to gentamicin, ampicillin or vancomycin have emerged as an important cause of nosocomial infection in ICUs. Prolonged stay in the unit, persistent intra-abdominal infection and prolonged broad-spectrum antimicrobial therapy with agents inactive against enterococci are common features in patients with enterococcal infection. Feces and urine of colonized patients are the usual sources of infection, and transmission on the hands of hospital staff is presumed to be the major route of cross-infection. The urinary tract, bloodstream and surgical wounds are the most common sites of infection.⁷

Bacteremia due to enterococci highly resistant to gentamicin ($\text{MIC} > 1000 \text{ mg/L}$) but susceptible to amoxicillin or vancomycin may be successfully treated with amoxicillin (or ampicillin) or vancomycin monotherapy.^{129,130} This is in contrast to enterococcal endocarditis, which requires combination treatment with amoxicillin or vancomycin plus an aminoglycoside for cure. Optimal treatment of infection with enterococci resistant to ampicillin, vancomycin and aminoglycosides is at present unclear, but linezolid and quinupristin-dalfopristin show some promise.

The rapid emergence of multiresistant enterococci, the difficulties posed by treatment of these infections and the specter of transfer of resistance to *Staph. aureus* are important reasons to limit the use of vancomycin as much as possible. Vancomycin should not ordinarily be used for perioperative prophylaxis, initial treatment of antibiotic-associated colitis, initial empirical treatment of febrile neutropenic patients, selective decontamination of the digestive tract or eradication of MRSA colonization.¹³¹

EXTENDED-SPECTRUM β-LACTAMASE-POSITIVE *K. PNEUMONIAE*

Extended spectrum β-lactamases (ESBL) providing resistance to broad-spectrum cephalosporins were first detected in *K. pneumoniae* in 1983.¹³² Resistance is due to readily transmissible plasmids which encode for ESBL and for aminoglycoside and quinolone resistance. The β-lactamases are usually susceptible to inhibitors such as clavulanic acid and sulbactam, which may assist with identification of these strains in the laboratory.¹²⁵ Approximately 14% of *K. pneumoniae* and 6% of *Esch. coli* isolated from patients in ICUs in the USA in 2002 were ESBL positive.¹³²

Infection with ESBL-positive *K. pneumoniae* usually involves the urinary tract, the respiratory tract or wounds.¹³² Enteric colonization and transmission on the hands of hospital staff appear to contribute to epidemic spread. Treatment is with a carbapenem such as imipenem–cilastatin, meropenem or ertapenem.

GRAM-NEGATIVE BACILLI WITH INDUCIBLE β -LACTAMASES

Another important source of infection due to multiresistant Gram-negative bacilli is the selection of organisms with chromosomally encoded class I β -lactamase production. *Pseudomonas*, *Enterobacter*, *Citrobacter* and *Serratia* spp. are the organisms that most frequently produce class I β -lactamase (see Ch. 15). Induction of enzyme production or selection of stably depressed mutant cells which constitutively manufacture class I β -lactamase at a high level may lead to development of resistance to β -lactams during treatment.^{133,134} Enzyme production is strongly induced when organisms are exposed to cephalosporins of groups 1 and 2 (see Ch. 13), cefoxitin or imipenem–cilastatin, but is only weakly induced by exposure to groups 3 and 4 cephalosporins, ureidopenicillins and monobactams. Induced enzyme production ceases promptly when treatment with the inducing antibiotic is stopped. Selection of stably depressed mutants constitutively producing large amounts of β -lactamase occurs when inducible strains (especially *Ps. aeruginosa* and *Enterobacter cloacae*) are exposed to broad-spectrum cephalosporins, ureidopenicillins or monobactams. Resistance persists even when treatment with the antibiotic responsible for selecting the mutant strain is stopped. Development of resistance during treatment occurs in approximately 10–20% of patients,¹³⁴ and spread within the ICU may result in multiresistance in 30% of ICU isolates of *Ent. cloacae*.¹³³

Imipenem–cilastatin, despite being a strong inducer of class I β -lactamase, is not susceptible to the enzyme's action. Alternative regimens include imipenem–cilastatin monotherapy or combination therapy using imipenem–cilastatin plus an aminoglycoside or a fluoroquinolone selected on the basis of careful susceptibility testing.¹³⁵ Patients treated with a broad-spectrum cephalosporin, ureidopenicillin or monobactam for an infection due to an initially sensitive strain should be carefully observed for the emergence of resistant mutants during treatment.

MULTIRESISTANT ACINETOBACTER BAUMANNII

Multiresistant *A. baumannii* is an occasional cause of epidemics of infection in ICU patients. Epidemic strains are resistant to many broad-spectrum cephalosporins, and resistance to quinolones, carbapenems and aminoglycosides is also common. Colonization and infection of the respiratory tract in artificially ventilated patients is a common feature of epidemics, and improvements in the methods used to sterilize ventilator equipment has led to termination of epidemics.¹³⁶ In most patients *A. baumannii* merely colonizes the respiratory tract; however, it may be responsible for pneumonia and other serious infections. Imipenem–cilastatin alone, or in combination

with an aminoglycoside, is often appropriate treatment. Polymyxin B, colistin and tigecycline may be effective in the treatment of strains with multidrug resistance.

A frequent theme for many epidemics caused by multiresistant bacteria has been the widespread use of antibiotics in response to increased resistance in other commonly isolated bacterial species. For example, vancomycin resistance in enterococci has emerged following increased use of vancomycin to treat suspected or proven MRSA (or methicillin-resistant *Staph. epidermidis*) infections. Similarly, epidemics of infection due to multiresistant *K. pneumoniae* and *A. baumannii* have followed increased use of group 4 cephalosporins and imipenem–cilastatin.¹³⁵ Thus the increased use of potent antibiotics with ever broader spectra of activity acts as a stimulus to the evolution of new epidemics of ever more resistant pathogens. The effect is to mortgage the future of antibiotic treatment to pay for our present practices. While there is no one solution to this problem that can be applied to all ICUs, the use of prescribing guidelines which encourage the use of older narrow-spectrum antibiotics and limit the use of new broad-spectrum antibiotic agents should prolong the utility of new drugs, delay the emergence of resistant strains and set a better example for prescribing patterns in the rest of the hospital¹³⁷ (see Ch. 11).

Infections associated with implanted medical devices

Michael Millar and David Wareham

There is a wide variety of implanted medical devices in use. This diversity is reflected in the range of infections associated with these devices. Device-associated infections account for 50% of hospital-acquired infections which have considerable economic and health costs.¹ Some of the more common and serious infections are covered in this chapter. These include infections associated with orthopedic implants, prosthetic heart valves, cardiac pacemakers, intravascular devices, cerebrospinal fluid drainage and pressure monitoring devices, urinary drainage catheters and peritoneal dialysis catheters. Ventilator-associated pneumonia is covered in Chapter 41.

PATHOGENESIS OF IMPLANT-ASSOCIATED INFECTIONS

Medical implants may be exposed to micro-organisms prior to, or at the time of, placement of the implant, through spread of bacteria from a contiguous site, via the bloodstream from a distant site or through a breach in the natural barrier to infection (such as the skin). Implants predispose to infections through a wide range of mechanisms including local tissue damage, compromise to local vascular perfusion, by providing both protected niches for microbial proliferation and surfaces for microbial attachment and biofilm formation, and by compromising local immunity. The majority of implanted medical devices in use today elicit a local immune response which depletes complement and reduces phagocytic and oxidative burst-dependent bactericidal activity of neutrophils.²

A biofilm consists of micro-organisms adherent to a surface often in a secreted polymer matrix. Biofilms on clinical implants almost always form within a complex matrix of both microbial secreted, polymer and host-derived molecules. Adhesion to conditioned surfaces is facilitated in some bacteria by specific adhesins, for example *Staphylococcus aureus* has both fibronectin- and fibrinogen-binding surface proteins. Biofilm forming *Staph. epidermidis* strains may produce an extracellular polysaccharide known as polysaccharide intercellular adhesin (PIA). This promotes the development and maturation of the biofilm and is under complex regulatory

control, enabling the organism to respond to the local environment.³ Adhesion and biofilm formation are probably both prerequisites for the development of implant-associated infections.

Almost all infections associated with implants are caused by bacteria or fungi (most frequently *Candida* spp.). Bacteria associated with implant infections include not only Gram-positive bacteria, particularly staphylococci, but also enterococci, corynebacteria and Gram-negative bacteria such as Enterobacteriaceae, *Pseudomonas* spp. and *Acinetobacter* spp. Viruses, protozoa or helminths are rarely associated with implant infections. In the natural world and at sites of microbial colonization, such as the human oral cavity, biofilms usually consist of polymicrobial consortia. Biofilms associated with implant infection may be polymicrobial but more frequently consist of single strains of bacteria. Once a biofilm has formed, the micro-organisms within the biofilm are relatively resistant to both host defense factors and antimicrobial drugs.⁴ As a consequence, infections are difficult to treat and device removal is frequently required to cure the infection.

Understanding the molecular biology of biofilm formation and stabilization has the potential to inform the development of new strategies for the prevention and treatment of biofilm-associated infections.⁵⁻⁸

DETERMINANTS OF BIOFILM ANTIBIOTIC RESISTANCE

Bacterial biofilms tend to show much higher levels of resistance to antimicrobial agents than planktonic cells.⁹ There are many potential mechanisms to explain this. Growth phase and growth rate are key determinants of antimicrobial susceptibility.¹⁰ Slowly growing bacteria are much less susceptible to the bactericidal activity of antimicrobials such as β-lactams. A proportion of micro-organisms in a biofilm are nutrient deprived and grow very slowly.¹¹ Binding of antimicrobials to extracellular matrix macromolecules and dead bacteria, protection of viable bacteria deep in the matrix by inactivating

enzyme activity from surrounding bacteria¹² and changes in ionic gradients leading to changes in antimicrobial diffusion may also give some protection to biofilm bacteria. Alterations in microbial physiology associated with the biofilm mode of growth probably also contribute to reducing antimicrobial susceptibility. A recent report suggests that binding of antimicrobials to periplasmic glucans may be an important mechanism of resistance of biofilm bacteria to some antibiotics in *Pseudomonas aeruginosa*.¹³ Microelectrode analysis of oxygen concentrations in *Ps. aeruginosa* biofilms¹⁴ suggests that only the bacteria at the air–biofilm interface have sufficient oxygen for growth, and so it may be that oxygen utilization and poor diffusion are at least as important as the diffusion of antimicrobial agents in determining antimicrobial resistance. A genetic locus has been described in *Ps. aeruginosa* which is important in regulating phenotype (slow-growing, small colony variants), propensity to biofilm formation and antibiotic resistance.¹⁵

Cell-to-cell interactions in surface-associated bacterial populations are determined by quorum-sensing molecules. Interference with bacterial cell signaling mechanisms has the potential to control microbial colonization of implants;^{8,16} for example, RNA III inhibiting peptide (RIP) inhibits biofilm formation by *Staph. aureus* and when combined with antibiotics can inhibit biofilm formation on implants in rats.¹⁷ Eukaryotic cells may also respond to bacterial signaling molecules,¹⁸ and this is an important consideration should targeted disruption of bacterial signaling become a therapeutic strategy for patients with implant infections. Much of the human commensal flora is biofilm associated and could also be disrupted by therapeutic strategies targeting bacterial intercellular signaling.

USE OF ANTIBIOTICS FOR THE PREVENTION OR TREATMENT OF IMPLANT-ASSOCIATED INFECTIONS

Basic principles for the prevention of implant-associated infections include the control of patient risk factors for infection (e.g. diabetes and obesity), optimization of the conditions under which devices are implanted, and ensuring that those who insert and care for medical devices are appropriately trained and experienced.

One of the simplest and most cost-effective strategies for the prevention of infections associated with some types of medical implant has been the use of perioperative antimicrobial prophylaxis following the principles that supra-inhibitory concentrations of an antimicrobial (with an appropriate spectrum of activity) are present at the site of surgery at the time the operative procedure starts. Further details are given in the sections on specific implant-associated infections.

Some antibiotics reach high concentrations and retain antimicrobial activity in biofilms, such as quinolones and rifampicin (rifampin). Both in-vitro¹⁹ and clinical studies support the use of rifampicin as adjunctive treatment, particularly for

staphylococcal infections associated with medical implants. Vancomycin has a place in the treatment of infections caused by methicillin-resistant staphylococci but is probably inferior to β-lactam antibiotics for implant-associated infections caused by methicillin-susceptible strains.¹ Among the newer agents for the treatment of Gram-positive infections, daptomycin and tigecycline have demonstrated activity in vitro against organism-embedded biofilms.²⁰ With the exception of catheter-associated urinary tract infection, the empirical treatment of the majority of implant-associated infections discussed in this chapter would include the use of a glycopeptide such as vancomycin ± rifampicin ± an agent with activity against Gram-negative bacteria (such as a fluoroquinolone). Further details of antibiotic selection and duration of treatment are given in the sections describing treatment of infections associated with specific types of medical implant.

Use of antibiotics is not without adverse consequences; for example, administration of a single dose of a semisynthetic penicillin poses a risk of anaphylaxis of approximately 0.04%, of skin rash of 5% and of *C. difficile* antibiotic-associated colitis of >0.01%.²¹ Antibiotic exposure may promote the formation of biofilms by some organisms. In *Ps. aeruginosa*, subinhibitory concentrations of aminoglycosides facilitate adhesion to plastic surfaces via induction of a transmembrane signaling system which modulates cell-surface adhesiveness.²²

Recommendations in this chapter are based on the principle that antibiotics should only be used when there is evidence that the benefits of use outweigh the risks.

INFECTIONS ASSOCIATED WITH SPECIFIC TYPES OF MEDICAL IMPLANT

INFECTIONS ASSOCIATED WITH ORTHOPEDIC IMPLANTS

The mean cost of hip replacement across nine European countries reported in 2008 was over €5000 (~US\$7200).²³ The number of hip and knee replacements carried out each year is increasing both in Europe and North America.²⁴ Infection of implanted joints adds substantial additional economic costs and morbidity.²⁵

The risk of infection is probably highest in the first 2–3 years, with combined rates of hip and knee implant infection of 6.5 per 1000 joint-years for the first postoperative year, 3.2 per 1000 joint-years during the second year and 1.4 per 1000 in subsequent years. The risk of prosthetic joint infection varies with a number of factors, including the type of prosthesis, operator experience and duration of procedure(s), together with host-dependent risk factors including old age, immune compromise, obesity and diabetes mellitus.^{1,26,27} In the UK National Health Service, hip and knee implant surgery has been subject to mandatory surveillance of surgical site infection since April 2004. There were over 140 000 primary prosthetic hip or knee implant procedures in England and Wales

in the year 2007–8, and an additional 10 000 revision hip or knee procedures.²⁸ Rates of infection for hip and knee arthroplasty of 3.3% have been recorded over the 4-year period from April 2004, of 0.8% for total hip prostheses and 0.4% for knee prostheses.²⁸ Approximately one-quarter of infections involve the deep tissues. The infections that have been recorded are those which present in hospital. A proportion of orthopedic implant infections present weeks or even in some cases years after the initial procedure so rates of infection may be underestimated by short durations of follow-up. In the UK surveillance is being improved to try to capture infections that develop following hospital discharge.

Comparison of rates of infection by center requires risk adjustment. In the UK a risk index is used to measure variation in risk factors which comprise measures of the likely microbial contamination of the wound, determination of the degree of severity of underlying systemic disease and the duration of the operation.²⁹ In part, the differences between the rates of infection for different types of orthopedic implant procedure reflect the frequency and severity of risk factors in patients undergoing the various procedures.

CLASSIFICATION OF PROSTHETIC JOINT INFECTIONS

Several staging systems have been proposed for prosthetic joint sepsis but consensus is lacking. The most widely accepted system is that formulated originally by Coventry³⁰ and modified by Gillespie:³¹

- *Stage 1* infections are defined as those occurring within 1 month of surgery. Patients with stage 1 infections typically present with signs of sepsis as well as local signs of infection, with local erythema and wound discharge. The organisms most commonly recovered from stage 1 infections derive from the patient's skin, bacteria in operating room air, or the skin of members of the surgical team.^{32,33}
- *Stage 2* infections are defined as those that occur after 1 month but within 2 years of surgery. The infections are also thought to derive from the introduction of organisms of low pathogenicity, such as coagulase-negative staphylococci and *Propionibacterium* spp., at the time of surgery. Patients typically exhibit gradual impairment of prosthetic function (i.e. early loosening of the prosthesis and increasing joint pain).
- *Stage 3* infections are arbitrarily defined as infections that occur more than 2 years after surgery and are assumed to derive from hematogenous seeding of the joint.

In practice there is considerable variation in presentation and it is difficult to definitively identify a source of infection. The majority of infections can be prevented by measures that target the perioperative period and this observation is consistent with colonization at the time of operation being the major determinant of the risk of subsequent infection.

MICROBIOLOGY

Gram-positive organisms, particularly staphylococci, are the most frequent isolates. Streptococci, corynebacteria, propionibacteria and enterococci are found less frequently, and rarely Gram-negative bacilli, anaerobes or fungi, particularly following gross contamination of the operation site or in association with sinus formation or other lesions, leading to a breakdown in natural barriers to infection.²⁵

DIAGNOSIS

The clinical presentation ranges from an acute illness with systemic signs of infection of varying severity to insidious illness associated with local pain and perhaps joint loosening. *Staph. aureus* bloodstream infection can lead to seeding of prosthetic joints and an acute onset of joint infection.³⁴ When a patient with an implant and few other risk factors for infection develops signs and symptoms of infection associated with inflammation at the site of the implant, then the diagnosis may be relatively straightforward. A more frequent scenario is the insidious development of non-specific signs and symptoms of infection.³⁵

Diagnostic problems arise because of the difficulty in sampling the surface of the implant. Joint infection with coagulase-negative staphylococci, which are the most frequent cause of prosthetic joint infection, is rarely associated with bacteremia. There may be leukocytosis and raised non-specific markers of infection such as C-reactive protein. Ultrasound may show evidence of an effusion and may be used to facilitate aspiration. Conventional radiography is usually normal but may reveal bone loss and loosening around a chronically infected prosthesis. Newer radiological approaches, such as positron emission tomography and the use of labeled antimicrobial peptides, have the potential to improve the diagnostic sensitivity of radiological methods.

Identifying causative agents of infection has important implications for both treatment and prognosis. It is important to try to optimize the chance of a positive culture result by avoiding the use of antimicrobial agents in the period immediately preceding joint aspiration or open tissue biopsy. Multiple samples (up to six) should be sent to the laboratory for culture. The isolation of identical organisms from three such specimens is highly predictive of infection.³⁶ Histopathological analysis of tissue samples as well as the white cell count in aspirated synovial fluid can also be helpful. The place of molecular microbiological methods in the diagnosis of prosthetic joint infections remains unclear at the present time.

TREATMENT

The treatment of prosthetic joint infections requires the integrated use of antimicrobials with surgical management,

and tailoring the overall management strategy to the patient's particular circumstances, taking account of comorbidities and life expectancy.^{27,36} Traditionally infections associated with prosthetic joints have been managed by a two-stage exchange arthroplasty in which the colonized device is removed and the site debrided. The patient is then treated for an extended period with antibiotics based on the results of culture samples collected at the time of the surgery. When clinical signs of infection have resolved and the non-specific markers of infection such as C-reactive protein have normalized, then a new device is implanted.

A number of other approaches have been tried, including initial irrigation and debridement with retention of the device, one-stage exchange arthroplasty (in both of these cases combined with prolonged antimicrobial therapy), and the use of prolonged suppressive antimicrobial therapy.³⁷ There is evidence that each of these approaches can be appropriate and successful in selected patients. Debridement with retention of the colonized prosthesis followed by indefinite durations of suppressive antimicrobial therapy has also been used in patients where exchange arthroplasty is not feasible or where the quality of life associated with prolonged immobilization is unacceptable to the patient.³⁸

The optimum antimicrobial treatment for infections associated with prosthetic devices is not known. Staphylococci are the most frequent infecting organisms and there is a wide range of drugs available, including isoxazole penicillins (such as flucloxacillin), clindamycin, linezolid, vancomycin, sodium fusidate, rifampicin, trimethoprim, tetracycline and quinolones, depending upon the antimicrobial susceptibility of isolates and clinical indications.

Animal models and clinical data^{39,40} support the inclusion of rifampicin in treatment regimens. Rifampicin cannot be used as a single agent because of the risk of mutational resistance and should not be used if the infecting organism is shown to be resistant in vitro. For strains susceptible to methicillin, an isoxazole penicillin is recommended in combination with rifampicin; for patients with methicillin-resistant organisms or with a history of allergy to penicillin, then vancomycin can be combined with rifampicin.

Fluoroquinolones are highly bioavailable when administered orally and attain high joint fluid concentrations in experimental animal models of staphylococcal prosthetic joint infection and in clinical trials of oral therapy in chronic osteomyelitis, so may have a place in oral treatment, particularly after a period of treatment with intravenous antibiotics.³⁷ When used for staphylococcal infections in particular, antimicrobial susceptibility should be confirmed in vitro, and treatment with fluoroquinolones should be combined with another agent to limit the possibility of quinolone resistance developing during treatment. Fluoroquinolones generally have excellent activity against Gram-negative bacteria and may be the drugs of choice for susceptible Gram-negative infections. Carbapenems, cephalosporins and aminoglycosides may also have a place depending upon the laboratory findings and clinical picture.

Liposomal amphotericin preparations are the drugs of choice for fungal prosthetic joint infections. Rifampicin, sodium fusidate and fluoroquinolones such as ciprofloxacin are well absorbed orally and have been used in combinations for oral treatment or suppression of infection.⁴¹

The optimum duration of antibiotic therapy is unknown. Durations of 4–6 weeks are usually given for revision arthroplasty and longer durations (>3 months) for retained prostheses.³⁸

There are a number of newer antimicrobial agents, including linezolid, daptomycin and tigecycline, but their role in the treatment of orthopedic implant infections is yet to be defined.^{27,42}

PREVENTION

Pooled analysis of four randomized placebo-controlled trials of antibiotic prophylaxis in prosthetic joint surgery demonstrates a 76% reduction in infection (odds ratio 0.24; 95% CI, 0.15–0.37).³² The classic study by Hill et al⁴³ shows that the cumulative benefit of prophylaxis increases the further out the patient is from surgery; 99.5%, 99.3% and 99% of patients randomized to antibiotic prophylaxis remained free of prosthetic joint infection at 12, 24 and 36 months, respectively, compared with 97.5%, 97% and 96% in the control group during the same periods. The duration of perioperative prophylaxis in these trials ranged from 24 h to 2 weeks. Subsequent studies of antibiotic prophylaxis in orthopedic and other types of surgery have shown unequivocally that no added benefit is gained by extending prophylaxis beyond 24 h.^{44,45}

Giving prophylactic antibiotics by other routes, such as incorporation into the polymethyl methacrylate (PMMA) cement, has been examined in several studies. A randomized trial in a large number of primary total hip arthroplasties demonstrated that the use of antibiotic-impregnated cement was equivalent to systemic antibiotic therapy alone; 13 late infections occurred in the systemic antibiotic prophylaxis group and nine in the antibiotic-impregnated cement group.⁴⁶ An analysis of 10 905 cemented primary hip arthroplasties in the Norwegian Arthroplasty Register suggests that combined use of systemic prophylactic antibiotics and antibiotic-impregnated cement is associated with a lower range of infection than either intervention alone (5-year incidence of infection 0.2% in the combined prophylaxis group vs 0.8% with systemic prophylaxis alone, $p = 0.001$).⁴⁷ However, a randomized trial comparing systemic prophylactic antibiotics alone with combined systemic antibiotic/antibiotic-impregnated cement regimens is lacking.

The use of late antibiotic prophylaxis after successful joint implantation to prevent hematogenous prosthetic joint infection, particularly with invasive dental procedures, is a routine practice of most orthopedic surgeons.⁴⁸ However, this has come under scrutiny, given the very low rates of

late hematogenous infection seen in large series (7–11% of all prosthetic joint infections)^{49,50} and the absence of studies demonstrating efficacy or cost benefit.^{51,52} A decision analysis study of antibiotic prophylaxis for dental procedures to prevent prosthetic joint infections concluded that US\$480 000 would need to be spent to prevent a single case of late prosthetic joint infection and that adoption of routine penicillin prophylaxis would actually result in more deaths than not using prophylaxis because of adverse effects from the prophylactic drugs.⁵³ A retrospective study of 3490 patients with prosthetic joints found that only seven developed prosthetic joint infection temporally related to a dental procedure.⁵⁰ Five of these seven had underlying co-morbidity that predisposed them to infection, such as diabetes mellitus or rheumatoid arthritis. Based on these data, recent recommendations for the use of antibiotic prophylaxis in patients with prosthetic joints undergoing invasive procedures include patients with rheumatoid arthritis with a prosthesis implanted within the past year, an overt oral infection, a prolonged dental procedure (>115 min) and, possibly, diabetes mellitus or chronic corticosteroid therapy.⁵⁴

The prevention of infections with troublesome pathogens such as methicillin-resistant *Staph. aureus* (MRSA) has been attempted by decontamination of colonized individuals before surgery⁵⁵ and by the use of selective admission policies to beds ring-fenced for elective orthopedic surgery.⁵⁶ In addition to the use of prophylactic antibiotics, many orthopedic procedures are carried out in theatres supplied with ultra-filtered air over the operating field. The benefits of ultra-filtered air are much reduced when antimicrobial prophylaxis is used. The use of ultraviolet light to sterilize operating room air has also been shown to be effective. There is insufficient evidence to support the cost-effectiveness of use of impermeable clothing or ventilation suits in orthopedic implant surgery.

INFECTIONS ASSOCIATED WITH PROSTHETIC HEART VALVES

Prosthetic valve endocarditis is harder to diagnose and to treat than native valve endocarditis. Prosthetic valve endocarditis develops in 3–6% of patients within 5 years of valve implantation.⁵⁷ The risk of prosthetic valve endocarditis is highest within the first 2–3 months after surgery and then falls to 0.1–0.7% per patient-year thereafter. Prosthetic valve endocarditis has high associated mortality (in excess of 30%) which is highest when endocarditis develops within 60 days of operation.^{57,58} Mitral and aortic valve replacements seem to have similar levels of risk of associated endocarditis. Mechanical valves have a higher incidence of infection in the first 12 months after implantation, whereas bioprosthetic valves have a higher incidence than mechanical valves after 12 months post operation. The overall 5-year risk of infection associated with mechanical and bioprosthetic valves is similar.⁵⁹

CLASSIFICATION

Prosthetic valve endocarditis (PVE) is usually defined as early or late. Many currently favor a cut-off of 12 months post surgery. Infections presenting in the first 2 months after surgery are usually the result of infection during surgery, whilst those occurring up to 12 months may be nosocomial or community acquired. Coagulase-negative staphylococci, *Staph. aureus* and *Enterococcus* spp. are the commonest causes of early PVE.^{58,60} After 12 months, causes of PVE are more likely to be from the same groups of organisms that cause native valve endocarditis. The type of organism causing PVE probably contributes to the worst outcomes associated with early prosthetic valve endocarditis.

DIAGNOSIS

Signs and symptoms associated with PVE are similar to those seen with native valve endocarditis and include fever, new or changing murmur, congestive heart failure, petechiae, splenomegaly, embolic phenomena including strokes or transient ischemic attacks, shock and conduction abnormalities. Osler's nodes, Janeway lesions and Roth's spots are relatively infrequent. The features of presentation are in part related to the causative agent of infection; for example, *Staph. aureus* endocarditis is associated with a neurological event in 25–67% of cases and septic shock in 30%.⁶¹

Blood cultures are the key to identification of the etiological agents of endocarditis. Endocarditis is one of the few conditions associated with continuous bacteremia. A large volume of blood should be collected from the patient (>30 mL from an adult) as soon as the diagnosis is considered and before antimicrobial therapy has been started. When blood cultures remain negative despite strong clinical suspicion of endocarditis, then it is important to consider the possibility of infection with fastidious micro-organisms which require the use of special cultures, molecular or serological tests.

Transthoracic echocardiography detects larger vegetations (>10 mm) and has a sensitivity of <40% compared with a sensitivity of 77–100% for transesophageal echocardiography for the diagnosis of PVE.⁶² Transesophageal echocardiography is also much more sensitive for the detection of perivalvular abscess and valvular dysfunction. There may be advantages of using both transesophageal and transthoracic echocardiography.⁶³ The combination of clinical, laboratory and echocardiographic findings enables a decision on the likelihood of endocarditis to be made by comparison with the Duke criteria scoring system.⁶⁴

TREATMENT

There are many uncertainties with respect to the optimal treatment for PVE with the surgical approach, antimicrobial

choices and the role of anticoagulation.⁶¹ Effective intervention strategies often require a combined medical and surgical approach,⁶⁵ particularly when endocarditis is caused by *Staph. aureus*.⁶⁶ Guidelines on the treatment of PVE are given by both the British Society for Antimicrobial Chemotherapy⁶⁷ and the American Heart Association.⁶⁸

When there is evidence of complicated PVE, such as a new or worsening murmur, progressive congestive heart failure due to valvular dysfunction or abscess, new echocardiographic conduction abnormalities or evidence of intracardiac abscess or fulminant abscess, then treatment should be started as soon as blood cultures have been collected. Empirical treatment of early PVE should include vancomycin to take account of methicillin-resistant staphylococci. In patients who suffered nosocomial bacteremia around the time of prosthetic valve implantation, consideration should be given to covering the microbes associated with bacteremia at that time.⁶⁹

A decision to replace a prosthetic valve requires that a wide range of different factors are taken into account, including cardiac and valvular functional status, evidence of persistent bloodstream infection despite antibiotic treatment, relapse of endocarditis following cessation of treatment, evidence of persistent sepsis despite appropriate antimicrobial treatment for 10 days, and co-morbidities.

The duration of antimicrobial therapy for PVE is longer than for native valve endocarditis as is the duration of combination therapy. The addition of rifampicin to treatment regimens for staphylococcal infection based on experience in osteomyelitis and prosthetic joint infections may be of value. The place of newer agents such as linezolid, a bacteriostatic drug,⁷⁰ and daptomycin remains unclear at the present time.

Fungal PVE frequently requires valve replacement and prolonged antifungal therapy. Liposomal amphotericin combined with 5-flucytosine has been recommended for PVE caused by *Candida* spp. and there is some evidence that prolonged suppressive therapy with oral azoles may reduce the risk of recurrent infection.⁷¹

PREVENTION

Prosthetic valves may be contaminated at the time of surgery or shortly thereafter with seeding as a consequence of bacteremia.⁶⁹ Strategies to reduce the use of invasive medical devices in these patients, such as intravascular catheters and urinary catheters, would be expected to reduce the risk of PVE. Antimicrobial prophylaxis makes an important contribution to reducing the risk of microbial colonization associated with surgery, using antimicrobials with activity against staphylococci such as isoxazole penicillins, cephalosporins and/or aminoglycosides. Surgical technique is also a major factor in determining the risk of PVE.

There is little evidence that use of antibiotic prophylaxis for dental or non-dental procedures reduces the overall risk of endocarditis, so recent guidelines do not recommend the use of prophylactic antibiotics for patients with prosthetic

valves undergoing dental or non-dental surgical interventions, unless the operation is at a site of suspected active infection⁷² (see Ch. 46).

PACEMAKER DEVICE INFECTIONS

Cardiac pacemakers are increasingly used to control heart function. The reported incidence of pacemaker-associated infection varies from 0.1% to 20%, with a mortality of up to 70%.⁷³ Although pacemaker-associated infections can present years after implantation, 25% of infections present within 2 months of implantation. The risk of pacemaker infection may be higher when pacemakers have been replaced than following first implantation. Infections can arise around the pulse generator, along the pacing leads or within an intravascular compartment when there are transvenous endocardial tracking leads. Co-morbidities which predispose to pacemaker infection include diabetes mellitus, malignancy, corticosteroids and skin diseases.⁷⁴ Multiple pacemaker insertions and inexperienced operators are also associated with higher rates of infection.⁷⁵

MICROBIOLOGY

Although the most frequent isolates in pacemaker-associated infections are staphylococci, a wide range of other microorganisms have been reported, including in particular Gram-negative bacilli, propionibacteria and fungi.⁷³

DIAGNOSIS

The clinical presentation of pacemaker infection depends on whether it involves the pulse-generator pocket or the pacing leads. Infection of the pulse-generator pocket typically occurs shortly following implantation or battery exchange, and manifests with localized erythema, pain and fluctuance, occasionally with erosion of the overlying skin.^{74,75} Rarely, migration of infection from the pocket produces pericardial involvement when epicardial pacing leads are used, or bloodstream infection with the use of endocardial pacing leads. Infection of endocardial pacing leads typically presents as a primary bloodstream infection that varies in severity, depending on the causative organism. Coagulase-negative staphylococci tend to cause an indolent febrile illness in contrast to fulminant sepsis with *Staph. aureus*. In either case, signs and symptoms of right-sided endocarditis are often present, including fever and chills (>80%), septic pulmonary emboli (20–45%) and tricuspid regurgitation (25%).^{76,77}

A presumptive diagnosis of a pulse-generator pocket infection can usually be made on clinical grounds alone and is confirmed by a percutaneous aspirate from the pocket that shows micro-organisms on Gram stain or in culture. Diagnosing

infection of an epicardial pacing lead can be more challenging unless bloodstream infection is present. Pericarditis or mediastinitis can usually be diagnosed by CT or MRI. Patients with endocardial pacing lead infections, in addition to manifesting signs of right-sided endocarditis, frequently have persistent bloodstream infection, despite appropriate antimicrobial therapy.^{64,76} Echocardiography shows vegetations on the endocardial leads and/or the tricuspid valve, and is valuable for confirming infection. Transesophageal echocardiography, with a sensitivity that ranges from 90% to 96% (compared with a 22–43% sensitivity seen with transthoracic echocardiography) is preferred.^{76–79}

TREATMENT

Treatment usually requires combined medical and surgical management.⁷³ The overwhelming evidence is that for pacemaker-associated endocarditis the entire pacemaker system should be removed. Recent studies suggest that a new system can be implanted at a different site at the time of removal of the old system without an increase in recurrence rate by comparison with delayed replacement. Open heart surgery may be required to remove endocardial leads that have been in place for long periods.

There are no randomized comparative studies of antibiotic treatment protocols for pacemaker-associated infections. Most recommend treatment durations similar to those used for endocarditis, with antibiotic choice determined by in-vitro testing of isolates. Drugs with activity against methicillin-resistant staphylococci should be used when no organism can be cultured. The American Heart Association recommends 14 days of antimicrobial treatment after device removal and the first negative blood culture and 4 weeks of therapy when there is evidence of *Staph. aureus* bloodstream infection.⁶⁸

PREVENTION

The basic principles for reducing the risk of prosthetic device-associated infection apply to pacemakers (see introductory section). Perioperative antibiotic prophylaxis significantly reduces the risk of pacemaker-associated infection⁸⁰ both for primary procedures and for replacement of infected devices.⁸¹

INTRAVASCULAR DEVICE-ASSOCIATED INFECTIONS

The majority of patients admitted to acute hospitals will have an intravenous catheter placed to facilitate medical care. This may be for administration of fluids, electrolytes, blood products, drugs, nutritional support and for hemodynamic monitoring. Widespread use of peripheral and central venous

access devices have led to these devices becoming the major risk factor for hospital-acquired bloodstream infection.^{82–85} The attributable mortality for these bloodstream infections is up to 25%.⁸⁶

The central vascular catheter infection rate varies from <1 to 15 episodes/1000 days of central line use, depending upon the patient population, type of device and a range of other factors.⁸⁷ The cost of a central vascular catheter-associated infection can be many thousands of dollars per episode, depending upon the virulence of the infecting agent. Complications of vascular access device infections include septic thrombophlebitis, endocarditis, septic shock and the dissemination of septic emboli.

PATHOGENESIS

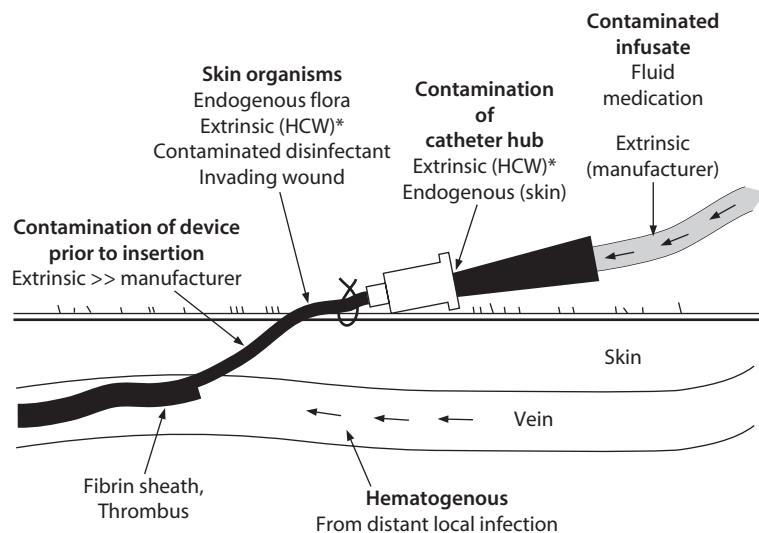

Vascular access device-associated infections can develop as a consequence of contamination of infusates, contamination of the luminal surface of the catheter from hubs and other connections, through migration of micro-organisms from the skin surface along the outside of the catheter, or through bloodstream spread from a distant site^{77,88–90} (Fig. 42.1). There is some evidence that infections which develop in the first 2 weeks after implantation of the device are most frequently derived from migration of bacteria along the outside of the catheter, while those that present 2 weeks or more after implantation are more frequently intraluminal.^{91–93} This is important when considering the potential benefits associated with the use of antimicrobial locks for the treatment of vascular access device-associated infections.

MICROBIOLOGY

Although staphylococci are the most frequent cause of intravascular device-associated infection, there are a wide range of other bacteria (including particularly Gram-negative bacilli and yeasts) that may be associated with intravascular access device-associated infection.

DIAGNOSIS

Diagnostic methods for vascular access device-associated infections have been subject to a recent review by the Infectious Diseases Society of America.⁹⁴ These include recommendations on blood cultures and catheter tip cultures. Clinical findings that point to vascular access device-associated infection include evidence of inflammation at the exit site (particularly when inflammation extends subcutaneously), fever and rigors associated with catheter manipulations, and septic shock in a patient with an intravascular device and without other risk factors for septic shock (e.g. immunocompetent

*HCW: health care worker

Fig. 42.1 Routes of microbial colonization in the pathogenesis of intravascular device-related bloodstream infection.

individuals receiving long-term intravenous feeding following bowel resection for trauma).⁹⁵ The isolation of staphylococci or other skin bacteria from multiple blood cultures, *Bacillus* spp. or fungi would also point to a potential vascular access device source of infection. Semiquantitative culture methods can be used to identify colonization of a device once it has been removed (>15 cfu/mL from a 5 cm segment of the catheter tip).^{89,96} Culture of indistinguishable isolates from blood and from the device is strong evidence implicating the intravascular device in the etiology of bacteremia.^{89,97,98}

In many groups of patients, particularly those with longer-term surgically implanted devices such as Hickman and Broviac catheters, hemodialysis catheters and venous ports, device removal and replacement may carry substantial risks as well as costs. In these groups, since less than half of the episodes of bloodstream infection are related to the intravascular device,^{99,100} considerable emphasis is given to trying to improve diagnostic methods, and even if the intravascular device is thought to be the source of infection frequently attempts will be made to eradicate infection without device removal.

Numerous studies have shown quantitative differences in the concentration of micro-organisms in blood collected through intravascular devices compared with blood collected from a peripheral vein when there is a device-associated infection.^{101–103} A relatively cost-effective way of estimating the differences in microbial numbers between blood collected from a vascular access device and peripheral blood is to use the differential time to positivity.¹⁰⁴ When a blood culture bottle is continuously monitored using an automated microbial growth detection device (as is widely used in diagnostic laboratories) the time to detection of positivity is a function of microbial numbers in the inoculated blood. Assuming that the blood volumes are similar, then detection of positivity in the blood drawn from the intravascular device more than 2 h

before positivity in the blood drawn from the peripheral site is highly predictive of an intravascular device-associated infection. This technique is particularly appropriate for longer-term devices in which infection is frequently intraluminal but probably less effective for short-term intravascular devices where infection may be on the outside of the catheter, or in patient populations in whom antimicrobial substances may be present in samples. When there are large numbers of bacteria in blood drawn through an intravascular catheter these can be visualized using techniques such as acridine orange leukocyte cytoxin staining and this technique can provide a rapid diagnosis.^{99,105} When peripheral blood cultures cannot be obtained, cultures may be drawn through different catheter lumens. A three-fold difference in quantitative blood cultures obtained from different lumens is suggestive of device infection in this instance; the value of differential time to positivity in this setting is uncertain.¹⁰⁶ Other methods that have been used to diagnose intravascular device-associated infection include luminal brushing^{107,108} and quantitative microbial DNA detection.¹⁰⁹

TREATMENT

When a vascular catheter is suspected of being a source of infection and the catheter is no longer strictly required, it should be removed as soon as possible. Short-term vascular catheters can often be removed relatively easily and a new catheter inserted at another site. Long-term central venous devices should be removed when there is evidence of device-associated infection and also persistent exit site infection, infection extending along the tunnel, evidence of endocarditis, septic thrombosis or septic pulmonary emboli, persistent bacteraemia or candidaemia despite appropriate antimicrobial chemotherapy, or when infection is caused by

Staph. aureus-resistant species such as JK corynebacteria, *Stenotrophomonas* spp., *Burkholderia* spp., *Pseudomonas* spp., *Mycobacterium* spp., filamentous fungi or *Malassezia* spp. There are significant rates of recurrent bloodstream infection; for example for coagulase-negative staphylococcal vascular access device-associated infection, the risk of recurrent bacteraemia is c. 20%.¹¹⁰ Studies have shown an increased mortality rate in patients with vascular access device-associated candidemia when the catheter is left in place compared with prompt removal. This is a particular concern in infants.^{111,112}

If the vascular access device is left in place, it is mandatory that the patient receives antibiotics through the infected line. There is some evidence that antibiotic locks can improve the outcome for patients, in particular by reducing the risk of recurrent infection.^{113–117} Although there is a lower risk of infection associated with venous ports, there is also evidence that treatment of port-associated infections is less likely to be effective (without device removal) than infections associated with transcutaneous venous catheters.^{118,119} Initial therapy for suspected intravascular device-associated infection should usually incorporate an agent with activity against methicillin-resistant staphylococci (probably a glycopeptide) and an agent with activity against Gram-negative bacilli. Initial therapy can be modified based on microbial isolates and their susceptibilities. The duration of treatment for uncomplicated intravascular device-associated infections is usually in the range of 7–10 days. Complications such as endocarditis may require much longer durations of treatment. *Staph. aureus* vascular access device-associated infection requires a longer duration of treatment. In immunocompetent patients and when the device has been removed it may be possible to restrict the duration of antibiotic treatment to 14 days. In immunocompromised patients, or where there is evidence of complications such as endocarditis, treatment should be given for a minimum of 4 weeks.^{120,121}

Fluconazole can be used for candida vascular access device-associated infection in non-neutropenic patients¹²² following removal of the intravascular device. In immunocompromised patients, those with complicated infections or those with infections caused by fluconazole-resistant species or strains, current evidence favors the use of amphotericin preparations.^{123,124} The place of newer antifungal agents such as caspofungin and voriconazole is yet to be defined.

Patients may develop recurrent bloodstream infection weeks or months after treatment for vascular device-associated bloodstream infection and this may be associated with other complications such as endocarditis, retinitis and vertebral osteomyelitis.^{123,125,126}

PREVENTION

Widespread recognition of the costs and consequences of infection associated with intravascular devices has led to the development of practices which reduce these risks

and these have been included within strategies to improve patient safety such as the ‘Saving 100 000 Lives’ campaign in the USA.¹²⁷ Risk reduction measures include the use of barrier precautions for central venous catheter insertion (such as sterile gloves), chlorhexidine-based skin disinfection pre-implantation of the device, improved device designs such as Hickman or Broviac catheters which incorporate a Dacron cuff (which provides a mechanical barrier to microbial migration from the skin surface along the outside of the intravascular device), use of novel dressings, and the use of antimicrobial locks. Chlorhexidine preparations have been shown to be superior to povidone-iodine for skin decontamination prior to device insertion and are also now recommended for decontamination of hubs and connections.^{128,129} Two percent chlorhexidine may be more effective than lower concentrations.¹³⁰

Trial data suggest that chlorhexidine-impregnated sponge dressings reduce the risk of vascular access device-associated bloodstream infection in patients with short-term central venous catheters.^{131–133}

Antimicrobial venous catheters

A number of antimicrobial impregnated venous catheters have been marketed over the last 10 years. The antimicrobials that have been incorporated have included silver sulfadiazine with chlorhexidine,^{134,135} minocycline–rifampicin,⁹⁸ micro-dispersed silver^{136,137} and silver–platinum.^{138,139} Heparin bonded to venous catheters with benzalkonium chloride has also been shown to reduce microbial colonization.^{140–142} A recent systematic review concluded that heparin-coated or antibiotic-impregnated central venous catheters are more effective at preventing bloodstream infection than those using chlorhexidine and silver sulfadiazine or silver impregnation.¹⁴³

Antimicrobial locks

It is not clear that prophylactic use of systemic antibiotics at the time of vascular access device implantation reduces the risk of device-associated infection.¹²⁹ Continuous infusion of vancomycin in intravenous feeding solutions has been shown to reduce the rates of coagulase-negative staphylococcal bacteraemia in low birth weight infants¹⁴⁴ but runs the theoretical risk of promotion of antibiotic resistance.

A number of randomized controlled trials have shown that rates of bloodstream infection can be greatly reduced by using antimicrobial lock solutions. Recent meta-analyses support the use of antimicrobial locks to prevent infection in patients with long-term devices.^{145,146} These lock solutions have both anticoagulant and antimicrobial activities. Solutions that have been used include heparin with vancomycin 25 µg/mL ± ciprofloxacin (2 µg/mL), minocycline EDTA, taurolidine citrate and trisodium citrate. The benefits of use of antimicrobial locks is increasingly recognized within best practice guidelines.¹²⁹

INFECTIONS ASSOCIATED WITH CEREBROSPINAL FLUID SHUNTS AND EXTERNAL DRAINAGE DEVICES

The pathological consequences of an excess of cerebrospinal fluid (CSF) within the ventricles of the brain can be ameliorated by draining the CSF to the exterior or to a distant body cavity from which it can be reabsorbed. Types of CSF shunt are shown in Figure 42.2.

CEREBROSPINAL FLUID SHUNT-ASSOCIATED INFECTION

Implantation of a CSF shunt is amongst the most frequent of neurosurgical procedures.¹⁴⁷ Although infection is a common complication associated with shunts,^{148,149} rates may have declined in recent years.^{150–153} The highest risks of infection are at the extremes of age (preterm infants and the elderly).^{154,155} There is a significant mortality associated with CSF shunt infections^{156,157} in addition to the other adverse consequences of prolongation of hospital stay and associated morbidities such as an increased risk of seizure disorders.¹⁵⁸ Internalized shunt systems may have a reservoir to allow access to the CSF such as an Omaya reservoir and may also have valve systems to regulate pressure and flow. The rates of infection between ventriculoatrial and ventriculoperitoneal shunts are similar.¹⁵⁹

A number of risk factors have been identified for shunt-associated infections and these include CSF leak, infant maturity and breaches in surgical technique.^{160,161} The pathogenesis of CSF shunt infections is probably similar to that of other implant-associated infections, micro-organisms being derived from intraoperative colonization, hematogenous seeding¹⁶² or retrograde spread of infection along the catheter from a distant site.^{148–150,163} The benefits of prophylactic intraoperative antibiotics suggest a significant proportion of infections arise at the time of the implantation of the device (see Prevention, below).

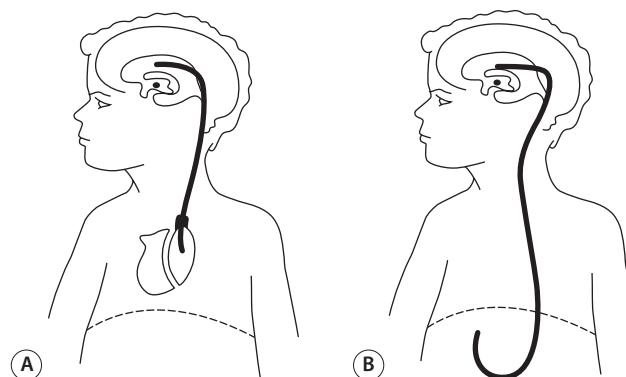

Fig. 42.2 Schematic of (A) ventriculoatrial (VA) and (B) ventriculoperitoneal (VP) cerebrospinal fluid shunts.

Microbiology

The great majority of shunt infections are caused by staphylococci^{148,164,165} and, more rarely, Gram-negative bacilli. The latter are associated with high rates of morbidity and mortality.¹⁶⁶ A wide variety of microbes have been associated with shunt infections, reflecting the various potential routes of infection and individual patient risk factors.^{167–169}

Diagnosis

Clinical signs and symptoms of CSF shunt-associated infections may be non-specific and include fever, headaches and lethargy. Classic signs of meningitis such as neck stiffness are present in a minority of patients.^{170,171} There may be signs and symptoms related to the drainage site, so there may be intracardiac lesions and complications associated with intracardiac infections with ventriculoatrial shunts^{172,173} and signs and symptoms of abdominal disease with those with ventriculoperitoneal shunts.^{174,175} Blood cultures are frequently positive in patients with ventriculoatrial shunt-associated infections but infrequently positive in those with ventriculoperitoneal-associated infections.^{149,176}

CSF changes may not be dramatic, with median CSF white cells counts of <100 cells/mm³.¹⁴⁹ The classic CSF findings of a high white cell count, raised CSF protein and low CSF:serum glucose ratio are often not seen in external ventricular drain (EVD) infections.¹⁷⁷ There are some data suggesting that levels of CSF lactate or serum procalcitonin may be useful in identifying individuals with bacterial EVD infections.¹⁷⁸ CSF culture may also be negative, particularly when collected by lumbar puncture. Positive microbial cultures are more frequent when CSF is directly aspirated from the shunt.¹⁷⁹ Radiological imaging can be helpful, particularly when there is involvement of the drainage site.

Treatment

The optimum approach to treatment of CSF shunt infection is complete removal of the shunt system with or without external CSF drainage through a ventriculostomy catheter if required.^{148,156,176,180} Attempted treatment of shunt-associated infections without removal of the shunt is associated with much lower cure rates, extended hospital stay and a greater risk of patient death. Bacterial meningitis following bloodstream invasion of meninges can be successfully treated without shunt removal.¹⁵⁹ The optimum therapy for shunt-associated infections is not defined. As the majority of agents of infection are methicillin-resistant staphylococci, vancomycin is appropriate both for empirical treatment and following determination of microbial susceptibility. Rifampicin is frequently added because of its high levels of CSF penetration and its activity against biofilm-associated microbes.^{37,181–183} For Gram-negative infections, imipenem is best avoided because of the risk of seizures.¹⁸⁴ Fourth-generation cephalosporins and meropenem are usually well-tolerated and reach supra-inhibitory concentrations in the CSF.

It is unclear the extent to which intraventricular antibiotics improve outcomes for patients. Intrathecal aminoglycosides and glycopeptides have been widely used in the treatment of shunt infections but there are no randomized controlled trials that have confirmed the benefit. A study in neonates with Gram-negative meningitis showed a higher mortality in infants given intrathecal gentamicin than in those given systemic gentamicin.¹⁸⁵ Many centers which use intrathecal aminoglycosides also measure drug levels in the CSF but, again, the relationship between levels and toxicity or patient outcome have not been defined.^{186–188} When vancomycin is used intrathecally it is usually administered in doses of 5–20 mg every 24 h and again there are no trial data on the relationship between drug concentrations in the CSF and either toxicity or outcome.

Infection with multiresistant Gram-negatives can present particular challenges; for example, carbapenem-resistant *Acinetobacter baumanii* is an increasingly common cause of infection following intensive care unit admission for head trauma. Isolates may be resistant to a wide range of agents with few available options for treatment. Combined use of intrathecal and intravenous polymixins may be the only available treatment options in addition to removal of colonized device components.¹⁸⁹ Linezolid achieves high levels in the CSF and there are increasing reports of success in the treatment of multidrug-resistant Gram-positive ventriculitis where conventional approaches have failed.¹⁹⁰

Prevention

Attempts to reduce the frequency of shunt-associated infection have included extreme measures to avoid contamination of the shunt or components¹⁹¹ and a variety of changes to perioperative protocols.¹⁹² There is evidence that preoperative shaving increases the risk of shunt-related infections.¹⁹³ Recent systematic reviews have concluded that systematic antibiotic prophylaxis does reduce the incidence of shunt-associated infection.¹⁹⁴ Antibiotics used in prophylaxis studies have included trimethoprim with sulfamethoxazole, trimethoprim with rifampicin and cephalosporins such as cefuroxime which achieves superinhibitory CSF concentrations. The use of antibiotic-impregnated shunts has also been associated with a reduction in the frequency of shunt infection.^{195,196}

EXTERNAL VENTRICULAR DRAIN (EVD)-ASSOCIATED INFECTION

Infection at the exit site is the most frequent infective complication of an EVD followed in decreasing order of frequency by ventriculitis, cerebritis, subdural empyema, osteomyelitis and complications consequent on the dissemination of infection.¹⁹⁶ Over 8% of patients with an EVD will develop positive CSF cultures.¹⁹⁷ Risk factors for infection include prolonged duration (>5 days) and irrigation.^{198,199} Although algorithms describing the management of EVD-related ventriculitis have

been published,¹⁹⁶ it is important to base antibiotic choices on the prevalent causes of infection in a local context.

CATHETER-ASSOCIATED URINARY TRACT INFECTIONS

Twenty-five percent of patients will have a urinary catheter inserted at some time during their hospital stay.²⁰⁰ Rates of colonization of urinary catheters approach 100% by 30 days of catheterization and consequent urinary tract infection is a major cause of morbidity and mortality in individuals with long-term urinary catheters. The risk of catheter-associated urinary tract infection is higher in females than in males, in patients with co-morbidities (e.g. diabetes) that predispose to infection, when other foreign bodies are associated with the urinary drainage systems such as stents, and with increasing duration of catheterization. The costs associated with catheter-associated urinary tract infection are relatively low by comparison with many other hospital-acquired infections,²⁰¹ however, the aggregated costs are considerable. Urinary tract infections accounted for nearly 20% of hospital-acquired infections in a recent UK prevalence study²⁰² and catheterization was the major risk factor in that study.

Silver alloy-coated urinary catheters have lower rates of catheter-associated infection than non-coated catheters.²⁰³ Although tricosan has been shown to reduce biofilm formation on urinary catheters,²⁰⁴ intrinsic and acquired tricosan resistance preclude the use of tricosan as a routine preventive strategy.²⁰⁵ Shanks et al have reported that heparin may promote biofilm formation by *Staph. aureus*.^{206,207} Whether or not this is an important effect in patients is not known at this time.

Pathogenesis

Micro-organisms may contaminate the urinary catheter at the time of insertion or may migrate extraluminally from the per urethral area or intraluminally as the result of contamination of connections. Catheter-associated urinary tract infections are usually associated with the formation of biofilm on the catheter but can occasionally arise, particularly if there is back-flow of urine from a catheter drainage bag allowing inoculation of the bladder with large numbers of micro-organisms.

Microbiology

Patients with long-term urinary catheters who receive repeated courses of antibiotics for suspected catheter-associated infection or for other reasons are frequently colonized with antibiotic-resistant Enterobacteriaceae, *Ps. aeruginosa*, enterococci, staphylococci and/or fungi.

Diagnosis

Clinical criteria are an unreliable basis for the diagnosis of catheter-associated urinary tract infection. A patient with a

transurethral catheter will not have dysuria and frequency, and suprapubic tenderness may be attributable to the irritating effects of the catheter on the bladder. Elderly patients particularly may not be febrile even in the presence of life-threatening infections.²⁰⁸

Bacteriuria may be a consequence of catheter colonization with or without associated infection. Pyuria has a high specificity for symptomatic catheter-associated urinary tract infection but may not be present in a large proportion of patients with symptomatic bacteriuria,²⁰⁹ particularly when there is infection with Gram-positive cocci or yeasts.²¹⁰ Tests that may be useful in non-catheterized patients, such as for leukocyte esterase and bacterial nitrite, perform poorly in the catheterized patients.²¹¹

Treatment

Bacteriuria is common in patients with long-term urinary catheters, yet in the majority treatment is rarely required.²⁰⁹ Treatment of asymptomatic catheter-associated bacteriuria has not been shown to be of benefit and may actually be detrimental to patients^{212,213} other than in the context of pregnancy or urological procedures.²¹⁴ Unnecessary antibiotic treatment promotes colonization with antimicrobial-resistant species and increases the risk of antibiotic-associated complications such as *C. difficile* diarrhea.

In patients with signs and symptoms that may be attributable to urinary tract infection, and in the absence of other sources of infection, it may be reasonable to initiate antibiotic therapy which can be modified if required following the results of in-vitro sensitivity testing. In a recent study²¹⁵ in a large teaching hospital in the USA, it was found that over 30% of patients treated with antibiotics for catheter-associated bacteriuria did not have symptoms or signs consistent with infection, and were considered to have been inappropriately treated with antibiotics. It may be appropriate to treat asymptomatic catheter-associated bacteriuria in some specific groups of patients such as those who are immunocompromised²¹⁶ but these groups are exceptional. Recent guidelines have advocated that urine samples should not be routinely sent for microbiological testing from asymptomatic catheterized patients²¹⁷ because of the tendency of clinicians to prescribe on the basis of microbiological findings.

Prevention

There are few randomized controlled trials of prevention strategies for catheter-associated urinary tract infection. Avoiding unnecessary catheterizations, ensuring that trained professionals insert and care for urinary catheter systems, use of closed and dependent drainage systems, and avoidance of prolonged periods of catheterization all probably contribute to reducing the risk of catheter-associated urinary tract infection though with little support from randomized controlled trials.

Antimicrobial prophylaxis may reduce the frequency of catheter-associated urinary tract infection in patients with short periods of catheterization but this practice may lead to infections with difficult to treat antibiotic-resistant bacteria and yeasts and is probably best avoided.²¹⁸ Other practices which are best avoided because of lack of benefit or detriment to patients²⁰⁰ include the use of anti-infective lubricants for catheter insertion, soaking the catheter in antimicrobial agents before insertion, use of topical agents of disinfection to the urethral meatus, continuous irrigation of the bladder and periodic instillation of anti-infectives into the bladder or collection system,²¹⁹ and closed catheter drainage systems with sealed connections.²²⁰

A number of antimicrobial urethral catheters have been developed and evaluated, several of which have been shown to be associated with a lower risk of catheter-associated urinary tract infection, including in particular silver hydrogel catheters.^{221,222} A recent systematic review²²³ concludes that antimicrobial urinary catheters can prevent or delay the onset of catheter-associated bacteriuria. The systematic review suggested that there may have been systematic overestimation of the effect sizes in many of the randomized and quasi-randomized trials reviewed because of drop-outs and exclusions. The effects of antimicrobial catheters on substantive outcomes such as bloodstream infection are also not known.

INFECTS ASSOCIATED WITH PERITONEAL DIALYSIS CATHETERS

Over the last 30 years dialysis through peritoneal catheters has become the treatment of choice for many patients with end-stage renal disease. The major complication associated with peritoneal dialysis is peritonitis. Sixty percent of patients undergoing peritoneal dialysis will develop an episode of peritonitis within the first 12 months following initiation of dialysis.²²⁴ Recurrent episodes of peritonitis compromise the ability of the peritoneum to act as the dialysis membrane and is the common reason for patients being transferred to hemodialysis.

Peritonitis is a more frequent complication than catheter exit site or tunnel infection, suggesting that spread of microorganisms from connections along the lumen of the catheter is the most important route of infection.²²⁵ Nasal carriers of *Staph. aureus* are more likely than non-carriers to develop both exit site infections and peritonitis.²²⁶ Dilution of host defense elements such as immunoglobulin and complement and the relatively high osmolality and low pH of the dialysate probably increase the risk of dialysis-associated peritonitis.²²⁷

Microbiology

Although the majority of peritonitis cases are associated with isolation of coagulase-negative staphylococci from peritoneal fluid samples, a wide range of other microbes have been associated with peritonitis, as has been reported with other

transcutaneous devices. *Staph. aureus* is particularly associated with exit site and tunnel infections.²²⁸

Diagnosis

Signs and symptoms include cloudy dialysate and abdominal pain or tenderness and fever.²²⁸ Shock is unusual in association with coagulase-negative staphylococcal peritonitis but may be a feature of peritonitis caused by Gram-negatives and *Staph. aureus*.

Exit site and tunnel infection may be diagnosed by local signs and symptoms. Laboratory findings include a raised dialysate white cell count of >100 cells/mm³. White cells are usually predominantly neutrophils but may be dominated by other cell types when peritonitis is caused by unusual pathogens such as mycobacteria or fungi.²²⁸

Treatment

Current guidelines suggest that overall >80% of peritoneal dialysis-associated peritonitis should be cured without removal of the peritoneal catheter.²²⁹ Intraperitoneal antibiotics achieve suprainhibitory concentrations both in the peritoneal cavity and in the bloodstream. A recent systematic review of treatment of peritoneal dialysis-associated peritonitis showed that intraperitoneal antibiotics were effective and (based on the results of one study) perhaps more effective than intravenous antibiotics in reducing treatment failures. A number of different intraperitoneal antibiotic regimens were effective.²³⁰ Empirical regimens can include cephalosporins with or without an aminoglycoside.²³¹ It is probably not necessary to use a glycopeptide unless there is evidence to support infection with MRSA or resistance to the empirical regimen is reported by the laboratory. Aminoglycosides are probably best avoided in patients with residual function (urine output >100 mL per day).²³²

Removal of the dialysis catheter may be necessary to control infection or to prevent recurrent infection which is particularly likely with *Staph. aureus*, *Ps. aeruginosa* and fungal infection. The optimal antimicrobial therapy for fungal peritonitis has not been defined. Fluconazole combined with flucytosine can be effective for susceptible strains.²²⁸ The role of newer antifungals such as voriconazole, caspofungin and liposomal amphotericin preparations is ill-defined.

Prevention

The 2005 International Society for Peritoneal Dialysis guidelines²²⁹ make specific recommendations for the prevention of peritoneal dialysis-related peritonitis. These emphasize the importance of surveillance of infection rates, the use of prophylactic antibiotics at the time of insertion of the device, recommendations for minimizing exit site care that target the control of *Staph. aureus* and requirements for training, including training

in practical methods (particularly for connection and disconnection), minimizing the risk of translocation of micro-organisms from the bowel and criteria for use of antifungal prophylaxis.

The use of a Y connection allows simultaneous connection of the drainage and infusion bags, minimizing the number of connections and disconnections that have to be made. Randomized trials have shown a reduction in the rate of peritoneal dialysis-related peritonitis when these Y connections are used.²²⁵ These types of system have become further refined.²³³

Application of antimicrobials around the cannula exit site has been shown to reduce the risk of *Staph. aureus* exit site and tunnel infections but there are some concerns about the long-term consequences of this strategy, particularly with respect to the selection of antibiotic resistance.²³⁴ Strategies involving anti-staphylococcal immunizations have so far been unsuccessful in reducing either exit site infections or peritonitis.²³⁵

43 Antiretroviral therapy for HIV

Anton Pozniak

Before 1988 the management of HIV was primarily the treatment and prevention of opportunistic infections. When zidovudine became available on compassionate grounds to those patients with AIDS, the era of antiviral therapy for HIV began. Early studies with zidovudine monotherapy showed short-term benefits in symptomatic patients in delaying disease progression¹ and the results of one of the first AIDS treatment trials, ACTG 019, suggested that even asymptomatic patients with a CD4 count of less than 500 cells/mm³ should be treated.² However, by 1993, the usefulness of HIV treatment was questioned. The results of the Concorde trial indicated little benefit in early intervention³ and ACTG 155⁴ showed no advantage of dual therapy with zidovudine and zalcitabine over zidovudine or zalcitabine monotherapy, generating a mood of therapeutic pessimism.

All that changed by mid-1995, when the results of several large-scale prospective studies proved that dual nucleoside analog regimens, especially zidovudine–didanosine, effectively delayed disease progression and prolonged life. Both the Delta and ACTG 175 trials^{5,6} established the superiority of dual therapy over monotherapy and paved the way for the understanding of the importance of the use of surrogate markers, particularly viral load and CD4 levels, in measuring the efficacy of a regimen as well as the role of resistance in virological failure. At the same time, phase II studies of another dual nucleoside regimen with zidovudine and lamivudine demonstrated impressive CD4⁺ and viral load benefits up to 1 year of follow-up.⁷ Dual nucleoside-reverse transcriptase inhibitor (NRTI)-based regimens became commonplace, and AIDS-related mortality began to decrease.

In 1996, treatment of HIV changed dramatically for several reasons:

- First, there was an improved understanding of the pathogenesis of HIV infection.
- Second, tests became available to measure plasma HIV RNA levels down to below 1000 copies/mL.
- Third, a new and powerful class of drugs, the protease inhibitors, was introduced which, when added to the two nucleoside ‘backbone’ analogs, were capable of completely suppressing plasma HIV RNA levels. At the 10th International Conference on AIDS in 1996, the optimism surrounding the results of these triple drug regimens led to a belief that eradication of the virus and a cure was possible.

As a result of increasing use of this highly active antiretroviral therapy (HAART), hospital admission rates for HIV-related complications and mortality rates decreased dramatically, AIDS hospice units closed and patients returned to work. Opportunistic infections, such as those caused by cytomegalovirus (CMV), *Mycobacterium avium* complex (MAC) and toxoplasmosis became exceedingly rare.⁸ Published data in the late 1990s estimated the mortality rate in patients with CD4 counts of less than $100 \times 10^6/\text{L}$ had fallen by nearly two-thirds to less than 8 per 100 patient-years. In stark contrast at this time of hopes and expectations the epidemic rose exponentially in the resource-poor world where there was little access to HIV therapies and diagnostics. The global pandemic of HIV was established.

Further pathogenesis studies documented reservoirs of HIV in latently infected resting T lymphocytes and other long-lived cell populations, making it unlikely that HIV could be eradicated by antiretroviral therapy alone.⁹ Strategies to sustain suppression of viral replication in the long term were required. Drug development concentrated on therapy that was potent, simple to adhere to, and could be used against resistant strains. The non-nucleoside analogs with their low pill burden, lack of food requirements and a perceived lack of long-term toxicity made them an increasingly common first-line treatment option. New classes of drugs blocking HIV entry such as fusion inhibitors, chemokine receptor antagonists and HIV integrase inhibitors preventing HIV from being integrated into host DNA are now available in the clinic.

In addition to drugs that inhibit targets in the viral replication cycle, immunotherapeutic approaches have been assessed using the cytokine interleukin (IL)-2 which results in increases in CD4 counts but had no impact on clinical outcome in trials where it was used in combination with antiretroviral regimens as the CD4 cells were non-functional.¹⁰⁻¹²

Therapeutic vaccines are also being pursued, which might improve specific immune responses and assist immunological control of HIV replication. Their clinical effectiveness remains unknown.

Sustained inhibition of viral replication results in partially reconstituting the immune system and substantially reducing the risk of clinical progression and death. The long-term efficacy of current antiretroviral regimens is becoming clearer and patients who have successful control of HIV therapy can live relatively normal life spans; for

example, a 20-year-old individual starting HAART can expect to live for another 43 years on average, and a 35-year-old can expect 32 more years of life.

Mortality rates become similar to that of the general population after the sixth year of follow-up among patients whose CD4 counts reach 500 cells/mm³.¹³ It appears that patients have to take therapy lifelong and that interruptions in therapy are associated with an increased risk of cardiovascular events.^{14,15} Patients' adherence to current regimens has to be very high to ensure virological success and limit the risk of resistance emerging.

Although antiretroviral therapy is extremely successful, there are still many challenges and problems, some of which are emerging, such as long-term metabolic, bone and cardiovascular complications of therapy.^{16–18} For parts of the world with the highest HIV rates the problem is still access to therapy, monitoring and medical care.

INITIATING ANTIRETROVIRAL THERAPY

AIMS OF TREATMENT

With currently available antiretroviral agents, eradication of HIV infection is not likely to be possible;¹⁹ thus, the aim of treatment is to prolong and improve quality of life by maintaining suppression of virus replication for as long as possible.

The objective of antiretroviral therapy is to reduce and sustain plasma viral load levels to below the level of detectability (<50 copies/mL). If patients are adherent to therapy, the likelihood of a viral load rebound and drug resistance is minimal. However, in spite of inhibition of viral replication in plasma, lymph nodes and other sites, reservoirs of HIV infection in latently infected resting macrophages and T lymphocytes remain. Bursts of viral replication from these reservoirs can be detected in patients with long-term viral suppression but whether or not new cells continue to be infected as a result of these bursts is still an area of debate. However, even in patients who have sustained, undetectable levels of plasma viral load for several years, discontinuation of antiretroviral therapy results in rapid rebound of plasma viral load to pre-treatment levels.²⁰

The three groups of treatment-naïve patients for whom treatment might be considered are patients with primary HIV infection, patients with asymptomatic HIV infection and patients with symptomatic HIV disease or AIDS.

PRIMARY HIV INFECTION

The burst of viremia in acute primary HIV infection usually resolves in 2 months and this period is the focus of research into giving early treatment. There is a rationale for treatment during the 2- to 6-month period after this, so-called recent primary HIV infection, and it is based on the probability that virus replication in lymphoid tissue is still not controlled during this time.²¹

Clinical trials information regarding treatment of acute HIV infection is limited.²² Multiple studies have shown conflicting results of therapy with varying short-term effects on immunological markers.²³ A randomized prospective study is needed to weigh the risks and long-term benefit of treatment regimens initiated during acute infection. This strategy is being examined by the Medical Research Council (MRC) SPARTAC study and results are anticipated in 2010.

The rationale for starting treatment during or shortly after infection is to attempt to maintain specific and robust CD4 helper HIV responses,^{24–27} which are generally lost, with the exception of long-term non-progressors²⁶ with chronic HIV infection.²⁸ Such immune responses appear to be maintained in people treated with potent antiretroviral therapy shortly after primary HIV infection. Some data suggest that there is more rapid and complete immune reconstitution in patients starting therapy during primary infection than in those starting treatment later.²⁹ There is, however, no evidence to date that any of these immunological benefits persist indefinitely with continuing treatment or after treatment is withdrawn.

Potential benefits of treating acute HIV infection

Decrease the severity of acute disease and reduce morbidity associated with high viraemia and CD4 depletion during acute infection

Reduce the risk of onward transmission of HIV

Limit loss of CD4-rich gastrointestinal lymphoid tissue that occurs during the first weeks of infection, although data are limited and the clinical relevance is unclear^{30,31}

The possible benefits of treatment during primary infection with HIV should be considered against the known risks of drug toxicity,^{32,33} the associated risk of development of drug resistance and the difficulties of long-term adherence. The optimal duration or optimal drugs to use in therapy for patients with acute or recent HIV infection is unknown. The potential need for lifelong treatment should be a consideration in making the decision to treat or not. As non-nucleoside reverse transcriptase inhibitor (NNRTI) transmitted resistance is more commonly seen than protease inhibitor (PI) transmitted resistance, a protease inhibitor-based regimen should be given until drug resistance test results are available.

While data are lacking a pragmatic approach would be to consider treatment of primary infection outside a prospective study when patients have neurological involvement, any AIDS-defining illness or a CD4 cell count persistently <200 cells/mm³ (i.e. for 3 months or more).³⁴

CHRONIC HIV INFECTION

The aims of antiretroviral therapy are to reduce the viral load which will lead to improved and/or preserved immune function and consequently reduce HIV-associated morbidity and mortality. Another possible benefit that is being explored is the potential to reduce HIV transmission, especially if there are continued high-risk behaviors.³⁵

Delaying therapy until the CD4 cell count is <200 cells/mm³ is associated with a substantially greater risk of disease progression and death. As the risk persists for a significant period after treatment is started, every effort should be made to start treatment before the CD4 cell count has fallen to <200 cells/mm³.

Symptomatic HIV infection

International guidelines recommend initiation of antiretroviral therapy in patients with a history of AIDS-defining illness or symptomatic HIV infection. One exception to this might be someone with tuberculosis who presents with a high CD4 count when the TB may be not a manifestation of immune suppression.

Asymptomatic disease

The timing of antiviral therapy in patients who are asymptomatic is an area of active debate and research. Until we have the results of a controlled, prospective study comparing early and deferred therapy (START trial), treatment guidelines rely largely on data from observational cohort studies.^{6,7} Currently, these guidelines state that the optimal time to start therapy for an asymptomatic patient is around a CD4⁺ count of 350 cells per cubic millimeter (mm³).

Most physicians will use this 350 CD4 cell threshold as the main criterion for starting, but should patients or subgroups of patients start earlier than that? One of the driving forces for considering starting earlier is the impact of non-AIDS-related morbidity and mortality because of the effect of viremia on driving inflammatory and neoplastic processes independent of the CD4 count.

The SMART study helped us to understand this concept of viremia being harmful. SMART was a prospective, randomized, multicenter, cohort study, comparing treatment being discontinued when the CD4 T-cell count exceeded 350 cells/mm³ and reinitiated when the CD4 T-cell count fell to <250 cells/mm³ with continuous antiretroviral therapy. Mortality was largely due to causes other than AIDS, and several non-AIDS-defining conditions such as hepatic failure, renal disease, cardiovascular disease and non-AIDS malignancy were greater in participants randomized to treatment interruption than in those who received continuous therapy.^{36,37}

When a subgroup analysis of the SMART study (in which treatment-naïve patients with CD4 T-cell counts of >350 cells/mm³ were randomized to receive antiretroviral therapy either immediately or after the CD4 T-cell count dropped to <250 cells/mm³) was analyzed, the risk of opportunistic diseases and serious non-AIDS events was higher in the deferred-therapy arm than in the treatment arm, suggesting that delaying therapy until the CD4 T-cell count decreases to <350 cells/mm³ should be avoided.³⁸

A large observational cohort, the North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD),³⁹ showed that in the 8362 patients with a CD4⁺ count of 351–500 cells/mm³, deferral of therapy until

the CD4⁺ count had fallen to 350 cells/mm³ or less was associated with an increase of 69% in the risk of death, as compared with patients who initiated therapy when their CD4⁺ count was within the designated range. The majority of deaths for which cause was available were from ‘non-AIDS-defining’ causes and thought to be due to the inflammatory effect of HIV itself.

Other data sets support the notion of starting earlier but consider that the advantage of starting above 500 cells/mm³ rather than somewhere between 500 and 350 cells/mm³ may be small.⁴⁰

Other reasons for starting HAART early

Patients with a rapidly falling CD4 count (e.g. falling by >80 cells/mm³ per year on repeated testing) should be considered for initiation of therapy relatively earlier within the CD4 count range 350–500 cells/mm³

AIDS diagnosis (or any HIV-related co-morbidity)

- hepatitis B and C infection, where treatment is indicated or contemplated
- low CD4 percentage (e.g. <14%, where *Pneumocystis jirovecii* prophylaxis would be indicated)
- established cardiovascular disease (CVD) or a very high risk of cardiovascular events (e.g. Framingham risk of CVD more than 20% over 10 years)

Pregnant women

Persons with HIV-associated nephropathy

Potential benefits and risks of early therapy

Potential benefits

- Maintain a higher count and potentially prevent further irreversible damage to the immune system
- Decrease the risk for HIV-associated complications that occur even at high CD4 counts (e.g. tuberculosis, lymphoma, peripheral human papillomavirus-associated malignancies, neuropathy)
- Decrease the risk of non-AIDS-associated diseases such as cardiovascular disease, renal disease, liver disease, and non-AIDS-associated malignancies and infections
- Decrease the risk of HIV transmission to others

Potential risks

- Development of side effects and toxicities of treatment
- Development of drug resistance which may result in loss of future treatment options
- Treatment fatigue because of increased total time on medication
- Transmission of drug-resistant virus in patients who do not maintain full virological suppression

THERAPEUTIC STRATEGIES IN THE TREATMENT-NAÏVE PATIENT

The very dramatic fall in AIDS-related mortality and frequency of AIDS events in the developed world coincided with the introduction of HAART.⁴¹ Any HAART regimen should be individualized in order to achieve the best potency, adherence⁴² and tolerability, to minimize potential toxicity, and to avoid any likely drug-drug interactions. A measurement of a

regimen's success is achieving a viral load of <50 HIV-1 RNA copies/mL within 6–9 months of starting treatment.

BASELINE ASSESSMENT

Before starting treatment patients should be counseled about adherence and given appropriate information on the drugs they may be taking and their side effects.

A baseline assessment should be performed and should include HIV resistance testing to detect transmitted resistance screening for hepatitis B and C co-infection, routine hematology and biochemistry tests, a sexually transmitted infection screen and other tests as appropriate including co-receptor tropism and HLA B5701.

In addition, a full cardiovascular risk assessment should be undertaken and patients should be screened for diabetes and renal problems. A psychosocial history should also be taken to identify psychiatric problems, alcohol use and recreational drug use as well as safer sex knowledge and practice. A social and adherence assessment is essential.

In women of childbearing age, a discussion around plans for pregnancy and the use of contraception is important.

WHICH REGIMEN TO START?

When choosing a HAART regimen the advantages and disadvantages in terms of potency, adherence, toxicity and potential drug–drug interactions should be considered for each patient and therapy individualized accordingly.

Drug regimens that might be considered for a patient initiating antiretroviral therapy for the first time are listed below:

- A low-dose ritonavir ‘boosted’ protease inhibitor and two nucleo(t)sides
- A non-nucleoside reverse transcriptase inhibitor (NNRTI) such as efavirenz and two nucleo(t)sides
- Others include nucleo(t)side-sparing or integrase-based regimens, but these have been rarely used to date outside clinical trials.

TWO NRTIs PLUS A BOOSTED PROTEASE INHIBITOR

Protease inhibitors have a long history of clinical and surrogate marker efficacy in clinical practice.

Protease inhibitors are usually used in combination with low-dose ritonavir to provide a pharmacokinetic boosting effect. The rationale for this is that these drugs are extensively metabolized by the cytochrome P₄₅₀ system, resulting in short half-lives and low trough concentrations. Ritonavir is a potent inhibitor of cytochrome P₄₅₀ CYP3A and enhances plasma concentrations of other protease inhibitors, raising trough levels and extending the half-life. This improves

potency and is associated with a reduced risk of resistance development. In addition, a boosted protease inhibitor regimen can improve convenience by reducing dosage frequency and pill burden, and facilitating adherence. However, some toxicities (e.g. gastrointestinal upset) and lipid abnormalities may occur more commonly with some boosted protease inhibitor regimens.⁴³

Which boosted protease inhibitor?

The three main boosted protease inhibitors currently used in the treatment of naive patients are lopinavir, atazanavir and darunavir. Other boosted protease inhibitors include fosamprenavir and saquinavir:

- Lopinavir boosted with ritonavir is currently the only co-formulated protease inhibitor and is available in a heat-stable Meltrex tablet form. The other protease inhibitors are given with ritonavir separately. Lopinavir has a tendency to cause gastrointestinal intolerance, notably diarrhea.
- Atazanavir causes unconjugated hyperbilirubinemia by competitive inhibition of the uridine diphosphate-glucuronosyl transferase (UGT) 1A1 enzyme. This is only rarely of clinical significance.
- Darunavir can cause a mild rash.

There have been two recent randomized trials of boosted lopinavir, one versus boosted atazanavir (Castle study) and one versus darunavir (Artemis study). In essence, in terms of overall efficacy, the comparator arms both outperformed the lopinavir arm, mainly based on discontinuations due to higher toxicity rates of the lopinavir arms, especially gastrointestinal effects. Lipid abnormalities were also higher in the lopinavir arms in both of the studies.^{44,45}

NNRTI-BASED REGIMENS

These have gained much popularity in antiviral-naive patients because of the large clinical trial data available, lower pill burden, drug interactions and safety profile, as well as cost.

Which NNRTI?

Two NNRTIs are currently licensed for use in treatment-naive patients, nevirapine and efavirenz.

The 2NN study compared nevirapine with efavirenz. Both drugs were given in combination with stavudine and lamivudine in treatment-naive individuals. At 48 weeks of the study the difference in virological suppression did not reach criteria necessary to demonstrate non-inferiority of nevirapine. However, two patients taking nevirapine died, one from hepatic toxicity and one from septicemia related to Stevens–Johnson syndrome.⁴⁶

Nevirapine

The toxicities and side effects of nevirapine are well known and are substantially higher in those with higher CD4 counts

and in women, hence it is recommended that nevirapine is not started in men with CD4 counts of >400 cells/mm³ and in women with CD4 counts of >250 cells/mm³.

Efavirenz

Efavirenz has demonstrated potent viral suppression in large randomized, controlled trials and cohort studies of treatment-naïve patients at up to 7 years of follow-up.^{47–49}

Efavirenz-based regimens have demonstrated superior virological responses to lopinavir protease inhibitor-based regimens, and comparable activity to atazanavir-based regimens.⁵⁰ The potency of efavirenz is independent of baseline viral load and CD4 cell count.

Efavirenz is associated with neuropsychiatric effects including dizziness, abnormal dreams, insomnia, hallucination and euphoria. These side effects are more pronounced in the first 1–2 weeks of treatment. Occasionally patients report disabling side effects which persist beyond this induction period, necessitating switching from efavirenz.

Congenital abnormalities have been observed in cynomolgus monkeys whose mothers were treated with efavirenz during pregnancy. While prospective studies of its use in pregnant women have failed to demonstrate an excess risk of congenital abnormalities, it remains the recommendation that alternatives are used in women trying to conceive or in those at higher risk of unplanned pregnancy.

NNRTI OR PI

There is still much discussion over which is the best regimen on which to start patients. Until recently we only had cohort data but the randomized trial ACTG A5142 compared efavirenz with lopinavir–ritonavir, plus two NRTIs. There was also a third arm with the boosted protease inhibitor and NNRTI in combination but without nucleosides. This ACTG A5142 study showed better virological responses with an efavirenz-based regimen compared with a lopinavir–ritonavir-based regimen, but it showed better CD4 cell responses and less resistance after virological failure with lopinavir–ritonavir plus two NRTIs.⁵⁰

A smaller randomized trial in Mexico, which compared the same agents (efavirenz versus lopinavir–ritonavir) in treatment-naïve participants who had CD4 cell counts of $<200/\text{mm}^3$, also suggested a virological advantage among efavirenz recipients.⁵¹

Recently ACTG A5202 compared efavirenz with ritonavir boosted atazanavir (combined with 2 different NRTI backbones) and showed similar efficacy.^{51a}

WHICH NUCLEOS(T)IDE BACKBONE?

Dual nucleos(t)ide combinations form the backbone of initial therapy regimens with either boosted protease inhibitors or non-nucleosides. In reality, although there are several possible

different combinations, there are only four combinations in common use. Three of these combinations have been co-formulated to simplify dosing. However, one combination (tenofovir and emtricitabine) is preferred by most physicians.

Tenofovir and emtricitabine

Tenofovir, when used with emtricitabine as part of an efavirenz-based regimen in treatment-naïve patients, has demonstrated potent virological suppression and was superior to zidovudine–lamivudine in virological efficacy up to 144 weeks. Renal impairment, with increases in serum creatinine, glycosuria, hypophosphatemia and Fanconi syndrome, has been reported with tenofovir use.

Renal function, urinalysis and electrolytes should be monitored in patients who are on tenofovir and alternative agents used in renal impairment. Tenofovir with emtricitabine has also been studied in combination with several different boosted protease inhibitors in randomized clinical trials; all such trials demonstrate good virological benefit.

Tenofovir plus either emtricitabine or lamivudine is the preferred NRTI combination for patients co-infected with both HIV and HBV, as these drugs have activity against both viruses.

Abacavir and lamivudine

Abacavir has the potential for serious hypersensitivity reactions which are observed in 5–8% of patients who start this drug. The risk for this reaction is highly associated with the presence of the HLA-B*5701 allele. Studies have shown that a negative HLA-B*5701 test is not associated with this reaction. Routine testing for HLA-B*5701 is recommended if abacavir is contemplated as part of the regimen.

Unfortunately there have been evolving issues with the use of abacavir:

- Data suggest that regimens given to patients with a starting viral load of $>100\,000$ copies/mL showed a significantly shorter time to virological failure in an abacavir–lamivudine arm compared with a tenofovir–emtricitabine arm.
- The D:A:D and other cohort studies have suggested a link between abacavir use and myocardial infarction.⁵² These data have been supported by some but not all studies and the mechanism is unknown. No such association has been seen with tenofovir.

Didanosine and lamivudine

Didanosine has to be taken fasting and has been linked to increased risk of pancreatitis and non-cirrhotic portal hypertension. In the ACTG 5175 study an inferior virological outcome was seen when it was used with lamivudine and a protease inhibitor.

The D:A:D study group have also implicated didanosine with the risk of myocardial infarction.

Zidovudine-lamivudine

Zidovudine-lamivudine is now considered an alternative rather than a preferred NRTI option, mainly because of the greater toxicity of zidovudine compared with tenofovir.

Bone marrow suppression, with macrocytic anemia and/or neutropenia, is seen in some patients. Zidovudine is also associated with gastrointestinal toxicity, fatigue, lipoatrophy and abnormal lipids.

PROTEASE INHIBITOR/NNRTI COMBINATIONS

The interest in protease inhibitor/NNRTI-based ('nucleoside-sparing') regimens has arisen out of concern over the long-term toxicities of NRTIs (such as lipodystrophy, pancreatitis and lactic acidosis). Although these combinations should be highly effective, dosing schedules tend to be complicated as both NNRTIs and protease inhibitors are substrates of the cytochrome P₄₅₀ system and have complex drug interactions. In ACTG 5142 the combination of efavirenz and lopinavir-ritonavir was as efficacious as the efavirenz nucleoside arms but had a higher rate of side effects and toxicities.

OTHER NOVEL COMBINATIONS

Nucleoside-sparing regimens combining a boosted protease inhibitor and an integrase inhibitor are under investigation.

Raltegravir-based regimen

An integrase inhibitor has been studied in phase III trials using a raltegravir-based regimen versus efavirenz in treatment-naïve patients. There were similar viral load data at 48 weeks but a faster rate of becoming virologically undetectable on the raltegravir regimen, the significance of which is unknown. The overall toxicity rate, especially for neuropsychiatric events, was lower in the raltegravir arm.

Maraviroc-based regimen

A randomized, double-blind study (MERIT) compared the CCR5 antagonist maraviroc with efavirenz, both in combination with zidovudine-lamivudine, in treatment-naïve participants.⁵³

Only participants who had CCR5 virus and no evidence of resistance to any drugs used in the study were enrolled at 48 weeks. The HIV RNA (<50 copies/mL) results did not meet the set criteria to demonstrate non-inferiority for maraviroc (65.2% vs 69.2% for efavirenz patients). CD4 counts increased by an average of 170 cells/mm³ in the maraviroc arm and by an average of 143 cells/mm³ in the efavirenz arm. Toxicity of maraviroc was low. The result was influenced by the lack of sensitivity of the tropism test used in determining

whether patients had R5 tropic virus and underestimated the number with dual X4 R5 tropic virus, leading to virological failure in such subjects.

MONITORING TREATMENT

Patients on HAART should have their CD4 count and plasma viral load levels monitored at regular intervals. Laboratory evaluations are usually performed at 2- to 4-week intervals initially and then eventually about 3 monthly, unless specifically needed. On effective therapy, plasma viral load falls rapidly as viral replication is inhibited. By 4 weeks a fall of greater than 1 log, and by 3–6 months a fall to <50 copies/mL, in viral load should be expected.

TOXICITY OF ANTIVIRAL AGENTS

All antiviral agents can cause side effects and toxicities. Some are more linked to a class of drug, such as rash and hepatitis which are commoner with NNRTIs or dyslipidaemia with protease inhibitors. The thymidine analogs AZT (zidovudine) and D4T (stavudine) are both associated with the development of lipoatrophy which can lead to significant changes in body shape and is only slowly reversible once the drug is stopped. One proposed mechanism is drug-induced damage to mitochondria. Other side effects are more drug specific, such as anemia with AZT, neuropathy with stavudine, hypersensitivity with abacavir and jaundice with atazanavir. The latter two problems are genetically linked. In the case of abacavir, by screening out patients who are HLA-B*5701 positive, hypersensitivity reactions can be prevented completely. Efavirenz, which is commonly used in first-line therapy, causes short-lived neuropsychiatric symptoms. Occasionally these can be severe and the drug needs to be stopped. In some patients these are linked to very high drug levels. Again a genetic basis for high drug levels can often be found in patients who have a cytochrome P₄₅₀ 2B6 enzyme deficiency. Enfuvirtide had an almost 100% rate of injection-site reactions but the other new drugs raltegravir and maraviroc have good tolerability profiles.

Tenofovir is associated with decreases in renal tubular function which are usually clinically benign. It has, however, been linked to cases of Fanconi syndrome.

An association between an increased cardiovascular risk and the use of antivirals has been found for abacavir and more recently for lopinavir-ritonavir.

The most common reason for stopping antiretroviral agents is toxicity. These are often short lived and are usually gastrointestinal, but anemia, neuropathy and rash are also important. Long-term toxicities such as lipodystrophy are becoming less common in resource-rich countries as physicians have a choice of drugs other than thymidine analogs. The situation is worsening in many resource-poor countries where no such choice exists. As most antiviral regimens in drug-naïve populations have similar efficacy, the advantages of one drug over another can be its side effect profile.

TREATMENT FAILURE AND SALVAGE THERAPY

FIRST TREATMENT FAILURE

One measure of treatment success is whether complete viral suppression is achieved; any evidence of ongoing viral replication indicates treatment failure. Once treatment failure is suspected, a repeat confirmatory viral load should be performed. There are several reasons why the viral load may increase on therapy and not all are the result of the development of viral resistance.

Causes of treatment failure

Major causes of treatment failure

- Insufficient drug exposure due to poor adherence
- Drug–drug interactions leading to poor pharmacokinetics
- Drug toxicity leading to cessation of the regimen

Less common causes of treatment failure

- Lack of potency
- Inadequate drug absorption
- Inability of the agents to penetrate viral reservoirs
- Primary drug resistance acquisition at the time of infection

Starting treatment at a late stage of HIV disease (high HIV RNA levels⁵⁴ and/or CD4⁺ count <100 cells/mm³) has also been strongly associated with early virological failure.⁵⁵ Lifelong adherence to therapy is crucial, as demonstrated in studies of adherence. Counseling and directly observed therapy, rather than self-administered therapy, result in significantly better viral load and CD4 responses.

TRANSIENT INCREASE IN VIRAL LOAD

If a patient's viral load rises to just above detectable (50–500 copies/mL), the viral load count should be repeated as soon as possible, preferably within 2 weeks. The patient should be clinically assessed to determine any contributing factors such as drug–drug interactions, poor adherence, coexisting infections and/or vaccinations, which can all increase the viral load transiently. Rises in viral load to just above detectable levels occur in a significant proportion of patients on treatment.^{56,57} Those whose viral load is transiently detectable because of laboratory assay-related problems or other factors will show no further rise or revert to undetectable, and are called 'blips'. Patients who develop virological failure show further increases in viral load. Whether viral 'blips' are associated with an increased future risk of virological failure is unclear for those who have already achieved viral suppression. One study showed no such association,⁵⁶ but another suggested that, although a low-level viral 'blip' was not a predictor of failure, those with repeated episodes or sustained low-level viral rebound were more likely to experience future virological failure.⁵⁷ Patients with frequent 'blips' should be monitored more regularly than others.

SUSTAINED VIRAL LOAD REBOUND

Falls in CD4 count and clinical disease progression is the usual outcome in patients whose viral load continues to rise towards pretreatment levels.⁵⁸ Although resistance to all drugs in a treatment regimen may not be detected in patients experiencing virological failure, a persistently high viral load on treatment will lead to the accumulation of resistance mutations. For some drugs, such as lamivudine and NNRTIs, mutations at one position in the reverse transcriptase gene usually emerge at low levels of viral load rebound and result in significant phenotypic resistance. Reduced susceptibility to other drugs usually requires the accumulation of two or more mutations, as can occur with ongoing viral replication. Thus, changing therapy should be considered if viral replication persists and other therapeutic options exist to completely suppress it. However, a decision to switch to a second regimen is complicated, and depends on several factors, including addressing the etiology of virological failure. A change of therapy should be considered if HIV load has never become undetectable or after being undetectable on antiviral therapy has subsequently becomes consistently detectable.

CHOICE OF SUBSEQUENT REGIMEN

PROTEASE INHIBITOR FAILURE

Optimal virological responses to a second or subsequent regimen will be obtained only when adherence is maximized and ineffective drugs are eliminated from the regimen. Resistance testing and a history of drug exposure will help guide drug choices. Patients who begin therapy with a combination of two NRTIs and a protease inhibitor retain susceptibility to NNRTI as long as baseline resistance tests show wild-type virus.

Patients failing on unboosted protease inhibitor therapy are often difficult to treat because of broad cross-resistance within this class.^{55,59,60} In recent years, use of low-dose ritonavir-based boosted protease inhibitor regimens have changed this and if treatment failure is due to poor adherence, primary protease mutations will usually not be found on resistance testing.

Newer protease inhibitors such as tipranavir and, especially, darunavir usually have good activity, even when several primary protease mutations are present, and can be used in case of prior protease inhibitor failure dependent on the genotype.

NNRTI FAILURE

Patients who begin therapy with a combination of two NRTIs and an NNRTI retain susceptibility to protease inhibitors. Unfortunately, there is broad cross-resistance

between efavirenz and nevirapine. Thus, they cannot be used reliably after failure of other drugs in the same class. The second-generation NNRTI etravirine has activity against some NNRTI-resistant strains but activity depends on the genotypic resistance that has developed to the existing agents. Fortunately it has excellent activity against the common K103N mutation often seen as a lone NNRTI mutant in early efavirenz failure.

SUBSEQUENT VIROLOGICAL FAILURE

Virological failure on treatment can be defined as a confirmed HIV RNA level >400 copies/mL after 24 weeks of prior therapy or >50 copies/mL after 48 weeks, or a repeated detectable HIV RNA level after prior suppression of viremia.

In the past, for those who had experienced virological failure on two or more HAART regimens (often referred to as ‘salvage therapy’), the therapeutic approach and goal of therapy were very different as, with the drugs then available, complete viral suppression was rarely achievable. Partial viral suppression became the goal of therapy; even viral load reductions of $>0.5 \log_{10}$ copies/mL which resulted in clinical improvement implied that such salvage regimens were worth pursuing.⁶¹ However, continuing viral replication on antiretroviral therapy selects for further resistance, limiting future options; eventually the viral load will rise, CD4 will fall and patients will progress to AIDS and death.

ASSESSMENT OF THE HIGHLY EXPERIENCED PATIENT

Any new therapeutic regimen should have the optimal chance of success. Adherence problems should be carefully explored and the impact of the patient’s social and psychological condition on adherence explored.

The following should all be considered prior to changing treatment:

- A detailed history of prior antiretroviral therapy and the reasons why the patient changed drugs.
- A resistance test, preferably while still on failing treatment.
- Data from prior resistance tests as mutations may have been lost over time because of lack of drug pressure (e.g. 184V mutation and protease inhibitor mutations).
- Retrospective resistance testing of stored plasma taken at the time of previous treatment failure in patients who have interrupted therapy.
- An assessment of any potential current and future drug–drug interactions and conditions that might lead to drug malabsorption.

With the development of next-generation boosted protease inhibitors and NNRTIs active against viruses with key mutations and new classes of entry/fusion drugs and integrase inhibitors, the aim of treatment in highly treatment

experienced patients is to achieve undetectable viral loads. This can be achieved in the majority but there remains a small minority in whom an effective suppressive regimen cannot be constructed. These patients are the new ‘salvage’ group.

Over the last 5 years several studies (Torro, Power, Duet, Resist, Motivate and Benchmark) have defined an effective antiretroviral strategy for managing highly treatment-experienced patients. The principles of treatment are that new regimens should contain, whenever possible, three fully active drugs based on patient history and resistance testing. If three fully active drugs are not available, data suggest that most patients will still respond using two fully active drugs plus drugs with partial activity, with at least one of these drugs coming from a new class. If possible, the regimen should also contain an active boosted protease inhibitor.^{62–66}

It should be noted that when agents from new classes are used in a regimen where they are, in effect, the only active drug, then resistance to that drug usually occurs within weeks. This phenomenon is seen with the integrase inhibitor raltegravir, the NNRTI etravirine, the entry inhibitor enfuvirtide and the CCR5 inhibitor maraviroc.

Patients who have few options based on history and resistance testing are difficult to manage and have limited choices. Options include the following:

- *Treatment interruption.* Treatment interruption, however, has not been shown to be associated with any durable benefit and may be associated with a rapid increase in viral load and decrease in CD4 count, with or without clinical progression, and an increase in non-HIV complications such as cardiovascular, renal or hepatic problems.^{67–69}
- *A nucleoside-only regimen.* Cohort studies suggest continued immunological and clinical benefits if the HIV RNA level is maintained at $<20\,000$ copies/mL.^{70,71} There is evidence from cohort studies that continuing therapy, in the presence of viremia, decreases the risk of disease progression.⁷²

Switching patients to a nucleosides-only regimen may be of benefit as not only will this strategy reduce the amount of drug taken but also decrease some of the toxicity, preventing further resistance mutations occurring to the other classes of drug.⁷³

Monotherapy with or continuing nucleosides, including lamivudine, are strategies that have been used when there are few options available. Data suggest that lamivudine may reduce viral fitness and reduce viral load by maintaining the M184V mutation.^{74,75}

OTHER PATIENT POPULATIONS

Pregnant women and children require special consideration as far as antiviral therapy is concerned but the principle of using antiviral therapy to reduce the viral load to below detectability remains the same. Detailed guidance for their management can be found at http://aidsinfo.nih.gov/ContentFiles/Pediatric_Guidelines.pdf and at <http://aidsinfo.nih.gov/ContentFiles/PerinatalGL.pdf>, and as published by the British HIV Association.⁷⁶

Hepatitis C (HCV)

In patients co-infected with hepatitis C, treatment can be considered at any CD4 cell count for HCV genotypes 1a, 1b or 4, as it will potentially slow the progression of liver disease. Starting HAART should also be considered for those with HCV genotypes 2 or 3 who do not clear the virus with HCV therapy or who are intolerant to the HCV treatment.

For some patients with CD4 counts of <200 cells/mm³, it may be preferable to initiate antiretroviral therapy and delay HCV therapy.

Important drug interactions occur between ribavirin and didanosine, leading to pancreatitis and lactic acidosis. This means that they should not be used together. Zidovudine should also be avoided because both it and ribavirin can cause anemia. There are also some concerns with abacavir and ribavirin at lower doses.

Hepatitis B (HBV)

HAART should be started in those with active HBV co-infection irrespective of CD4 cell count to try to reduce the rate of liver disease progression. It is important that the HAART regimen contains two antiretroviral drugs that are active against HBV. Tenofovir and either emtricitabine or lamivudine are the preferred drugs for initial treatment of HBV in co-infection as they have activity against both HBV and HIV. Discontinuation of these drugs may potentially cause serious hepatocellular damage resulting from reactivation of HBV.

Tuberculosis co-infection

Rifamycins are essential drugs for the treatment of tuberculosis. Rifampicin (rifampin) is the most potent inducer of hepatic enzymes, especially CYP3A4, which then results in significant decreases in exposure to ritonavir-boosted or unboosted protease inhibitors. This can lead to antiretroviral treatment failure. Co-administration of rifampicin and nevirapine or efavirenz is associated with lower NNRTI drug exposures and greater variability in plasma NNRTI drug levels. This does not have such an impact on efavirenz, especially in patients of low body weight. In most patients, adjusting the dose of efavirenz and then performing drug levels can allow safe co-administration. Nevirapine dosing cannot be increased without substantially increasing the risk of hypersensitivity reactions. Nevirapine use in tuberculosis co-infection has been associated with an increased risk of virological failure compared to its use in non-tuberculosis-infected patients.

Rifabutin is a less potent inducer of cytochrome enzymes and has fewer and less severe drug interactions with antiretroviral drugs. Rifabutin has been successfully used instead of rifampicin in treating tuberculosis in HIV-negative patients. It can be regarded as an alternative in HIV-positive patients, especially to avoid drug interactions with rifampicin.

CHAPTER**44**

Infections of the upper respiratory tract

Nicholas A. Francis and Christopher C. Butler

Upper respiratory tract infections (URTI) are the most common symptomatic human infections in developed countries¹ and the most common reason for patients to consult a healthcare professional.^{2,3} The vast majority are managed by self-care, with annual consulting rates in primary care varying from 125 to 1110 per 1000 registered patients.⁴ As only complicated cases are generally seen in hospitals, this chapter will focus mainly on primary care and community perspectives.

Despite their high incidence, there are major gaps in the evidence base underpinning management. For example, although most of these infections are self-limiting with a low incidence of complications, there are limited tools to predict accurately which few will go on to develop a prolonged course or become complicated. Similarly, distinguishing those patients who are likely to benefit from antibiotic treatment from the majority who do not benefit remains a major challenge in everyday clinical practice. Faced with this uncertainty, clinicians frequently follow what they consider a cautious approach and prescribe antibiotics, even when they know the average patient is unlikely to benefit.⁵⁻⁸ However, many patients are satisfied with non-antibiotic management if they feel they have been examined thoroughly and received a full explanation.⁹ Nevertheless, antibiotics continue to be widely used for these infections.^{10,11} Indeed, URTI are the most common reason for antibiotics to be prescribed. Widespread unnecessary antibiotic prescribing not only wastes healthcare resources and leads to a cycle that encourages further consulting in the future,¹² it is also the main driver of increasing antibiotic resistance.¹³ Antibiotic prescribing for these infections varies widely between countries¹⁴ and within primary care settings in countries,¹⁰ suggesting there remains considerable scope for rationalizing their use.

Improving the quality of antibiotic prescribing for URTI depends on enhanced diagnosis, better communication within the consultation, empowering healthcare consumers to confidently self-manage their illness, and behavior-change interventions aimed at clinicians and the public so that the emerging evidence is translated into changes in the real world.

Here, we focus on the evidence supporting management for the four commonest URTIs.

THE COMMON COLD (CORYZA)

The common cold (coryza), which is often also called an acute URTI, is defined as inflammation in the nasal or pharyngeal mucosa, in the absence of any other defined upper respiratory tract infection. The common cold needs to be distinguished from other causes of rhinitis, such as allergic rhinitis. Common colds are almost invariably caused by viruses, with rhinoviruses, adenoviruses, influenzae, parainfluenzae and respiratory syncytial virus (RSV) the main causes.¹

EFFECTIVENESS OF ANTIBIOTICS

Antibiotics are not effective in shortening or reducing symptom severity.¹⁵ There is some evidence of benefit for people with purulent nasal discharge¹⁵ and in children with persistent nasal discharge (10 days or more).¹⁶ However, only one in every four to eight will receive benefit from treatment, and this comes at a cost of risk for side effects. Given the infrequency of serious complications, the lack of long-term benefits and the minimal short-term benefits, it is hard to justify treatment with antibiotics for these conditions.

OTHER TREATMENTS

Antihistamines are not effective by themselves, but oral decongestants in adults,¹⁷ and the combination of oral decongestants and antihistamines in adults,¹⁸ produce some symptomatic benefit. There is no evidence of benefit from steam¹⁹ or from vitamin C initiated after the onset of symptoms.²⁰ However, prophylactic vitamin C may result in a shorter duration of illness.²⁰

ACUTE SORE THROAT

Acute sore throat is one of the most common presentations in primary care. Controversies in management relate mainly to the place of antibiotic treatment, prognosis and diagnostic testing.

ANTIBIOTIC TREATMENT

A Cochrane review included 27 studies with a total of 12 835 patients with sore throat and found that spontaneous resolution was common, with 82% of those taking placebo being symptom-free by 1 week.²¹ Antibiotics marginally reduced symptom duration. Six patients need to be treated with antibiotics for one fewer person to be symptomatic at day three, and 21 need to be treated for one to benefit by day seven. On average, antibiotics reduce symptom duration by around 16 h. Analysis of 1839 patients from 11 studies found that those who had positive throat cultures for group A streptococcus are more likely to benefit from treatment (number needed to treat [NNT] of 3.7 for one more patient to be pain-free at 3 days).

ACUTE RHEUMATIC FEVER

One of the main arguments for antibiotic treatment is that it reduces the risk of acute rheumatic fever (ARF). The Cochrane review and a recent meta-analysis²² found evidence for a protective effect from antibiotic treatment. However, the studies contributing to both of these analyses were all conducted in the 1950s and early 60s when the incidence of ARF was much higher. Indeed, none of the trials reporting since 1961 had a single case of ARF. A retrospective cohort study of respiratory tract infections between 1991 and 2001, which included more than a million cases of sore throat, found virtually no cases of acute rheumatic fever or acute glomerulonephritis after sore throat.²³ Furthermore, the incidence of ARF started declining before antibiotic use became widespread. Therefore, while there is historical evidence for a relative benefit from treatment with antibiotics in the prevention of ARF, the absolute benefit in Western societies, where the incidence of ARF is now vanishingly small, is minimal. Clinicians need to take this context into account when making prescribing decisions. Those working in developing countries and with other populations at higher risk of developing ARF should consider prescribing antibiotics more readily, while clinicians working in Western countries should not prescribe antibiotics to prevent ARF.

QUINSY

The evidence for a preventive effect from antibiotics for quinsy largely comes from a study in the 1950s which used intramuscular penicillin.²⁴ More recent studies have included only nine

cases of quinsy between them,²⁵ and therefore it is difficult to draw conclusions from them.

A UK case-control study found that around two-thirds of cases of quinsy presented without prior consultation for sore throat. In those that did consult with sore throat before the development of quinsy, antibiotic treatment did not appear to protect against the development of quinsy. Risk factors for quinsy include smoking, male gender and aged 21–40.²⁵ Another retrospective analysis of 1 065 088 cases of sore throat in a UK general practice database found that antibiotic use for sore throat was associated with a reduction in quinsy within the month following diagnosis. However, the incidence of quinsy is so low that 4300 patients need to be treated to prevent one case.²³

IDENTIFICATION OF STREPTOCOCCAL INFECTION

A number of approaches are available for identifying those individuals with sore throat who have an infection caused by group A streptococcus (GAS), including clinical scoring systems, rapid antigen detection tests (RADTs) and throat culture. All have pitfalls and costs and therefore decisions about uptake need to include consideration of the benefit of identifying those with a GAS infection. There is no international consensus on the advantage of identifying and treating those with GAS.²⁶ North American, French and Finnish guidelines stress the importance of treating patients with GAS in order to prevent ARF. However, this is not the case with many other European guidelines. A review of international guidelines found considerable inconsistency in studies cited, with North American guidelines more likely to cite North American authors.²⁷

Regardless of interpretation of the evidence for preventing ARF, it may still be worth identifying those with a GAS infection as these patients derive greater symptomatic benefit from antibiotic treatment. Clinical scoring systems clearly have the greatest potential utility, as they are generally simple and cheap. The most widely used scoring system, developed by Centor and colleagues, awards one point for each of the following: temperature >38°C, no cough, tender anterior cervical adenopathy, and tonsillar swelling or exudate.²⁸ This system was modified by McIsaac et al to increase its performance by adding one point for those aged 3–14 years and subtracting one point for those aged 45 years or more.²⁹ When combined with use of throat culture for those with mid-range scores, this clinical score achieved a sensitivity of 83–85% and a specificity of 92–94%.³⁰ However, many have argued that it is not sufficiently valid to be used on its own for detecting GAS. In a recent study in children, the modified Centor scoring system was found to produce an area under the receiver operating curve (ROC) of only 0.65–0.7.²⁶ This is clearly not adequate when detection of GAS is critical. However, it may have some value for identifying those who are at a greater likelihood of benefiting from antibiotic treatment.

RADTs are a potentially useful tool. However, one of the challenges in using both RADTs and throat swab culture is that up to 20% of the healthy population carries GAS in their throat. As asymptomatic carriers will also get viral throat infections, the presence of GAS does not confirm active infection. That being said, using a RADT in patients with McIsaac's modification of the Centor score >2 gives a sensitivity of 78% and a specificity of 97% for detecting GAS.²⁶ These tests are likely to play an increasing role, but before widespread uptake into everyday care, further research is needed that evaluates their impact on antibiotic use, symptoms and their cost-effectiveness.

Throat culture is the most accurate way of detecting the presence of GAS, but its use involves cost of transporting the specimen, plating, culture and the communication of results – both to the practitioner and then ultimately to the patient. Furthermore, its use may involve a delay of treatment (or unnecessary initiation of treatment in many patients), which may negate the benefit of identifying the organism. If accuracy of identification is the main aim, as those in the ARF prevention camp contend it is, then it is hard to argue for anything but throat culture. However, if one believes that reducing antibiotic use is not likely to result in a resurgence of ARF, then throat culture may be less of an important clinical tool.

ANTIBIOTIC CHOICE

When a decision to prescribe antibiotics is made, an agent active against GAS should be selected. In most countries penicillin V continues to be the therapy of first choice, and erythromycin for those allergic to penicillin.

DIPTHERIA

Antibiotics are an essential but adjunctive part of treatment, and do not obviate the need for antitoxin.

Corynebacterium diphtheriae is moderately susceptible to penicillin and also susceptible to amoxicillin, erythromycin and clindamycin. Erythromycin remains active, apart from a few strains of the *mitis* biotype, and is preferred for the treatment of the index case as well as household contacts or known carriers.³¹

ACUTE EPIGLOTTITIS

This rapidly progressive and life-threatening illness is encountered mainly in children, but is increasingly being recognized in adults. It is caused by infections with *Haemophilus influenzae* type b, which may often be cultured from the blood as well as from the local lesion. The favorable impact of conjugate vaccines on *H. influenzae* meningitis has also fortunately reduced the incidence of acute epiglottitis in childhood. Treatment is as much concerned with maintaining the

airway as with control of the infection. Ampicillin has been widely used in the past but the relative rarity of the condition does not allow objective judgment of its continued benefit. Ampicillin resistance is now widespread in *H. influenzae*, and a cephalosporin, such as cefotaxime or ceftriaxone, is now preferred on account of β-lactamase stability, high potency and excellent safety records.

Acute croup (laryngotracheobronchitis) is largely viral in etiology (RSV, parainfluenza), but may also occasionally be bacterial in nature (*M. pneumoniae*). The differential diagnosis of croup includes acute epiglottitis, diphtheria, and many non-infectious conditions. Pseudomembranous croup is a severe bacterial tracheitis.³² *Staphylococcus aureus* is most commonly involved, although sometimes with other organisms,³³ and treatment should include a β-lactamase-resistant penicillin.

ACUTE SINUSITIS

Acute sinusitis is an acute inflammation of the paranasal air spaces that is usually the result of a viral or bacterial infection. In the USA, sinusitis affects one in seven adults and is the fifth most common reason for antibiotic prescription.³⁴ As most cases of sinusitis are caused by viral infections,³⁵ the benefit from antibiotic treatment for most of these infections is marginal. However, antibiotics continue to be widely used; in the USA, 96% of pediatricians report treating sinusitis with antibiotics 'always' or 'frequently'.³⁶

ANTIBIOTIC TREATMENT

The effectiveness of antibiotics for acute sinusitis has been assessed in three recent systematic reviews and one meta-analysis of individual patient data.^{37–40} All of these reviews found overall benefit from antibiotic treatment. However, the benefits are small, and therefore of questionable clinical relevance, and the rate of spontaneous improvement is high. Both effect size and rate of spontaneous resolution depend on the inclusion criteria of the studies selected. Those using clinical criteria had a lower effect size (NNT of 15 for one additional cure at 8–15 days in the meta-analysis of individual patient data) and higher rate of spontaneous improvement (80%), while those that included studies using radiological or microbiological definitions of sinusitis had slightly larger effect sizes and a slightly lower rate of spontaneous resolution (68%).

Patients diagnosed with 'acute sinusitis' clearly have a widely differing clinical course and will vary in their response to antibiotic treatment. As such, diagnostic criteria are important. The vast majority of patients are managed in primary care and therefore the use of microbiological culture or imaging studies is not feasible and clinical criteria must be used. A systematic review examining the predictive value of signs and symptoms found that purulent nasal discharge as a symptom, purulent nasal discharge as a sign, pain in teeth, pain on bending forward, and

two phases to illness, were predictive in one or more studies.⁴¹ However, they found that the studies used different 'gold standards' and their results were inconsistent. Bacterial sinusitis appears to be unlikely in those who have had symptoms for less than 7 days, and, as such, duration of illness of a week or more is a common diagnostic criterion in guidelines.⁴² However, the most recent meta-analysis found that, although those with a longer prior duration of illness were more likely to have a prolonged course, those who had been unwell for a week or more were no more likely to benefit from antibiotic treatment.³⁹ The only factor found to predict a greater response to antibiotics in this study was purulent discharge seen in the pharynx (NNT = 8 in this group). In a secondary analysis of data from 300 participants feeling generally unwell and feeling unable to work were predictive of prolonged duration of sinusitis. No factors predicted response to antibiotics.⁴³

So where does this leave clinicians faced with a patient with sinusitis-like symptoms? No systematic review has demonstrated a significant reduction in complications from antibiotic treatment and symptomatic improvement for most patients is modest. Conversely, those who receive antibiotics are more likely to experience adverse effects.³⁸ Therefore, antibiotic therapy should not be given to most people with suspected acute sinusitis. However, it is still not clear whether certain subgroups of patients will benefit from antibiotic treatment. Patients with signs of serious illness are intuitively more likely to benefit from treatment, and are usually excluded or do not agree to be randomized into placebo-controlled studies. Treatment should therefore not be withheld in this group. Another factor that may be helpful in identifying those more likely to benefit, and importantly in reducing prescribing for the majority, is the use of point of care testing. Use of a C-reactive protein point of care test has been shown to be associated with reduced antibiotic prescribing for acute sinusitis in an observational study,⁴⁴ but its use for sinusitis has not yet been evaluated in a trial. Until further improvements in diagnostics become available it seems sensible to broadly follow the advice of major guidelines and consider antibiotic treatment primarily in those with purulent nasal secretions (and particularly those with purulent secretions seen in the pharynx) or who have a 'double worsening', who have been unwell for 10 days or more and have moderate to severe symptoms.^{40,42}

For those in whom antibiotic therapy is initiated, there is no evidence of superiority for one agent over another. Choices should provide coverage for the most common causative organisms, *Streptococcus pneumoniae*, *H. influenzae* and *Moraxella catarrhalis*. Most guidelines recommend amoxicillin as first-line therapy.^{40,45} There is also no clear evidence over optimal duration of therapy. Most trials have used relatively long courses (10 days) and so this duration has therefore been adopted by many guidelines. However, a recent meta-analysis of data from 12 randomized controlled trials found no significant benefit from longer courses compared with shorter courses (3–7 days). This may simply reflect the lack of benefit from treatment for most patients and may not be representative of the optimal duration for selected patients with more severe symptoms.

OTHER THERAPIES

All patients with sinusitis should be given advice about analgesics. Intranasal corticosteroids appear to offer marginal benefit,⁴⁶ with those having milder symptoms possibly benefiting more.⁴⁷ No other therapies have been shown to have clear benefits, although topical saline appears to have some beneficial effects for those with more chronic symptoms.⁴⁸

ACUTE OTITIS MEDIA

Acute otitis media (AOM) is one of the most common disorders of childhood – by the age of 3 years 80% of children have had at least one episode.⁴⁹ Nearly 40% of older children eventually have six or more episodes.⁵⁰ AOM is also the most common reason for antibiotic prescription for children, accounting for 45–53% of antibiotics prescribed for children in one US study.⁵¹

The most common bacterial pathogens implicated in causing AOM are *Str. pneumoniae*, non-encapsulated *H. influenzae*, *Mor. catarrhalis* and group A streptococcus.⁵² However, viral respiratory pathogens can be isolated from up to 75% of children with AOM and can be detected in the middle ear fluid of 48%.⁵³

Risk factors for AOM are: use of a pacifier, attendance in a day-care centre, not being breastfed, presence of siblings, passive smoking, craniofacial abnormalities and presence of adenoids.⁵⁴

DIAGNOSIS

Diagnosis of AOM on clinical grounds is not accurate.^{55,56} By definition, a middle ear effusion (MEE) is a prerequisite to the diagnosis, and most guidelines recommend using evidence of an MEE and evidence of inflammation in the middle ear to make the diagnosis.⁵⁷ An MEE is not easy to assess using simple otoscopy, but can be improved through the use of pneumatic otoscopy, which has a high sensitivity (94%) and specificity (80%) in diagnosing MEE.⁵⁰ Although this technique requires some training, it is simple and cheap and has the potential to improve diagnostic accuracy in community settings. Tympanometry is another method for diagnosing MEE that is simple and objective. It has a similar sensitivity to pneumatic otoscopy, but a slightly lower specificity.⁵⁰

EFFECTIVENESS OF ANTIBIOTIC TREATMENT

Most children (80%) with AOM spontaneously recover within a week.⁵⁸ The most recent systematic review from the Cochrane Collaboration found that antibiotics had no overall effect on pain at 24 h, but a slight reduction in pain at 2–7 days, with an NNT of 15.⁵⁸ A subsequent meta-analysis

of individual patient data from 1643 children found that the subgroups most likely to benefit were children under 2 years of age with bilateral otitis media (NNT = 4) and those with otorrhea (NNT = 3).⁵⁹

PREVENTING MASTOIDITIS

Treating AOM with antibiotics may prevent serious complications such as mastoiditis. However, a recent retrospective cohort study from the UK has called this into question. The records of over 2.5 million children were examined, identifying 854 cases of mastoiditis.⁶⁰ Most (two-thirds) had not seen their general practitioner prior to the development of the mastoiditis, and therefore could not have benefited from antibiotic treatment. There was a reduction in the risk of developing mastoiditis following AOM in those treated with antibiotics, but the number needed to treat was impractically large (NNT = 4831). The costs of increased microbial resistance from widespread antibiotic use may outweigh any symptomatic benefits. Furthermore, antibiotic prescribing results in increased re-consultations.^{61,62}

OTHER TREATMENTS

A systematic review examined decongestants and antihistamines for AOM and found a small reduction in persistent AOM in those who took both decongestants and antihistamines. There were no benefits in terms of early cure rates, symptom resolution, prevention of surgery or other complications. There was also a large increase in side effects from both interventions and the authors concluded that the marginal benefits were outweighed by these adverse effects.⁶³

REDUCING ANTIBIOTIC USE

We have outlined the evidence supporting reduced antibiotic prescribing for most upper respiratory tract infections. However, reducing antibiotic use is not always easy to achieve. One of the main approaches is to try to improve diagnostic accuracy. Clinical diagnostic criteria and clinical prediction rules have already been mentioned, and their use can make a significant contribution to improving management. Near-patient tests are likely to play an increasing role. A near-patient C-reactive protein test is already widely used in Scandinavian countries, and use of this test has been shown to reduce antibiotic prescribing for lower respiratory tract infections safely.⁶⁴

Interventions aimed at changing clinician behavior tend to be more effective if they are interactive rather than didactic.⁶⁵ From behavior-change theories we also know that they are more likely to be effective if they addresses the 'why' of change (i.e. the importance of change, outcome expectations and beliefs about consequences) as well as the 'how' (i.e. confidence in making changes, self-efficacy and beliefs

about control).⁶⁶ New approaches that address these issues using blended learning (combination of online and face-to-face learning) are being developed.⁶⁷

Education of patients through mass-media campaigns achieves important effects.^{65,68} Parental education at the time of the consultation has been shown to reduce antibiotic use and consulting for AOM.^{69,70} Training clinicians to provide parents with an 'interactive' booklet on respiratory tract infections reduces antibiotic prescribing for a range of such infections.⁷¹ Multifaceted interventions that combine professional and patient education have consistently been shown to have some (generally modest) effect on prescribing.^{65,68,72-75}

Finally, the use of a delayed antibiotic prescribing approach has been shown to safely reduce prescribing for sore throat,⁷⁶ otitis media,^{77,78} common cold⁷⁹ and uncomplicated cough,⁸⁰ and has been promoted as a useful technique for managing respiratory tract infections in primary care by the UK National Institute for Health and Clinical Excellence (NICE) guidelines.^{81,82}

CHAPTER**45**

Infections of the lower respiratory tract

Lionel A. Mandell and Robert C. Read

Respiratory infections are usually divided into those involving the upper and those involving the lower respiratory tract. The former typically include infections of the sinuses, the tonsillopharyngeal area and the middle ear. Lower respiratory tract infections include acute bronchitis, acute exacerbations of chronic bronchitis and pneumonia. Pneumonia is further subdivided into community-acquired, healthcare-associated and hospital-acquired infections.

Acute lower respiratory tract infections are a significant cause of morbidity and mortality worldwide and most occur in developing countries where poverty and inadequate medical care contribute to the high mortality rates. Pneumonia continues to be the most common cause of death from infectious diseases worldwide. Although our understanding of the various etiological agents and the pathogenic mechanisms involved in various respiratory infections has increased, our ability to diagnose accurately the causative agent(s) has not kept pace. This means that often the physician initiates treatment on an empirical basis and in far too many situations antibiotics are used when the infection is viral in nature.

ACUTE BRONCHITIS

Lower respiratory tract infections are typically divided into either bronchitis or pneumonia. These can also be thought of as infections involving the airways and the pulmonary parenchyma, respectively. Acute bronchitis is very common and can be viewed as one end of a continuum that extends from bronchitis to pneumonia. While it is generally not a particularly serious infection, it still has a considerable economic impact because of the frequency of physician visits and the fact that despite the lack of any compelling evidence supporting antimicrobial therapy, physicians who diagnose acute bronchitis prescribe antibiotics for 66% of such patients.¹

In the USA it is estimated that acute bronchitis results in approximately 12 000 000 visits to physicians per year at a cost of \$200–300 million.²

ETIOLOGY AND EPIDEMIOLOGY

The most common infectious agents are viruses, and typically respiratory viruses such as rhinovirus, corona virus, adenovirus and influenza virus are implicated. Other viral agents include respiratory syncytial virus (RSV), parainfluenza virus, measles virus and herpes simplex virus.^{3–5}

While the term ‘atypical respiratory pathogens’ can include a large and diverse number of etiological agents, by convention they usually refer to *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae* and *Legionella* species. *Mycoplasma* and *Ch. pneumoniae* and the etiological agent of whooping cough, *Bordetella pertussis*, are the most commonly encountered non-viral causes of acute bronchitis.⁶

Like many other respiratory infections, acute bronchitis is most common during the winter months. The mean attack rate in developed countries is 87 cases per 100 000 persons per week, reaching a peak of 150 cases per 100 000 during the winter season.⁷

PATHOGENESIS

In cases of acute bronchitis the disease process is limited to the mucous membrane lining the tracheobronchial tree. The mucous membrane becomes edematous and hyperemic and increased bronchial secretion is typically seen. Epithelial injury is usually mild to moderate but in cases of influenza virus infection there may be fairly significant epithelial damage.

Studies of pulmonary function during attacks of acute bronchitis have demonstrated abnormal findings in both airway resistance and reactivity. Such results are in keeping with the association that has been described between an increased incidence of mild asthma and patients with a history of recurrent episodes of acute bronchitis.⁸

The increased airway reactivity and resistance may manifest themselves clinically as a persistent cough lasting up to several weeks following the initial infection.

CLINICAL MANIFESTATIONS

The predominant symptom is cough. This may last up to several weeks and, depending upon the etiological agent, may be non-productive or productive of either mucoid or purulent sputum. In some cases the sputum may be mucoid initially, but if secondary bacterial infection results it may become purulent. Patients may also experience a burning retrosternal sensation on inspiration.

Physical examination may reveal the presence of rhonchi or coarse rales but bronchial breath sounds should not be heard.

The patient may be febrile but usually does not appear particularly ill. The exceptions to this are herpes simplex infection or bronchitis complicating influenza, which can produce marked malaise.

DIAGNOSIS

The diagnosis of acute bronchitis in an otherwise well adult is usually obvious from the clinical features. If there is any question of pneumonia, a chest radiograph will exclude the presence of a pulmonary infiltrate.

In general, it is not worth obtaining blood samples for serology or sputum for Gram stain and culture.

TREATMENT

Acute bronchitis is a common condition and most patients are managed at home. The treatment of acute bronchitis can be symptomatic or specific. Symptomatic treatment relies primarily upon maintenance of adequate hydration and cough suppression in those unable to sleep. If bronchospasm is a problem, then inhaled β_2 -adrenergic bronchodilators may be used. At present there is no evidence to support the routine use of oral or inhaled steroids. Smokers should be encouraged to stop.

In patients with underlying cardiopulmonary disease, an episode of acute bronchitis may precipitate cardiac failure and the patient may need to be admitted to hospital for appropriate ventilatory and cardiac support.

Antimicrobial chemotherapy is generally not recommended: a number of placebo-controlled trials have evaluated the role of antibiotics in acute bronchitis and there is minimal benefit at best. Antibiotics might be considered in patients with persistent, prolonged and worsening symptoms.

In such situations, doxycycline, or a macrolide (erythromycin, azithromycin or clarithromycin) should be considered.

ACUTE EXACERBATION OF CHRONIC BRONCHITIS

Chronic bronchitis is defined as the presence of a productive cough for at least 3 months of the year for 2 consecutive years. Chronic bronchitis itself constitutes a common component

of chronic obstructive pulmonary disease (COPD), a clinical entity characterized by reduced expiratory air flow that is relatively stable over several months of observation. The prognosis for COPD correlates best with the forced expiratory volume in one second (FEV₁), and when this falls below 50% of predicted value the prognosis worsens.

Most physicians do not differentiate among COPD, acute bronchitis and acute exacerbation of chronic bronchitis (AECB). In fact, even pneumonia is often simply included as part of the designation 'lower respiratory tract infections'. It is difficult to obtain accurate data on the exact economic impact of such entities, although COPD has been estimated to afflict one-fifth of the population of the USA.⁹ In the UK around 30 million working days are lost every year because of bronchitis, and the disease accounts for approximately 5% of deaths annually.¹⁰

ETIOLOGY AND EPIDEMIOLOGY

Chronic bronchitis is the result of a variety of insults to the lung over time. These include predominantly cigarette smoke, infection, and environmental pollutants and irritants. Once chronic bronchitis is established, the episodic worsening referred to as acute exacerbations of chronic bronchitis can be triggered by similar causes. For the purposes of this chapter, however, we will focus on infectious triggers.

Viruses account for up to 50% of acute exacerbations of chronic bronchitis and a variety of agents have been implicated: RSV, rhinovirus, influenza virus and parainfluenza virus. The remaining 50% of acute exacerbations are bacterial in nature, with the most common pathogens being *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Moraxella catarrhalis*. The role of atypical pathogens such as *M. pneumoniae* and *Ch. pneumoniae* is unclear but it is thought that they may account for a small percentage of infections.

Infection results in the release of inflammatory mediators and further impairment of mucociliary clearance. This in turn alters the local milieu, making it easier for pathogens to further colonize the airways. Progressive airway damage is thought to occur as the result of injury caused either by the pathogens themselves or by the host response to the various infective agents.

CLINICAL MANIFESTATIONS

The clinical manifestations of patients with AECB represent a common pathway of underlying pulmonary disease in the form of chronic bronchitis or emphysema and the acute exacerbation triggered by infection or environmental pollutants. Patients may present with any or all of the following: increase in dyspnea, sputum volume or sputum purulence. In 1987, Anthonisen and colleagues demonstrated that patients with at least two of these three findings experienced better clinical outcomes when treated with antibiotics than with placebo.¹¹

The Anthonisen classification refers to patients with one of these findings as type 3, two of the findings as type 2 and three of the findings as type 1. Other symptoms that may be noted during an exacerbation include wheezing, elevated temperature and a feeling of malaise.

The duration of an exacerbation can vary from a few days to several weeks. On average, most patients experience approximately three exacerbations annually, although significant variation has been described.

DIAGNOSIS

The diagnosis of AECB is usually clinical. Patients with a known history of chronic bronchitis who suffer periodic flare-ups are usually well aware of the signs and symptoms heralding the onset of an exacerbation. Increasing dyspnea, sputum volume and purulence are the main clues that an exacerbation has occurred.

One of the difficulties in defining etiology is that many, if not most, individuals with chronic bronchitis normally have bacteria in their respiratory secretions. These bacteria colonize the airways but during an exacerbation are present in higher numbers. *H. influenzae*, *Str. pneumoniae* and *Mor. catarrhalis* are the predominant pathogens. However, among those with severe exacerbations requiring admission to an intensive care unit (ICU) and mechanical ventilation, these pathogens seem to be present less frequently and organisms such as *H. parainfluenzae* and *Pseudomonas aeruginosa* are more frequently found, and bacteria in this context are often resistant to antibiotics.^{12,13}

In most patients treatment is begun empirically. In those with more severe underlying disease or in whom the exacerbations appear to be more serious, it may be worthwhile obtaining sputum samples for culture and susceptibility testing in order to rule out the presence of a resistant pathogen. Data are available suggesting that as the severity of the illness increases (as indicated by markers such as illness lasting longer than 10 years, more than four exacerbations per year, steroid therapy, recent antibiotics, and severe airway obstruction [$\text{FEV}_1 < 35\%$ predicted]) the microbiology becomes more complex.^{14,15}

On the basis of a clinical examination, it may be impossible to differentiate between an acute exacerbation of chronic bronchitis and pneumonia. In such cases, a chest radiograph is necessary.

Table 45.1 Stratification and treatment of acute exacerbations of chronic obstructive pulmonary disease²⁰

Category	Characteristics	Suggested treatment
Group 1	Postviral tracheobronchitis; previously healthy person	None
Group 2	Simple chronic bronchitis; young person; mild–moderate impairment of lung function ($\text{FEV}_1 > 50\%$ predicted); fewer than 4 exacerbations/year	No treatment or β -lactam antibiotic
Group 3	'Chronic bronchitis plus risk factors' older person; $\text{FEV}_1 50\%$ predicted or $\text{FEV}_1 50\text{--}60\%$ predicted but concurrent medical illnesses; CHF, diabetes mellitus, chronic renal disease, chronic liver disease, more than 4 exacerbations/year	Fluoroquinolone, amoxicillin–clavulanic acid, group 3 or 4 cephalosporin, ^a azithromycin or clarithromycin
Group 4	'Chronic bronchial sepsis', bronchiectasis, chronic airway colonization	Tailor antimicrobial treatment to airway pathogens

^aSee Ch. 13 for classification of cephalosporins.

CHF, congestive heart failure; FEV_1 , forced expiratory volume in 1 second.

From Lode H. Respiratory tract infections: when is antibiotic therapy indicated? *Clin Ther.* 1991;13:149–156.

TREATMENT

Anthonisen was the first to assess response to treatment based upon stratification of patients according to their symptoms.¹¹ A meta-analysis of nine randomized placebo-controlled trials of patients treated for AECB demonstrated a statistically significant improvement in outcomes in those treated with antibiotics.¹⁶ The effect size favored antibiotics in seven of the nine studies.

Despite such data, however, it is clear that routine antibiotic treatment fails in 13–25% of exacerbations.¹⁷ Such failures carry an economic burden because they require additional visits to physicians, additional treatment regimens and more days lost from work.

A number of risk factors have been defined for treatment failure. These include the presence of cardiopulmonary disease and increased frequency of pulmonary infections during the previous year (>4).¹⁷ A subgroup of patients is at risk, not only of treatment failure but also of respiratory failure. Mortality rates in hospital inpatients of 10–30% have been described, typically in patients older than 65 years, those with co-morbid respiratory and extrapulmonary organ dysfunction, and those residing in hospital before transfer to the ICU.^{18,19}

It has been suggested that stratification of patients according to risk factors will allow physicians to treat more appropriately. No single stratification scheme has been agreed upon but those that do exist attempt to rank patients according to increased risk factors for treatment failure and possibly admission to hospital. Three schema have been published to date: Lode – Germany (1991), Balter – Canada (1994), and Wilson – UK (1995).^{20–22} Their recommendations are summarized in Table 45.1.

Patients with AECB should be considered as being possibly infected with a 'core' group of pathogens such as *H. influenzae*, *Str. pneumoniae* and *Mor. catarrhalis*; those who are more complicated (such as elderly patients, patients with more frequent exacerbations and those with reduced lung function) may be infected not only by the core pathogens but also by Gram-negative bacilli such as the Enterobacteriaceae and *Ps. aeruginosa* or possibly resistant core pathogens.

The advantage of such an approach lies in the fact that they identify patients at increased risk of failure so that treatment may be initiated with antibiotic regimens most likely to be effective against all of the potential etiological pathogens.

A variety of adjunctive or supportive measures, including the use of bronchodilators, steroids (oral and/or inhaled) and oxygen therapy, may be necessary. Preventive measures such as cessation of smoking, annual influenza vaccination and administration of the pneumococcal vaccine should be emphasized.

COMMUNITY-ACQUIRED PNEUMONIA

Community-acquired pneumonia (CAP) has a significant impact on both individual patients and society, and pneumonia is currently the sixth leading cause of death in the USA with an estimated 3–4 million cases annually, accounting for more than 600 000 hospital admissions and 64 million days of restricted activity.²³

CAP is not a reportable disease so exact figures are not available. It is clear, however, that it has a significant impact on the individual patient and society as a whole. Most (80%) patients are treated as outpatients while 20% are admitted to hospital; it is these 20% who generate most of the costs. The annual costs of treatment are US\$4.8 billion (patients older than 65 years) and \$3.6 billion (patients under 65 years).²⁴

ETIOLOGY AND EPIDEMIOLOGY

As with many other infections, the incidence rates of CAP are greatest at the extremes of age. Although the overall annual rate of pneumonia in the USA is 12 cases per 1000 the rate is 12–18 cases per 1000 in children below 4 years of age and 20 cases per 1000 in people over 60 years age.^{25,26} Between the ages of 5 and 60 years, the annual rate ranges from one to five cases per 1000 and the incidence of CAP requiring admission to hospital in adult patients is 2.6 cases per 1000.²⁷

Risk factors for pneumonia have been defined and include the following: alcoholism, asthma, immunosuppression, institutionalization, and age greater than or equal to 70 years versus age 60–69 years.²⁸ Specific risk factors for pneumococcal infection include dementia, seizure disorders, congestive heart failure, cerebrovascular disease, COPD and HIV infection.²⁹

Numerous microbial pathogens are potential etiological agents, and patients may be infected with more than one agent. Such mixed infections are well described in hospital-acquired pneumonia, where multiple pathogens are present in more than half of the nosocomial pneumonia patients studied.³⁰ In CAP, the incidence of mixed infections is lower, ranging from 2.7% to 13% in well-defined studies of inpatients with CAP.^{31–33}

The single most important etiological agent is undoubtedly *Str. pneumoniae*. In a meta-analysis covering a 30-year period and including 7000 cases of pneumonia in which an etiological diagnosis was made, *Str. pneumoniae* accounted for two-thirds of all cases and for two-thirds of fatalities.³⁴

At one time it was thought that atypical pathogens such as *M. pneumoniae*, *Ch. pneumoniae* and *Legionella* species were

not important causes of pneumonia and that if they did cause infection they were usually mild and affected primarily the young. A study in 1997 of more than 2700 patients admitted to hospital with CAP ranked these pathogens second, third and fourth of all etiological agents meeting the criteria for a 'definite' diagnosis.³⁵ Another study described three outbreaks of *Ch. pneumoniae* in nursing homes with high attack and mortality rates.³⁶ These two studies have helped to dispel the earlier misconceptions surrounding infection with the atypical pathogens.

Gram-negative rods such as *Escherichia coli* and *Klebsiella* spp. are not particularly common causes of CAP but are nevertheless important to consider, particularly in elderly people or in those with co-morbid illness, especially if they are ill enough to require hospital treatment.^{31,37} There has been considerable debate about whether or not *Ps. aeruginosa* is a significant pathogen requiring treatment. The consensus is that, while it is certainly not common, it can occur in selected patients if risk factors such as a recent course of antibiotics or steroids or a prolonged stay in hospital are present.

PATHOGENESIS

The various etiological pathogens can gain access to the lower respiratory tract by a number of possible routes. These include inhalation, aspiration and hematogenous spread. For bacterial pneumonia, aspiration of organisms colonizing the oropharynx appears to be the most important route.³⁸ Pneumonia results when innate immunity, including macrophage phagocytosis, fails to eradicate the infecting pathogen, and a neutrophilic infiltrate is recruited.⁶

CLINICAL MANIFESTATIONS

Until relatively recently, physicians tended to divide cases of CAP into typical or atypical pneumonia based upon their clinical presentation. Typical or classic pneumonia refers to infection caused by bacterial pathogens such as *Str. pneumoniae* or *H. influenzae*, whereas atypical pneumonia refers to infection caused by the atypical pathogens (*M. pneumoniae*, *Ch. pneumoniae* and *Legionella* spp.). It was thought that those with classic bacterial pneumonia presented with fairly sudden onset of signs and symptoms with cough productive of purulent sputum, pleuritic chest pain and rigors. In contrast, those with atypical infection presented with an illness of undefined duration, a non-productive cough and often a frontal headache. It has become clear, however, that it is not possible to determine the etiological agent from a careful history, physical examination, and non-specific laboratory tests and chest radiographs.

The symptoms of CAP may be constitutional and non-specific or they may be localized to the respiratory tract and be fairly specific for respiratory infection. The former category includes such findings as malaise, anorexia, myalgias

and arthralgias, chills and rigors; the latter includes shortness of breath, pleuritic chest pain, cough and sputum production.

In elderly patients the findings may be imprecise because constitutional symptoms such as confusion may predominate and there may be fewer findings related to the respiratory tract.

DIAGNOSIS

The problem of the diagnosis of CAP has generated much debate among physicians. Unfortunately, despite extensive testing even in university medical centers, no specific etiological agent may be found in up to one-half of the cases. In routine clinical practice, the etiological agent is determined in approximately 25% of cases but results in a change in antimicrobial therapy in less than 10% of cases.³⁹ Furthermore, an improvement in clinical outcome does not always result from identification of the etiological agent.

Generally, diagnostic tests fall into two categories: clinical and invasive/quantitative. Clinical testing relies on information obtained from the patient history, physical examination, and selected tests or procedures such as chest radiography, sputum Gram stain, and blood and sputum cultures. Invasive/quantitative methods include bronchoscopic techniques, pleural fluid aspiration and (in selected cases) lung biopsy. As a rule, the clinical method is too sensitive and lacks specificity while the invasive/quantitative methods require special expertise and laboratory support, and are more costly.

CLINICAL EVALUATION

The first step is to determine whether the patient has pneumonia rather than some other infective process such as bronchitis, or whether a non-infectious etiology (e.g. congestive heart failure, pulmonary embolism) is the cause of the patient's problem. If a diagnosis of pneumonia is made, the next step is to determine the etiological agent if possible. Unfortunately, it is impossible to accurately identify the pathogen based on clinical findings, even when multiple clinical variables are used.^{31,40} There is significant intraobserver variation in the ability to elicit abnormal physical findings and the sensitivity and specificity of the history and physical examination are currently undetermined.⁴¹

CHEST RADIOGRAPH

The presence of an infiltrate on the chest radiograph can help to establish the diagnosis of pneumonia but does not determine the causative pathogen. However, the radiograph is important in defining the presence of a lobar or multilobar infiltrate and in assessing the severity of illness and prognosis.

LABORATORY ASSESSMENT

Routine laboratory assessment is unnecessary for ambulatory patients with CAP, who are likely to be managed as outpatients. However, for those ill enough to require admission to hospital (or even for those considered for admission), a complete blood and differential count, serum electrolytes, liver function tests, serum creatinine and an oxygen saturation assessment should be obtained. Significant abnormalities have been identified as risk factors for a complicated course or increased mortality. These abnormalities can be used to assess mortality risk and to help in the site of care decision.⁴²

MICROBIOLOGICAL ASSESSMENT

Sputum Gram stain and culture

Of the two tests, the sputum Gram stain is more reliable, but is regarded as neither sensitive nor specific, though in some laboratories the test has made a positive contribution to early diagnosis.⁴³ Many patients are unable to produce a sputum sample, and of those samples produced a significant percentage may not be adequate. Although current data suggest that atypical pathogens are responsible for 20–25% of all CAP cases, none is detectable by the sputum Gram stain. There is also considerable inter- and intraobserver variation in Gram stain interpretation.⁴⁴ The sputum culture also lacks sensitivity and specificity. Even in patients with confirmed pneumococcal pneumonia based upon positive blood cultures, a simultaneously obtained sputum culture tested positive in only one-half of patients.⁴⁵

Blood cultures

The incidence of positive blood cultures in ambulatory patients with CAP is less than 1%.⁴⁶ In hospital inpatients it ranges from 6.6% to 17.6% but may reach 27% in patients in ICUs.³² The most common pathogen is *Str. pneumoniae*, and pneumococcal pneumonia is complicated by bacteremia more frequently than pneumonia caused by other pathogens. It is generally recommended that blood cultures be obtained from all patients who are admitted with CAP but not from those treated in the community.

Serology

To determine the role of a specific micro-organism as a pathogen, serological assessments should be based on the results of paired (acute and convalescent) serum samples. Unfortunately, such results are never available at the time the initial treatment decision is being made. Therefore, other than helping to define the epidemiological role of selected pathogens, serological testing is not helpful and is not recommended for routine use.

Legionella urinary antigen

This test is easy to perform and yields rapid results with a sensitivity of 70% and specificity of 100%. It is limited by the fact that it identifies only *Legionella pneumophila* serogroup 1. However, this serogroup accounts for most *Legionella* infections.

DNA probes and amplification

Polymerase chain reaction-based methods are being used increasingly.⁴⁷ Unfortunately, rapid diagnostic techniques are not generally available and simply identifying the presence of a particular micro-organism does not confirm infection. There are, however, a few micro-organisms whose mere presence indicates infection. These include *M. tuberculosis*, *Coxiella burnetii* and *Pneumocystis jirovecii* (formerly *Pn. carinii*).

INVASIVE PROCEDURES

For most patients with CAP, invasive tests such as bronchoscopy, bronchoalveolar lavage, protected specimen brush and percutaneous lung needle aspiration are not required. However, they may be appropriate in certain situations (e.g. patients with fulminant pneumonia or those unresponsive to a standard course of antimicrobials), when it may be necessary to identify a resistant or fastidious pathogen or to rule out a non-infectious cause.

Thoracocentesis should be performed in CAP patients with a significant pleural effusion defined as a collection of greater than 10 mm thickness on the lateral decubitus view. The incidence of pleural effusion with pneumonia varies from 36% to 57% and is most common in patients with pneumococcal infection.⁴⁸

TREATMENT

Therapy can be directed or empirical. Directed therapy implies that the etiological agent is known and that therapy is aimed specifically at that pathogen. Empirical therapy is the more usual; it is, in effect, an educated guess and the physician institutes a course of treatment aimed at the most likely causes. Of these two options, directed therapy is clearly more desirable because it limits the breadth of spectrum required of the treatment agent(s), it may limit the number of drugs, reduces the adverse reactions associated with antibiotics, reduces antibiotic selection pressure and may result in less antimicrobial resistance.

Before discussing the various regimens, it is important to consider how the decision is made in terms of outpatient versus inpatient therapy and the problem of antimicrobial resistance.

SITE OF CARE DECISION

This decision is an important one, with considerable economic implications. The cost of inpatient care exceeds that of outpatient treatment by a factor of 15–20, and the cost of

hospital management accounts for most of the money spent annually on CAP in the USA.⁴⁹

In some cases it is immediately obvious that a patient can be treated outside the hospital; in other situations it is equally apparent that a patient requires hospital treatment and possibly admission to an ICU.

Effective prognostic scoring and outcome assessment tools are necessary to help physicians make the site of care decision. Such tools provide objective methods to assess the risk of adverse outcomes, including death.

Studies by Fine and others have attempted to identify patients at increased risk for adverse outcomes and to define independent predictors of mortality or poor outcome.^{34,42} However, weaknesses or design flaws were found in each of them.⁴⁹

The use of prediction rules may minimize unnecessary hospital admissions and help to identify patients who will benefit from care and intervention in the hospital and the ICU. The best known and most widely used prognostic tool is that of Fine.⁴² This is a two-step rule designed to identify patients at low risk for mortality. Points are given based on age, coexisting disease, and abnormal physical and laboratory findings, and patients are assigned to classes 1–5 based on the total number of points assigned. This scoring system has been used to triage low-risk patients towards outpatient therapy with a high degree of success.⁵⁰ Fine's rule has been adopted into recommendations published by the Infectious Diseases Society of America (IDSA), the American Thoracic Society (ATS) and the European Respiratory Society.^{51–53}

An alternative system of assessing severity, the CURB score, has been recommended by the British Thoracic Society⁵⁴ and the European Respiratory Society.⁵³ This score incorporates assessments of pulse rate, respiratory rate, renal function and mental status for the initial evaluation of patients, assigning 1 point for each abnormal feature (plus 1 for patients over 65 years of age in the CURB65 variation) and is much easier to use than the Fine score.

In assessing patients for severity, such scoring systems can only be a guide. Ultimately the physician must decide on grounds of clinical experience whether an individual patient with pneumonia warrants intravenous therapy, admission to hospital or management in an intensive care facility.

ANTIMICROBIAL RESISTANCE

Antimicrobial resistance among respiratory pathogens has become a major concern and it is important that clinicians understand and appreciate the general mechanisms and implications of this phenomenon. The emergence of resistance to penicillin among *Str. pneumoniae* isolates represents a gradual reduction in in-vitro susceptibility. The National Committee for Clinical Laboratory Standards defines strains for which the minimum inhibitory concentration (MIC) of penicillin is <1 mg/L as sensitive, 1.0–2.0 mg/L as

intermediate and ≥ 4 mg/L as resistant.⁵⁵ With *Str. pneumoniae*, the DNA incorporation and remodeling that results in resistance is from the DNA of closely related oral commensal bacteria (see Ch. 3). By such a process, our own flora can develop resistance when we are treated with antibiotics and pathogens such as *Str. pneumoniae* can subsequently acquire resistance coding DNA from our own colonizing microflora.⁵⁶ Pneumococcal resistance to β -lactams is due solely to the presence of low-affinity penicillin-binding proteins. Macrolide resistance, however, can occur either by target site modification or by an efflux pump (see Chs 3 and 22). The relative frequencies of the two mechanisms vary internationally but in North America account for approximately 45% and 55%, respectively, of resistant isolates. Reports of breakthrough pneumococcal bacteremia in patients treated with macrolides have highlighted concerns about resistance to this class of agents.^{57,58}

Resistance to ciprofloxacin and to newer fluoroquinolones among pneumococcal isolates has been reported.⁵⁹ Pneumococcal resistance to fluoroquinolones may be mediated by changes in one or both target sites (topoisomerase II and IV), usually resulting from mutations in the *gyrA* and *parC* genes, respectively, and possibly also by an efflux pump (see Ch. 3).⁶⁰ Of greatest concern, however, are the multidrug-resistant isolates, those that are resistant to two or more antibiotics having different mechanisms of action. In the USA, between 1995 and 1998, the proportion of invasive pneumococcal isolates that were resistant to three or more classes of drugs increased from 9% to 14%; there also were increases in the proportions of isolates that were resistant to penicillin (21% to 25%), cefotaxime (10% to 15%), meropenem (10% to 16%), erythromycin (11% to 16%) and trimethoprim-sulfamethoxazole (25% to 29%). These increases in frequency of resistance to multiple antimicrobial agents occurred in penicillin-resistant isolates only.⁶¹ Drug-resistant *Str. pneumoniae* is associated with various risk factors including the presence of co-morbidities, such as chronic heart, lung, liver or renal disease, diabetes, alcoholism, immunosuppression or use of antimicrobials within the previous 3 months.⁶² Infection with drug-resistant pneumococci results in invasive disease with higher mortality rates amongst hospitalized individuals.⁶³

Pathogens such as *H. influenzae* and the Enterobacteriaceae are also important to consider. *H. influenzae* is the third most common cause of CAP requiring admission to hospital and, while the Enterobacteriaceae are not particularly common, they are important because of the high mortality rates associated with them. Among such pathogens resistance is usually mediated by β -lactamases, and the highest prevalence of β -lactamase genes is found on plasmids rather than chromosomes. Members of the TEM and SHV families are the most successful of the plasmid-encoded β -lactamases, and the TEM-1 β -lactamase accounts for almost 80% of all plasmid-encoded β -lactamases.⁶⁴ The extended-spectrum β -lactamases include oxyimino enzymes that are TEM and SHV mutants and cephalosporinases unrelated to TEM and SHV enzymes (see Ch. 15).

THERAPEUTIC REGIMENS

Once the diagnosis of pneumonia has been made, the physician must decide whether to treat the patient outside or inside the hospital and this in turn will help to determine the appropriate therapeutic regimen. In most patients an empirical choice must be made; however, where the infecting pathogen is known, antibiotic choice can be guided by local knowledge of antimicrobial sensitivities and policies. The correct choice of antimicrobial(s) for empirical therapy has generated considerable discussion, and a number of societies have produced guidelines to help physicians with the initial management of patients with CAP.⁵¹⁻⁵⁴

Guidelines have served a number of useful functions. They have codified our management of patients with CAP and (at the very least) they have highlighted the gaps in our knowledge and have helped to direct future studies and research. Adherence to guidelines has had a significant pharmaco-economic effect, lowered mortality rates and shortened hospital stay.^{65,66}

The joint guidelines of the IDSA and the ATS⁵¹ make recommendations for outpatient and inpatient treatment of pneumonia, and draw a distinction between those individuals who do or do not have risk factors for drug-resistant *Str. pneumoniae* (DRSP) (Table 45.2). For outpatient treatment of previously healthy individuals with no risk factors for DRSP, these guidelines recommend a macrolide (azithromycin, clarithromycin or erythromycin) or doxycycline. In the presence of risk factors for DRSP, outpatients are recommended a 'respiratory' fluoroquinolone (moxifloxacin, gemifloxacin or levofloxacin [750 mg]) or a high dose β -lactam plus a macrolide or doxycycline. This latter recommendation also pertains to all inpatients (non-ICU). For inpatients requiring ICU treatment the IDSA/ATS guidelines recommend a β -lactam (cefotaxime, ceftriaxone or ampicillin-sulbactam) plus either azithromycin or a fluoroquinolone, except where *Pseudomonas* infection is suspected, in which case an antipneumococcal, antipseudomonal β -lactam (piperacillin-tazobactam, cefepime, imipenem or meropenem) plus either ciprofloxacin or levofloxacin (750 mg) is the recommended first-line regimen. Where community-acquired methicillin-resistant *Staphylococcus aureus* infection is suspected to be the cause of the pneumonia, these guidelines recommend the addition of vancomycin or linezolid to the regimen.

The recommendation for the use of macrolides in these guidelines relates to the coverage of atypical pathogens. A β -lactam would be the agent of choice for *Str. pneumoniae* but it would be ineffective against any of the atypicals. However, a macrolide provides good-to-excellent coverage for all these likely pathogens.

In North America the fluoroquinolones have assumed an important role in the management of CAP coinciding with rising resistance to β -lactams and macrolides, the appreciation of the potential importance of Gram-negative rods in selected CAP patients and the availability of the 'respiratory' fluoroquinolones which offer once-daily monotherapy, compared with the multiple dosing required if a β -lactam and macrolide regimen is used.⁵¹

Table 45.2 Empirical antimicrobial selection for community-acquired pneumonia (IDSA/ATS guidelines)**Outpatient treatment**

1. Previously healthy and no use of antimicrobials within the previous 3 months
 - A macrolide
 - Doxycycline
2. Presence of co-morbidities such as chronic heart, lung, liver or renal disease; diabetes mellitus; alcoholism; malignancies; splenectomy; immunosuppressing conditions or use of immunosuppressing drugs; or use of antimicrobials within the previous 3 months (in which case an alternative from a different class should be selected)
 - A respiratory fluoroquinolone (moxifloxacin, gemifloxacin or levofloxacin [750 mg])
 - A β -lactam plus a macrolide
3. In regions with a high rate (>25%) of infection with high-level ($MIC \geq 16 \mu\text{g/mL}$) macrolide-resistant *Streptococcus pneumoniae*, consider use of alternative agents listed above in (2) for patients without co-morbidities

Inpatients, non-ICU treatment

A respiratory fluoroquinolone
A β -lactam plus a macrolide

Inpatients, ICU treatment

A β -lactam (cefotaxime, ceftriaxone, or ampicillin–sulbactam) plus either azithromycin or a respiratory fluoroquinolone (for penicillin-allergic patients, a respiratory fluoroquinolone and aztreonam are recommended)

Special concerns

If *Pseudomonas* is a consideration

- An antipneumococcal, antipseudomonal β -lactam (piperacillin–tazobactam, cefepime, imipenem or meropenem) plus either ciprofloxacin or levofloxacin (750 mg), or
- The above β -lactam plus an aminoglycoside and azithromycin, or
- The above β -lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone (for penicillin-allergic patients, substitute aztreonam for above β -lactam)

If CA-MRSA is a consideration, add vancomycin or linezolid

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; ICU, intensive care unit.

Adapted from Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society of America; American Thoracic Society. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community acquired pneumonia in adults. *Clin Infect Dis*. 2007;44(suppl 2): S27–S72.

Many experts feel that penicillin still has a role to play in the treatment of pneumococcal pneumonia and that it is effective against infections caused by susceptible organisms. For strains of *Str. pneumoniae* with intermediate levels of resistance to penicillin higher doses may be used, as recommended in the IDSA/ATS guidelines. Unfortunately, the identity or susceptibility of the etiological agent is unknown in most cases at the time of initial antibiotic treatment.

Efflux resistance to macrolides results in low-level resistance, whereas the target change mechanism results in high-level resistance. Low-level resistance predominates in North America, while the latter is more frequent in Europe. In the USA and Canada, therefore, macrolides are still seen as having a significant role to play in the management of many patients with CAP.

For those treated in hospital, the guidelines divide patients into those treated on a medical ward and those treated in the ICU, and use the risk of infection with *Ps. aeruginosa* as a means of further subdividing ICU patients, reflecting the enhanced mortality rate and constitutive antimicrobial resistance associated with this organism.

The recent British Thoracic Society (BTS) guidelines (Table 45.3) provide an exhaustive evidence-based approach to the management of CAP patients.⁵⁴ They differ from the IDSA/ATS guidelines quite extensively. For outpatients, the BTS does not consider that atypical pathogens such as *M. pneumoniae* or *Ch. pneumoniae* are important enough to warrant routine coverage, and therefore treatment is aimed primarily at *Str. pneumoniae*, for which the drug of choice is amoxicillin. For hospital inpatients, the North American document divides patients into those managed on a ward or in the ICU, whereas the British guidelines consider hospital-treated patients under three categories: (1) not severe and admitted for non-clinical reasons or previously treated in the community (CURB65 0–1); (2) moderate severity

Table 45.3 British Thoracic Society recommendations for initial empirical treatment of community-acquired pneumonia

Type of patient	First choice	Second choice
Low severity (i.e. CURB65 = 0–1), home treated	Amoxicillin 500 mg p.o. every 8 h	Doxycycline 200 mg loading dose then 100 mg/day or clarithromycin 500 mg p.o. every 12 h
Hospital treated, not severe (i.e. CURB65 = 0–1)	Amoxicillin 500 mg p.o. or i.v. every 8 h	Doxycycline 200 mg loading dose then 100 mg/day or clarithromycin 500 mg p.o. every 12 h
Hospital treated, moderately severe (i.e. CURB65 = 2)	1. Amoxicillin 500 mg–1 g p.o. every 8 h + clarithromycin 500 mg p.o. every 12 h 2. If oral treatment not possible, amoxicillin 500 mg –1 g i.v. every 8 h or benzylpenicillin 1.2 g i.v. every 6 h + clarithromycin 500 mg i.v. every 12 h	Doxycycline 200 mg loading dose then 100 mg/day or levofloxacin 500 mg p.o. every 12 h or moxifloxacin 400 mg p.o. every 12 h
Hospital treated, severe (i.e. CURB65 = 3–5); consider critical care review	Amoxicillin–clavulanate 1.2 g i.v. every 8 h + clarithromycin 500 mg i.v. every 12 h (if <i>Legionella</i> strongly suspected, consider adding levofloxacin)	Benzylpenicillin 1.2 g i.v. every 6 h + either levofloxacin 500 mg i.v. every 12 h or ciprofloxacin 400 mg i.v. every 12 h or Cefuroxime 1.5 g i.v. every 8 h or cefotaxime 1 g i.v. every 8 h or ceftriaxone 2 g i.v. per day + clarithromycin 500 mg i.v. every 12 h (if <i>Legionella</i> strongly suspected, consider adding levofloxacin)

Adapted from Lim WS, Baudouin SV, George RC, et al. Pneumonia Guidelines Committee of the BTS Standards of Care Committee. BTS guidelines for the management of community acquired pneumonia in adults: update 2009. *Thorax*. 2009;64(suppl 3):iii1–iii55.

(CURB65 = 2); and (3) severe (CURB65 3–5). The first group is treated with amoxicillin, the second is given amoxicillin plus a macrolide (erythromycin or clarithromycin) and the third group is given a β -lactam (amoxicillin-clavulanate) plus intravenous erythromycin or clarithromycin. Fluoroquinolones are recommended as an alternative only for the second and third categories. In general, the potency and breadth of intravenous antibiotics recommended increases as severity increases. In moderately ill hospitalized patients treated in the UK, a simple β -lactam in combination with a macrolide is likely to be used, if clinicians follow the BTS guidelines. Individual hospital policies will be tailored to balance the requirement for potent therapy, with the need to keep antimicrobial activity as narrow spectrum as possible to avoid potential impacts on hospital ecology.

Initiation of treatment should not be delayed, particularly when dealing with patients over 65 years of age. A study of elderly patients presenting to emergency departments with CAP showed that those who received antibiotics within 8 h of presentation had a significantly lower 30-day mortality rate than those who waited longer for initiation of treatment.⁶⁷

Intravenous to oral sequential treatment is strongly recommended because it reduces costs, encourages patient mobility and allows earlier discharge from hospital. Ancillary measures such as supplemental oxygen, drainage of significant pleural effusions and hydration are also important.

The patient should be followed and objective parameters monitored. These include the resolution of cough, shortness of breath and elevated temperature and (for those in hospital) improvement in the oxygen saturation, C-reactive protein and white blood cell count.

UNUSUAL PATHOGENS

Staphylococcal pneumonia can be associated with a necrotizing pneumonitis, particularly when stains expressing Panton–Valentine leukocidin toxin are implicated. If such organisms are strongly suspected in patients with severe pneumonia, a combination of intravenous linezolid (600 mg every 12 h), intravenous clindamycin (1.2 g every 6 h) and intravenous rifampicin (rifampin) (600 mg every 12 h) should be added to the initial antibiotic regimen.⁵⁴

HEALTHCARE-ASSOCIATED PNEUMONIA

'Healthcare-associated pneumonia' refers to pneumonia in patients who have recently been hospitalized, had hemodialysis or received intravenous chemotherapy, or reside in a nursing home or long-term care facility.⁶⁸ They are distinguished by having a different pattern of microbial flora associated with the pneumonia (often Gram-positive organisms with a higher tendency towards antimicrobial resis-

tance) and also more severe disease, longer hospital stay and higher mortality rates. The dominant group in this class of patients generally comprises residents of nursing homes. Nursing home pneumonia or pneumonia in elderly residents of long-term care facilities is an important entity and is only now becoming the subject of serious clinical investigation. Pneumonia is the main cause of death among residents of such facilities, with acute mortality rates ranging from 5% to 40% per infection. It is the most common reason for transfer of nursing home residents to an acute care hospital, with approximately one-third of pneumonia patients requiring hospital admission.⁶⁹

ETIOLOGY AND EPIDEMIOLOGY

The incidence of pneumonia among residents of nursing homes is considerably higher than among persons living in the community, ranging from 1.2 to 2.5 episodes per 1000 resident days with a median incidence of 1 per 1000 resident days.⁶⁹ One of the difficulties in establishing the etiology of nursing home pneumonia is the fact that studies in this area have depended almost exclusively on results of sputum cultures. Such studies are compromised from the outset because over half the elderly patients do not produce any sputum. The likely pathogens are somewhat different from those in patients with CAP. In cases of CAP, the predominant etiological agents are *Str. pneumoniae* and the atypicals (in selected cases Gram-negative rods may be encountered). In nursing home pneumonia, *Str. pneumoniae* is still a significant pathogen, but (it is important to note that age >65 years and residence in a nursing home have been identified as risk factors for penicillin-resistant *Str. pneumoniae* infection) there is a greater proportion of cases caused by *Staph. aureus*, *H. influenzae* and Gram-negative rods in this population than in a younger cohort, and a disconcertingly high percentage of the *Staph. aureus* isolates are methicillin resistant.⁷⁰ Atypicals are more common in younger patients.

The role of anaerobes is still not definitely settled and appropriately designed studies to substantiate their role as pathogens in the elderly do not appear to have been undertaken.

In addition to aerobic and possibly anaerobic bacterial pathogens, viruses and *M. tuberculosis* must also be considered. Epidemics of influenza, RSV and parainfluenza have been described in such populations, and must always be considered if an institutional outbreak is encountered. The incidence of tuberculosis is substantially higher in the institutionalized elderly and must be included in the assessment of such patients.

PATHOGENESIS

A number of risk factors have been defined in a prospective cohort study of respiratory tract infections in nursing home residents.⁶⁹ Older age, male sex, inability to take oral medications

and swallowing difficulties were identified as independent risk factors for the development of pneumonia. Swallowing difficulty, confusion and altered levels of consciousness have often been evoked as surrogate markers for aspiration and by inference as indicators of infection with anaerobes.

Nasogastric tube feeding and tracheostomy have also been identified as potential risk factors for pneumonia, presumably because of the increased risk of aspiration.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The physician must be aware that in an elderly patient with pneumonia rather than a history of elevated temperature, chills and cough with purulent sputum, the story may be that of confusion, weakness, anorexia and falls. The difficulty in making a diagnosis of pneumonia in a nursing home population is enhanced by the fact that nursing homes lack laboratory and radiographic facilities and many often do not have a physician in attendance on a full-time basis.

Ideally, if a patient presents with findings suggestive of pneumonia, he or she should be evaluated by a physician and a chest radiograph obtained. If feasible, an expectorated sputum sample should be sent for Gram stain and culture, and for people with more serious illness in whom parenteral therapy or transfer to a hospital is contemplated, the following additional tests should be done: blood samples for culture and susceptibility testing, complete blood count and differential, serum creatinine, urine for *Legionella* antigen.

If pneumonia occurs in the setting of an influenza outbreak or if a particular case is suggestive of influenza infection, a nasopharyngeal swab should be obtained for rapid detection of viral antigen by polymerase chain reaction. Similarly, if tuberculosis is a possibility, sputum samples for microscopy and rapid culture should be obtained. In both of these circumstances respiratory precautions must be instituted and the patient should be isolated to prevent spread of the disease.

TREATMENT

As with any patient, the use of an antimicrobial directed at a known pathogen is the ideal; however, at the time that the treatment decision is made it is unlikely that a definitive etiological agent will have been identified. As with most cases of pneumonia, an empirical regimen is usually selected, based upon local epidemiology and susceptibility patterns and risk stratification of the patient.

The site of care decision is an important one and nursing home residents with pneumonia can be evaluated using the same prediction rules for hospital admission as are used for other patients with CAP.⁴² For most patients who can be treated in the nursing home setting, with no other risk factors for multidrug-resistant pathogens, a 'respiratory fluoroquinolone' such as moxifloxacin, gatifloxacin or levofloxacin

(according to availability), or a combination regimen consisting of amoxicillin-clavulanate, is generally recommended as first choice.^{70,71}

Influenza outbreaks in an institutional setting can be associated with high attack rates and mortality rates. Annual immunoprophylaxis using vaccines offers protection and is recommended for all residents. Zanamivir and oseltamivir are neuraminidase inhibitors with activity against both influenza A and influenza B. Both of these agents are approved for treatment of uncomplicated influenza and if given within 48 h of onset of symptoms may decrease the severity and duration of the symptoms.

HOSPITAL-ACQUIRED PNEUMONIA

Hospital-acquired or nosocomial pneumonia is by definition infection that occurs 48 h or more after admission to hospital. Although it is the second most common nosocomial infection in the USA, accounting for 13–18% of all hospital-acquired infections, it is the one most frequently associated with a fatal outcome, and is associated with significant morbidity and mortality.⁷¹

Current figures are based on estimates from hospital records because nosocomial pneumonia is not a reportable disease. It is considered, however, that currently more than 300 000 cases occur annually in the USA, resulting in an average increase in length of hospital stay of 8 days.⁷¹

Mortality figures range from 15% to 70%; however, the more relevant attributable mortality figures are estimated at 33–50%.

ETIOLOGY AND EPIDEMIOLOGY

The estimated rate of occurrence is 4–8 episodes per 1000 hospital admissions in non-teaching hospitals and 8 per 1000 in teaching hospitals.⁷¹ In patients who are intubated, the rate is up to 20 times higher than in non-intubated patients. Rates of ventilator-associated pneumonia are reported to be approximately 15 per 1000 ventilator days.⁷²

Risk factors for nosocomial pneumonia include increasing age, COPD, neuromuscular disease, decreased consciousness, aspiration, endotracheal intubation, thoracic and upper abdominal surgery, and nasogastric intubation. Of the various pathogens, perhaps the most important with defined risk factors are *Staph. aureus* (head injury, coma longer than 24 h and intravenous drug use) and *Ps. aeruginosa* (prior antibiotics, structural lung disease and steroid treatment).^{71,73}

The most common pathogens encountered in nosocomial pneumonia are the Gram-negative bacilli, which have been reported in up to 60% of cases, and *Staph. aureus*, which has been reported in up to 40% of patients. In infections occurring during the first 4 days of hospital stay, bacteria typically associated with CAP, such as *Str. pneumoniae* and *H. influenzae*, have also been reported.

The Gram-negative rods of interest are *Esch. coli*, *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp. and *Serratia marcescens*. *Esch. coli* is the third most common coliform isolated from patients with nosocomial pneumonia and appears to affect predisposed hosts such as the critically ill. *K. pneumoniae* is the most commonly isolated of the *Klebsiella* species and may cause severe necrotizing lobar pneumonia in the elderly, in alcoholics and in diabetics. *K. pneumoniae* and *Esch. coli* are the bacteria that most commonly carry the extended-spectrum β -lactamases, rendering them resistant to oxyimino β -lactams such as cefotaxime, ceftazidime and aztreonam.

Among *Enterobacter* spp., *E. cloacae* and *E. aerogenes* are the primary cause of nosocomial pneumonia and frequently colonize patients who have received a course of antibiotics. Resistance to group 4 cephalosporins among these pathogens may develop within days of treatment.

Proteus mirabilis and *Proteus vulgaris* can act as opportunistic respiratory pathogens in a manner similar to that of the *Enterobacter* spp. Indole-positive species such as *Pr. vulgaris* may undergo a single-step mutation to become constitutive high-level producers of β -lactamase enzymes, which is manifested as resistance to group 4 cephalosporins. *Ser. marcescens* preferentially colonizes the respiratory and urinary tracts and has been associated with common source outbreaks of pneumonia in the setting of inhalation therapy and contaminated bronchoscopes. Like all Enterobacteriaceae, this organism may spread to patients by hand transfer from healthcare personnel.

The non-fermentative Gram-negative bacilli of importance are *Ps. aeruginosa* and *Acinetobacter* spp. *Ps. aeruginosa* is one of the leading causes of Gram-negative pneumonia. The most common mechanism of infection is direct contact with environmental reservoirs, including respiratory devices such as contaminated nebulizers or humidifiers. *Acinetobacter* spp. can also result in serious nosocomial infection and has been shown to be an important cause of ventilator-associated pneumonia.

H. influenzae frequently colonizes the upper respiratory tract of individuals with predisposing conditions such as COPD. Most adult infections are caused by non-typeable strains and *H. influenzae* (along with *Str. pneumoniae*) can often be isolated from tracheal secretions following intubation. *Str. pneumoniae*, like *H. influenzae*, colonizes the oropharynx and, although it is predominantly a pathogen associated with CAP, *Str. pneumoniae* is being recognized with increasing frequency as a cause of hospital-acquired infection.⁷¹

Anaerobes may be found as pathogens in patients predisposed to aspiration. The anaerobes that have been implicated in nosocomial pneumonia are those that colonize the oropharynx, such as *Fusobacterium* spp., *Prevotella melaninogenica* and *Bacteroides ureolyticus*.

Legionella pneumophila serogroup 1 is the most common of the *Legionella* spp. to be associated with both CAP and hospital-acquired pneumonia. The exact mode of transmission is controversial and there is evidence for both aspiration and inhalation. Contaminated potable water and contaminated aerosols have been reported as sources of infection in hospitals.

It is important to realize that nosocomial pneumonia may be caused by multiple pathogens in any one patient, emphasizing the need for broad coverage when empirical treatment is initiated. Bartlett and colleagues demonstrated that more than one pathogen could be documented in over half of the cases studied.³⁰

PATHOGENESIS

The pathogenesis of nosocomial pneumonia is complex. Pathogens may gain access to the lower respiratory tract by inhalation, microaspiration or silent aspiration of oropharyngeal secretions, gross aspiration of gastric contents, hematogenous spread, translocation from the gastrointestinal tract, spread from a contiguous focus (e.g. pleural space) and direct inoculation during surgery.

For certain pathogens, such as *Mycobacteria* and *Aspergillus* spp., inhalation of aerosols is important. In patients being mechanically ventilated, contamination of a humidification reservoir may result in aspiration of potential pathogens directly into the airways. The most important mechanism, however, particularly for Gram-negative rods, is the microaspiration of bacteria colonizing the oropharynx.

Studies have shown that while oropharyngeal colonization by Gram-negative rods is unusual in healthy people, it occurs with increasing frequency in those with underlying disease.⁷¹ Once oropharyngeal colonization is established, the silent aspiration of these potentially virulent bacteria eventually results in the overwhelming of host defenses in the lung and the development of pneumonia.

In addition to the oropharyngeal–pulmonary route, the gastropulmonary route has also been suggested as a means of introducing pathogens to the distal airways. Normally, the acidic pH of the stomach provides a hostile environment to bacteria, rendering the stomach contents virtually sterile, but above pH 4 bacterial overgrowth may occur. However, studies of stress ulcer prophylaxis have failed to demonstrate a definitive correlation between colonization of the stomach by bacteria and pneumonia.^{74,75} A review of the literature concluded that the stomach should be regarded as an amplifier but not as the primary source of pathogens causing pneumonia and that the oropharyngeal–pulmonary route is more important than the gastropulmonary route.⁷⁶

In patients who are being mechanically ventilated, the endotracheal tube plays an important role in the pathogenesis of ventilator-associated pneumonia. The tube itself breaches the upper airway defenses, and the inflated cuff allows the oropharyngeal secretions containing various pathogens to collect until they eventually pass the inflated cuff to the distal airways. In addition, the tube acts as a template upon which a layer of biofilm is deposited.⁷⁷ Pieces of this biofilm containing millions of bacteria may subsequently break off and reach the distal airways, thereby seeding remote sites of the lung.

CLINICAL MANIFESTATIONS

Much of what has been said in the discussion of the clinical manifestations of CAP and nursing home-acquired pneumonia applies to nosocomial pneumonia. The findings will vary, depending upon the age of the patient and the severity of the illness. As with CAP and nursing home-acquired infection, the symptoms may be constitutional and non-specific or localized to the respiratory tract.

DIAGNOSIS

As with CAP, two approaches may be used: clinical and invasive/quantitative.

With the clinical approach, pneumonia is defined as the presence of a new pulmonary infiltrate unexplained by other obvious causes plus one of a number of additional features, such as elevated temperature, production of purulent sputum or leukocytosis. While the clinical approach is relatively easy and straightforward and is not associated with significant costs, it is overly sensitive and does not reliably discriminate among the various causes. The invasive/quantitative approach, on the other hand, generally has greater precision but requires special training and laboratory support, is associated with significant costs, and has the potential for serious adverse effects.

Whichever approach is used, every patient with nosocomial pneumonia requires a careful history, including risk factors for specific pathogens, a physical examination, postero-anterior and lateral chest radiographs, complete blood count, blood chemistry, blood cultures, and either oximetry or arterial blood gases.

Chest radiography is useful in helping to determine the extent of the pneumonia and the presence of a pleural effusion. Multilobar involvement, cavitation or rapid radiographic progression indicates the presence of a severe infection.

Routine blood counts and chemistry may indicate evidence of end-organ dysfunction and can be helpful in adjusting treatment regimens. Blood cultures may be useful in identifying the pathogen in up to 20% of patients with nosocomial pneumonia. The presence of a pathogen in blood indicates not only that it is the etiological agent but also that the patient is at increased risk for a complicated course.

Serology is not normally useful in the management of individual patients with nosocomial pneumonia. It may, however, be helpful for epidemiological purposes, although this is more likely to be the case in patients with CAP.

The value of sputum Gram stain and culture is controversial as there are significant problems with both the sensitivity and specificity of these tests. Most studies have been carried out in patients with CAP; however, the results can be extrapolated to patients with nosocomial pneumonia. In selected cases direct staining of sputum samples for fungi or mycobacteria, or direct fluorescent antibody staining for *Legionella pneumophila*, may help in directing therapy.

Invasive techniques are not performed routinely in patients with nosocomial pneumonia. However, invasive techniques should be considered in selected cases, such as:

- patients receiving appropriate empirical antimicrobial coverage but who are failing to respond
- certain immunocompromised patients
- patients in whom an alternative diagnosis (e.g. carcinoma) is suspected.

A number of methods have been developed to obtain samples of lower respiratory tract secretions that are not contaminated by oropharyngeal micro-organisms. They are endotracheal aspirate, protected catheter aspirate, protected specimen brush and bronchoalveolar lavage. The studies that claim to support these techniques suffer from a lack of standardization, which makes comparison difficult at best. The discordant findings among the investigators studying these techniques make it difficult for practitioners to determine the most effective method.

Other invasive tests include transthoracic needle aspiration, transbronchial biopsy, thoracoscopy and open lung biopsy. One study comparing invasive and non-invasive strategies for management of suspected ventilator-associated pneumonia showed that there was a statistically significant reduction in mortality, sepsis-related organ failure and antibiotic-free days in the cohort managed with invasive diagnostic tests.⁷⁸

TREATMENT

When devising an antimicrobial regimen, the patient, the pathogen and the drug should all be considered individually and the interactions among them taken into account.

PATIENT-RELATED FACTORS

These include any previous history of adverse reactions (and, in particular, anything suggesting type 1 hypersensitivity to any antimicrobial) and increasing age (since adverse drug effects are more common in elderly people). Macrolides, lincosamides, chloramphenicol and metronidazole are eliminated via the liver, while most other antibiotics are eliminated by the kidney. When treating women of childbearing age, it is important to determine if the patient is pregnant because teratogenicity and fetotoxicity must be considered.

PATHOGEN-RELATED FACTORS

Ideally, the narrowest spectrum agent associated with the least toxicity and lowest cost should be administered if the pathogen is known. Unfortunately, empirical therapy is usually the norm, and one must consider the likely pathogens based upon

local epidemiology, risk factors for pneumonia and for specific pathogens, and severity of illness. The prevalence of resistance among pathogens to various antimicrobials must also be considered.

DRUG-RELATED FACTORS

When selecting any antibiotic, the first step is to select an agent to which the pathogen is known or likely to be susceptible. Other considerations include pharmacokinetic and pharmacodynamic properties, toxicity, drug interactions and cost. Depending upon the class of antibiotic being used, different pharmacokinetic/pharmacodynamic parameters correlate more or less closely with clinical or therapeutic efficacy. For β -lactam drugs, macrolides and clindamycin, the time during which the antibiotic concentration at the site of action in the tissues is above the MIC for the organism correlates best with efficacy. However, for aminoglycosides, fluoroquinolones and vancomycin, the 24 h area-under-the-curve/MIC ratio correlates best. Higher ratios of peak serum concentrations to MIC (C_{\max}/MIC) have been shown to prevent the emergence of resistance during treatment with fluoroquinolones and aminoglycosides. Furthermore, aminoglycosides do not achieve high levels in lung tissue, and this problem is compounded by the fact that they are also relatively inactivated by the acidic pH present at the site of infection in the lung.

The approach to the management of patients with nosocomial pneumonia should take into account the risk factors, severity of illness and time of onset of the illness.^{79,80} The risk factors are for infection with specific pathogens; severity of illness is either mild to moderate or severe; time of onset refers to early versus late (i.e. <5 or ≥ 5 days, respectively). Based upon these variables, a hierarchical approach to the patient with nosocomial pneumonia has been developed. While it is recognized that a large number of bacteria are potential pathogens, there is a 'core' group of organisms that must be considered for each patient for whom antimicrobial coverage must be provided (Table 45.4). This group consists of Gram-negative bacilli (such as *Enterobacter* spp., *Esch. coli*, *Klebsiella* and *Proteus* spp., *Ser. marcescens*), *H. influenzae*, *Staph. aureus* and *Str. pneumoniae*. Depending upon the risk factors present and the severity of illness, anaerobes, methicillin-resistant *Staph. aureus*, *Legionella* spp., *Ps. aeruginosa* and *Acinetobacter* spp. should also be considered.

The American Thoracic Society regimens are presented in Tables 45.4, 45.5 and 45.6.⁷¹ Other countries have produced guidelines for local use which reflect variation in the target pathogens and choice of therapy. Until the evidence base surrounding nosocomial pneumonia improves, variations in practice are likely to continue. The decision to select an agent should be based upon the host, pathogen and drug-related issues outlined earlier. A few specific issues, however, deserve comment. Single-agent therapy is recommended in many situations. Although two drugs should be used to achieve synergistic or additive activity against *Ps. aeruginosa*, there are no

Table 45.4 Initial empirical antibiotic therapy for hospital-acquired pneumonia or ventilator-associated pneumonia in patients with no known risk factors for multidrug-resistant pathogens, early onset and any disease severity

Potential pathogen	Recommended antibiotic ^a
<i>Streptococcus pneumoniae</i> ^b	Ceftriaxone or Levofloxacin, moxifloxacin, or ciprofloxacin or
<i>Haemophilus influenzae</i>	
Methicillin-sensitive <i>Staphylococcus aureus</i>	
Antibiotic-sensitive enteric gram-negative bacilli	
<i>Escherichia coli</i>	Ampicillin–sulbactam or
<i>Klebsiella pneumoniae</i>	Ertapenem
<i>Enterobacter</i> spp.	
<i>Proteus</i> spp.	
<i>Serratia marcescens</i>	

^aSee Table 45.6 for recommended initial doses of antibiotics.

^bThe frequency of penicillin-resistant *Str. pneumoniae* and multidrug-resistant *Str. pneumoniae* is increasing; levofloxacin or moxifloxacin is preferred to ciprofloxacin. The role of other new quinolones, such as gatifloxacin, has not been established.

Adapted from the American Thoracic Society.⁷¹

Table 45.5 Initial empirical therapy for hospital-acquired pneumonia, ventilator-associated pneumonia and healthcare-associated pneumonia in patients with late-onset disease or risk factors for multidrug-resistant pathogens and all disease severity

Potential pathogens	Combination antibiotic therapy ^a
Pathogens listed in Table 45.4 and multidrug-resistant pathogens	Antipseudomonal cephalosporin (cefepime, ceftazidime) or Antipseudomonal carbapenem (imipenem or meropenem)
<i>Pseudomonas aeruginosa</i>	
<i>Klebsiella pneumoniae</i> (ESBL ^b)	
<i>Acinetobacter</i> species ^b	β -Lactam/ β -lactamase inhibitor (piperacillin–tazobactam) plus Antipseudomonal fluoroquinolone ^b (ciprofloxacin or levofloxacin) or Aminoglycoside (amikacin, gentamicin or tobramycin) plus Linezolid or vancomycin ^c
Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA)	
<i>Legionella pneumophila</i> ^b	

^aSee Table 45.6 for adequate initial dosing of antibiotics. Initial antibiotic therapy should be adjusted or streamlined on the basis of microbiological data and clinical response to therapy.

^bIf an extended spectrum β -lactamase-positive (ESBL^b) strain, such as *K. pneumoniae*, or an *Acinetobacter* species is suspected, a carbapenem is a reliable choice. If *L. pneumophila* is suspected, the combination antibiotic regimen should include a macrolide (e.g. azithromycin), or a fluoroquinolone (e.g. ciprofloxacin or levofloxacin) should be used rather than an aminoglycoside.

^cIf MRSA risk factors are present or there is a high incidence locally.

data to support the routine use of combination therapy for other bacterial pathogens in non-neutropenic patients.⁸¹

In patients who are either severely ill with risk factors and early onset or severely ill without risk factors but with late onset, combination therapy should be instituted. If the patient was not receiving any prior antibiotics and deep suction

Table 45.6 Initial intravenous, adult doses of antibiotics for empirical therapy of hospital-acquired pneumonia, including ventilator-associated pneumonia and healthcare-associated pneumonia in patients with late-onset disease or risk factors for multidrug-resistant pathogens

Antibiotic	Dosage ^a
Antipseudomonal cephalosporin Cefepime	1–2 g every 8–12 h
Ceftazidime	2 g every 8 h
Carbapenems Imipenem	500 mg every 6 h or 1 g every 8 h
Meropenem	1 g every 8 h
β-Lactam/β-lactamase inhibitor Piperacillin-tazobactam	4.5 g every 6 h
Aminoglycosides Gentamicin	7 mg/kg per day ^b
Tobramycin	7 mg/kg per day ^b
Amikacin	20 mg/kg per day ^b
Antipseudomonal quinolones Levofloxacin	750 mg/day
Ciprofloxacin	400 mg every 8 h
Vancomycin	15 mg/kg every 12 h ^c
Linezolid	600 mg every 12 h

^a Dosages are based on normal renal and hepatic function.

^b Trough levels for gentamicin and tobramycin should be <1 µg/mL; for amikacin they should be <4–5 µg/mL.

^c Trough levels for vancomycin should be 15–20 µg/mL.

Reproduced from the American Thoracic Society. From American Thoracic Society. Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. *Am J Respir Crit Care Med.* 2005;171:388–416.

aspirates or bronchoscopy samples fail to yield *Ps. aeruginosa* or other often-resistant pathogens such as *Acinetobacter* spp., treatment may be modified to a single-drug regimen.

Enterobacter spp. are among the most common causes of Gram-negative bacillary hospital-acquired pneumonia. A major concern with infection caused by this organism is that in the presence of a group 4 cephalosporin it can become a hyperproducer of β-lactamase.⁸²

The final issue is that of duration of therapy. Unfortunately, there are no appropriately designed randomized controlled trials that specifically address this issue. The general consensus, however, is that patients with severe infection caused by pathogens such as *Ps. aeruginosa* or *Acinetobacter* spp. should be treated for a minimum of 14 days, whereas patients with less severe infection may only require 7–10 days of treatment.

CHAPTER

46 Endocarditis

Kate Gould

Endocarditis is traditionally defined as an inflammation of the endothelial lining of the heart which usually results in the formation of 'vegetations' – platelet and fibrin aggregates which can enlarge to several centimeters in diameter. Endocarditis is most frequently infective in origin, and the definition has been expanded to include infection of intracardiac prosthetic material such as valves, patches, conduits, pacemaker/defibrillator leads and ventricular assist devices.

Estimates of the incidence of this condition vary but recent estimates based on Duke criteria¹ suggest that it is approximately 1 case per million of the population per year. The epidemiology of the condition is changing with a shift away from native valve endocarditis secondary to rheumatic heart disease cause by α -hemolytic streptococci to prosthetic endocarditis caused by staphylococci.

Treatment outcome and the requirement from surgery are also variable, depending on the patient, site of infection and the infecting organism. The most successful outcomes tend to be in right-sided endocarditis and the worst with fungal or enterococcal endocarditis.

William Osler first described 'malignant endocarditis' during the Gulstonian lecture in 1885.² At that time, the only treatment that could be offered was bed rest and serum from horses injected with the infecting bacteria. Following the discovery of penicillin there was hope of a cure, but it became clear that very high doses were needed, and even then there was a high risk of relapse when the antibiotic was stopped.

There followed an era of in-vitro and in-vivo experimentation from which the fundamental principles of therapy were determined.

The pathophysiology of endocarditis is such that the infecting micro-organisms are situated in the middle of a vegetation attached to a structure that has no blood supply. Thus, in order to reach these organisms, any therapeutic agent has to diffuse into the vegetation from the blood passing over it. In order to eradicate the infection, the therapeutic agent must also be bactericidal, since the body's usual host defence mechanisms may not penetrate into the vegetation.

The in-vivo experiments³ determined that in a rabbit model at least four times the minimum bactericidal concentration (MBC) of an agent was required in the serum to diffuse into a vegetation, and that antibiotic peaks and troughs were more successful than continuous dosing.

In-vitro experiments demonstrated that for some Gram-positive bacteria, penicillin, although having a minimum inhibitory

concentration (MIC) well within the sensitive range, was not cidal.⁴ This phenomenon was labeled as 'tolerance', but further work determined that in the majority of cases kill could be achieved by adding streptomycin and, latterly, gentamicin.

Current endocarditis treatment guidelines^{5,6} are still centered on these basic principles since very few evidence-based studies have been performed. This is despite the availability of newer agents which have superior pharmacokinetics to benzylpenicillin. Similarly, oral therapies with agents which have good bioavailability and achieve satisfactory serum levels are rarely recommended outside pediatrics.

Recommendations for duration of therapy vary. For right-sided endocarditis, and for left-sided endocarditis with small vegetations, 14-day regimens have been used successfully, but there is little evidence to support why longer treatments are necessary in other cases.

LABORATORY INVESTIGATIONS

Full identification of all isolates – if necessary with the assistance of a reference laboratory – is mandatory in endocarditis. Routine antibiotic testing for a wide range of agents should be followed by formal MIC testing. The method by which the MIC is determined is not important so long as it is adequately controlled.

Unfortunately, although the MBC is important in endocarditis, it is technically difficult to perform in a routine diagnostic setting, creating problems with reproducibility.

The ability to perform high-level susceptibility testing for gentamicin and streptomycin is also important.

ANTIBIOTICS

β -LACTAMS

Traditionally, if sensitive, penicillin has been the β -lactam of choice to treat endocarditis. The advantage is that it is narrow spectrum and MICs are generally very low. The disadvantages

are that it has a short serum half-life (<4 h), necessitating 4-hourly dosing regimens which are impracticable outside the intensive care arena. Benzylpenicillin also has a high sodium load which can be an issue in the elderly or patients with concomitant heart failure. It should also be remembered that given in high dose, especially in patients with renal impairment, penicillin can be neurotoxic.

There is no logical reason why other β -lactams such as ampicillin/amoxicillin or cephalosporins cannot be used in preference to benzylpenicillin.

GLYCOPEPTIDES

Glycopeptides are used as an alternative to β -lactams for patients with hypersensitivity to penicillin or who are infected with resistant bacteria. Glycopeptides are only slowly bactericidal, if at all, so must always be used in combination with another agent. Vancomycin is currently the glycopeptide of choice and in patients with normal renal function 1 g every 12 h should be used initially. Dosage can then be modified according to trough level, normally 10–15 mg/L, but increasing to 15–20 mg/L for staphylococcal isolates with an MIC \geq 2 mg/L. Teicoplanin may be considered for streptococcal endocarditis but at an initial dosage of at least 10 mg/kg every 12 h, then 10 mg/kg per day. As pharmacokinetics are unpredictable, levels must be measured at least weekly to ensure trough levels of at least 20 mg/L.

The role of the newer long-acting glycopeptides in the treatment of endocarditis has yet to be determined.

AMINOGLYCOSIDES

Animal studies have demonstrated the efficacy of combination therapy based on the traditional 8-hourly or 12-hourly regimens at a dose of 1 mg/kg. There is no evidence to suggest that once-daily gentamicin would be less effective but authorities are reluctant to recommend it on the basis that in some patients there may be a significant time period when serum levels are below 1 mg/L. Either way, levels should be monitored at least twice weekly, and more frequently in patients with renal impairment or who are on concomitant therapy with other nephrotoxic drugs.

OTHER ANTIBIOTICS

Guideline recommendations are just that: recommendations which may need to be modified for individual patients. Controlled trials are few but a recent study of daptomycin⁷ to treat staphylococcal bacteraemia did include some patients with endocarditis. There are numerous case reports which have documented the successful use of quinolones, linezolid, rifampicin (rifampin), clindamycin and co-trimoxazole for a range of infecting bacteria.

EMPIRICAL THERAPY (Table 46.1)

For some patients who have an indolent presentation, it may be possible to delay antibiotics until the results of blood cultures are available. In practice this is rarely possible and therapy must be commenced immediately.

Table 46.1 Empirical therapy

Acute presentation	Flucloxacillin (8–12 g i.v. per day in 4–6 divided doses), plus gentamicin (1 mg/kg i.v. every 8 h, modified according to renal function)
Indolent presentation	Penicillin (7.2 g i.v. per day in six divided doses) or ampicillin/amoxicillin (2 g i.v. every 6 h), plus gentamicin (1 mg/kg i.v. every 8 h, modified according to renal function)
Penicillin allergy Intracardiac prosthesis Suspected methicillin-resistant <i>Staphylococcus aureus</i>	Vancomycin (1 g i.v. every 12 h, modified according to renal function), plus rifampicin (300–600 mg p.o. every 12 h), plus gentamicin (1 mg/kg i.v. every 8 h, modified according to renal function)

PROSTHETIC DEVICE ENDOCARDITIS

Prosthetic device endocarditis presents the greatest challenge for medical therapy since not only is it necessary to combat micro-organisms within a vegetation, they may also form part of a biofilm. Surgical intervention may need to be considered early, treatment may need to be more prolonged and antibiotic combinations that include agents active in biofilms may be more effective. Unfortunately, owing to the lack of robust clinical data, recommendations are based on the ‘best guess’ approach and expert advice should be sought for individual cases.

STAPHYLOCOCCAL ENDOCARDITIS (Table 46.2)

The choice of antibiotic will depend on the sensitivity of the infecting strain. There is no evidence that adding gentamicin to flucloxacillin offers any benefit when treating methicillin-sensitive strains of *Staph. aureus* and is associated with an increase in adverse events. The addition of sodium fusidate or rifampicin is also not recommended.

Table 46.2 Antibiotic therapy for staphylococcal endocarditis

Methicillin sensitive	Flucloxacillin (2 g i.v. every 4–6 h)
Methicillin resistant/ penicillin allergy	Vancomycin (1 g i.v. every 12 h, modified according to renal function), plus rifampicin (300–600 mg p.o. every 12 h), or gentamicin (1 mg/kg every 8 h, modified according to renal function), or sodium fusidate (500 mg p.o. every 8 h)
Endocarditis in presence of intracardiac prosthesis	Flucloxacillin (2 g i.v. every 4–6 h) or vancomycin (1 g i.v. every 12 h, modified according to renal function), plus rifampicin (300–600 mg p.o. every 12 h), and/or gentamicin (1 mg/kg every 8 h, modified according to renal function), and/or sodium fusidate (500 mg p.o. every 8 h)

If vancomycin is used, the addition of a second agent is required. The choice depends on the sensitivity profile of the infecting organism. Teicoplanin is not recommended for staphylococcal endocarditis.

There are published case series which suggest that right-sided endocarditis can be successfully treated with either 14 days of intravenous therapy or 28 days of oral therapy. Examples of regimens include flucloxacillin alone, flucloxacillin plus rifampicin and quinolones.

STREPTOCOCCAL ENDOCARDITIS (Table 46.3)

With a few provisos (size of vegetation, septic emboli, intracardiac prosthetic material), endocarditis caused by streptococci with an MIC ≤ 0.1 mg/L for penicillin can be successfully treated with 14 days of combination therapy of a β -lactam plus gentamicin. For less sensitive strains, 14 days of combination therapy followed by a further 14 days of a β -lactam is recommended.

Endocarditis caused by *Streptococcus pneumoniae* is associated with a high mortality and has been ascribed to patient factors rather than antibiotic failure. Penicillin-resistant strains should be managed in the same way as enterococcal endocarditis.

Group B streptococcal endocarditis is frequently associated with diabetes and has a high mortality. Tolerance has been described in some strains, so 28 days of treatment, including 14 days of combination therapy with gentamicin, is recommended.

Str. gallolyticus (bovis) endocarditis is associated with underlying gut pathology and liver disease and so a potential source

should be sought. It should be treated according to its MIC for penicillin.

Nutritionally dependent streptococci are difficult to grow and appear tolerant to β -lactams, thus 28 days of combination therapy is usually advocated. For especially slow-growing isolates, treatment may need to be extended to 6 weeks.

For patients with documented penicillin allergy, a glycopeptide is generally advocated, but a carbapenem or daptomycin may also be considered.

ENTEROCOCCAL ENDOCARDITIS

Enterococci are usually tolerant to antibiotics and the range of available agents is more limited (Table 46.4), particularly for glycopeptide resistant strains. The use of new agents such as linezolid or daptomycin could potentially be life-saving in these circumstances.

Prolonged therapy (6–12 weeks) may be necessary, and relapse is not uncommon. For isolates with high-level gentamicin resistance, streptomycin should be used as an alternative if the organism is sensitive. For glycopeptide-resistant isolates, daptomycin should be used.

OTHER BACTERIA

Choice of agents and duration of therapy will vary according to the infecting organism. Difficulties obviously arise when the diagnosis is made by serology, as sensitivity testing cannot be performed.

Table 46.3 Antibiotic therapy of streptococcal endocarditis^a

Penicillin MIC (mg/L)	Penicillin or vancomycin and gentamicin 4 weeks	Penicillin 4 weeks	Ceftriaxone 4 weeks	Vancomycin or penicillin 4 weeks and gentamicin 2 weeks	Penicillin 4–6 weeks and gentamicin 4–6 weeks	Vancomycin 4–6 weeks and gentamicin 4–6 weeks
≤ 0.1	✓	✓	✓			
$\geq 0.1 < 0.5$				✓		
$0.5 - < 16$					✓	✓
≥ 16						✓

^aFor dosages please refer to Tables 46.1, 46.2 and 46.4.

Table 46.4 Treatment of enterococcal endocarditis

Antimicrobial regimen	Dose and route	Duration (weeks)	Comments
Ampicillin or penicillin, plus gentamicin	2 g i.v. every 4 h (2.4 g every 4 h) 1 mg/kg i.v. every 8–12 h	≥ 4 ≥ 4	
Vancomycin, plus gentamicin, or streptomycin	1 g i.v. every 12 h 1 mg/kg i.v. every 8–12 h 7.5 mg/kg every 12 h	≥ 4	Alternative for penicillin-allergic patient provided isolate is vancomycin susceptible (MIC ≤ 4 mg/L)
Daptomycin	4–8 mg once daily	≥ 4	For glycopeptide-resistant strains

For fastidious Gram-negative bacteria, known as the 'HACEK' group, initial therapy with ampicillin/amoxicillin plus gentamicin would be appropriate. If the infecting organism is ampicillin/amoxicillin resistant, consider ceftriaxone, a carbapenem, or another class of antibiotic according to sensitivity.

It has been estimated that *Coxiella burnetii* accounts for up to 5% of cases of endocarditis worldwide. A combination of doxycycline and a quinolone is recommended as first-line treatment, and this must be continued until titers return to normal. Patients should be followed up for at least 2 years.

FUNGAL ENDOCARDITIS

Fungal endocarditis is a rare and devastating condition which usually requires surgical intervention.

Ideally the antifungal agent(s) should be cidal, and as with bacterial endocarditis, the choice of agent will depend on the sensitivity of the strain of fungus implicated.

Amphotericin B plus flucytosine are traditionally the agents of first choice for *Candida*, although both are toxic. High-dose fluconazole (400 mg every 12 h) could be considered as second-line therapy, but it is only fungistatic. Caspofungin is fungicidal, but experience with its use in endocarditis is limited.

For other fungal species voriconazole or caspofungin should be considered as first-line empirical therapy.

PREVENTION OF ENDOCARDITIS

The role of antibiotics in the prevention of endocarditis is controversial. Over the past 5 years there has been a paradigm shift away from universal prophylaxis for at-risk patients undergoing dentistry due to lack of evidence for its efficacy.⁹ Some authorities (UK and USA) have taken a more cautious approach, limiting prophylaxis to only those patients for whom endocarditis would carry a higher mortality, for example those who have had previous endocarditis or who have intracardiac prostheses.^{10,11} For these

reasons, readers should refer to their local guidelines for further information.

Nevertheless, it should not be forgotten that individuals with structural cardiac abnormalities or devices are at higher risk of endocarditis than those with 'normal' hearts. When undergoing surgical procedures requiring antibiotic prophylaxis for surgical site infection, special consideration should be given to the risk of enterococcal bacteraemia and the prophylactic regimen adjusted accordingly.

CHAPTER

47 Infections of the gastrointestinal tract

Peter Moss

Infectious diseases may affect any part of the gastrointestinal tract from the mouth to the anus. Most infections of the mouth, oropharynx and esophagus are caused either by commensal organisms or by opportunist pathogens. These infections are usually secondary to underlying problems, either local (e.g. poor oral hygiene, malignancy) or systemic (particularly immunosuppression). Infections of the stomach are relatively unusual, with the exception of *Helicobacter pylori*, which is associated with peptic ulceration and gastric neoplasms. It is infections of the lower gastrointestinal tract, the small and large bowel, which are of the greatest clinical significance.

Intestinal infections usually present with diarrhea, sometimes accompanied by vomiting, abdominal pain and fever. In severe cases there may be dehydration, hypovolemic shock and renal failure. Persistent infection may cause anorexia and weight loss. Gastroenteritis may be caused by viruses, bacteria, protozoa or (rarely) by helminths. Symptoms and signs may be produced by one or more of a number of different pathological mechanisms. The clinical presentation of gastroenteritis rarely allows a specific diagnosis, and it is not usually possible to identify the causative organism, at least in the early stages of illness. Management is therefore usually empirical and is based on the recognition of common clinical syndromes. These include acute watery diarrhea, dysentery, persistent diarrhea with or without malabsorption, and enteric fever. Identification of these patterns, along with a knowledge of the likely pathogens in a particular location and patient population, will guide treatment in most cases.

EPIDEMIOLOGY

Gastroenteritis causing diarrhea with or without vomiting is the second most common infectious cause of death worldwide (behind lower respiratory tract infection). Although oral rehydration programs have cut the death toll significantly, it is estimated that over 2 million people die every year as a direct result of diarrheal disease.¹ Gastroenteritis is a major cause of morbidity as well as mortality, with a disease burden of 160 million disability-adjusted life years (DALY) worldwide.¹ The main burden falls on the poorest countries, where children can expect on average 3–6 bouts of infective diarrhea every

year, and 15–20% of deaths under the age of 5 are due to diarrheal disease.² In the Western world gastroenteritis is both less common and less likely to cause death, but it remains an important cause of morbidity and mortality. In Europe diarrheal disease is responsible for 39 000 deaths per year, and results in a burden of over three million DALY annually.¹

Viral gastroenteritis is a common cause of diarrhea and vomiting in young children in both developed and developing countries, but is less often seen in adults. The viruses responsible (principally rotavirus, norovirus and enteric adenoviruses) are spread from person to person, mainly by the feco-oral route, but also as an aerosol. Seasonal outbreaks are seen in developed countries, and in comparison with other diarrheal diseases there is less association with poverty and poor hygiene.

The main cause of adult gastroenteritis is bacterial infection. In developed countries this is often related to food poisoning, a problem exacerbated by modern methods of food production and the globalization of food supply. In less developed areas transmission is frequently by the direct feco-oral route or from a contaminated water supply. Massive water-borne outbreaks may occur, especially in association with natural disasters or war. Protozoal and helminthic gut infections are rare in the West but are widespread in developing countries.

In all parts of the world it is children who are at most risk of catching diarrheal disease and at most risk of dying from it. Mortality is mainly related to dehydration, although other factors such as malnutrition are important in developing countries. Elderly people are also at increased risk of complications from gastroenteritis. In the developed world certain other groups have a higher incidence of diarrheal disease: these include travelers to developing countries, the immunocompromised (especially in HIV infection) and infants in daycare facilities.

PATHOGENESIS OF ENTERIC INFECTION

Micro-organisms with the potential to cause enteric infection are ubiquitous, and the development of disease depends on a number of host and microbial factors:

- Host factors include age and general health, personal hygiene, specific and non-specific immunity, and composition of normal intestinal microflora.
- Microbial factors include a number of virulence traits which determine the pathogenic mechanisms responsible for causing gastrointestinal infection.

Bacteria can cause diarrhea in three different ways: mucosal adherence, toxin production and mucosal invasion (Table 47.1). Many species employ more than one of these methods. In most cases the first step in the pathogenic process is adherence to the intestinal mucosa, the exception being those bacteria which secrete toxin in food before consumption. A number of different molecular adhesion mechanisms have been elaborated, typically involving microbial cell surface proteins (often located on pili or fimbriae) which bind to specific host glycoproteins. Expression of many of these adhesion proteins is encoded by transmissible plasmids. Usually attachment to the mucosa is merely the prelude to invasion or toxin production, but a few organisms such as enteropathogenic *Escherichia coli* can produce mucosal damage and secretory diarrhea directly as a result of adherence.³

Some bacteria, having attached to the intestinal mucosa, simply colonize the surface epithelium. Others, such as *Shigella* species and the invasive strains of *Esch. coli*, penetrate and destroy the cells of the intestinal mucosa. Many different mechanisms may be involved in the invasive process, including attachment to transmembrane glycoproteins, production of cytotoxic exotoxins, and deliberate induction of host inflammatory response.⁴ Invasion leads to destruction of the epithelial cells and produces the typical symptoms of dysentery: low volume bloody diarrhea with abdominal pain.

Many bacterial enteric pathogens produce symptoms by means of toxin production. Gastroenteritis can be caused by three different types of bacterial toxin:

- Enterotoxins induce excessive fluid secretion into the bowel lumen without physically damaging the mucosa.
- Neurotoxins affect the autonomic nervous system, causing diarrhea and vomiting.
- Cytotoxins damage the intestinal mucosa and, in some cases, vascular endothelium as well.

Usually these toxins are produced by bacteria adhering to the intestinal epithelium, but neurotoxins (often stable to heat

and gastric acid) may be elaborated exogenously by pathogens in poorly prepared food.

The pathogenic mechanisms underlying viral gastroenteritis are less well understood. The initial event is again adhesion, a viral capsid protein binding to specific glycolipid receptors in the mucosal cell membrane. This is followed by invasion, mainly of mature villus epithelial cells in the small intestine. A direct cytopathic effect leads to cell death, causing villus shortening, relative loss of absorptive epithelial cells relative to secretory crypt cells, and decreased production of intestinal disaccharidases.⁵ In some cases (such as infection with Norwalk virus) there is significant mucosal inflammation, while in others (including rotavirus infection) there is little host inflammatory response. Diarrhea is probably produced by a combination of secretory/resorptive imbalance and disaccharide/fat malabsorption (which may persist for some time following acute infection).

Protozoa can cause diarrhea by both invasive and non-invasive mechanisms. *Entamoeba histolytica* (and probably *Balantidium coli*) attaches to the colonic mucosa by specific binding proteins. It then causes local destruction of the epithelium by a combination of lytic enzyme release and phagocytosis, leading to the clinical symptoms of dysentery.⁶ *Giardia lamblia* (*intestinalis*), by contrast, is very rarely invasive. The parasite attaches to the duodenal and jejunal mucosa using a combination of mechanical and molecular bonds. Local disruption of the brush border ensues, with disaccharidase deficiency. There may also be more extensive damage to the epithelium with partial villous atrophy and inflammatory infiltrates; this is probably due to a cellular immune response to infection.⁷ Several different pathogenic mechanisms may be important in the production of diarrhea by *Cryptosporidium parvum* (depending in part on the integrity of the host immune system), while the role of other parasites such as *Dientamoeba fragilis* and *Blastocystis hominis* in causing gastroenteritis remains unclear.

Although helminthic infection of the gut is very common, it rarely causes significant enteric symptoms. Schistosomal colitis can result from the inflammatory response to parasite eggs lodged in the bowel wall, and some nematodes (notably *Trichuris trichiura*) may cause symptoms due to superficial invasion of the colonic mucosa. Heavy worm infestations may cause mechanical problems such as obstruction or prolapse.

Table 47.1 Pathogenic mechanisms of bacterial gastroenteritis

Mechanism	Mode of action	Clinical presentation	Examples
Mucosal adherence	Effacement of intestinal mucosa	Moderate watery diarrhea	Enteropathogenic <i>Esch. coli</i>
Toxin production			
Neurotoxin	Paralysis of autonomic nervous system	Short-lived, profuse watery diarrhea and vomiting	<i>Bacillus cereus</i>
Enterotoxin	Fluid secretion without mucosal damage	Variable diarrhea ± vomiting	<i>Vibrio cholerae</i>
Cytotoxin	Damage to mucosa	Bloody diarrhea	Enterohemorrhagic <i>Esch. coli</i>
Mucosal invasion	Penetration and destruction of mucosa	Dysentery	<i>Shigella</i> spp.

SYNDROMIC MANAGEMENT OF GASTROENTERITIS

SYNDROMES

ACUTE WATERY DIARRHEA

Acute, self-limiting, watery diarrhea is the most common form of gastroenteritis. It is produced by direct or toxin-mediated damage to the secretory and absorptive gut mucosal cells, and may be caused by a number of different pathogens (Table 47.2). Specific microbiological diagnosis is rarely necessary, as antimicrobial therapy is not usually required. The morbidity and mortality of acute watery diarrhea is largely related to dehydration (especially in children), and by far the most important component of management is adequate rehydration. In most cases this can be achieved by oral rehydration solutions (ORS), although intravenous fluids may occasionally be needed. Antimotility agents are rarely helpful, and should definitely not be used in young children.

Dehydration is assessed clinically (Table 47.3) and treatment depends on the degree of fluid loss. Mildly dehydrated individuals should be given increased fluids; infants and children should continue feeding normally if possible. For moderate dehydration, ORS 75–100 mL/kg is given within the first 4 h, followed by further fluids to replace loss. Children should continue feeding once initial rehydration is completed. Intravenous rehydration is required only for severely dehydrated individuals with features of collapse. Several liters of intravenous fluid are usually required to overcome the features of shock: adults and older children should be given 30 mL/kg in the first 30 min, then 70 mL/kg over the next 2.5 h; the rates

should be halved for infants under 12 months.⁸ Maintenance of hydration can usually be achieved with ORS. In moderate and severe dehydration the patient must be reassessed regularly to ensure that adequate fluid is being given. Attention should also be paid to nutrition, acid–base status and electrolytes, especially if the diarrhea is prolonged. Oral zinc (20 mg/day for 14 days; 10 mg/day age <6 months) should be given to children with acute diarrhea, at least in developing countries, as this decreases both the severity of the acute episode and the incidence of diarrhea in the following 2–3 months.⁹

Antimicrobial therapy is rarely indicated in the empirical management of acute watery diarrhea. Antibiotics may lead to a decrease in the duration and severity of symptoms in some cases, but the improvement is small, and the condition is usually mild and self-limiting anyway.¹⁰ Even in situations where acute watery diarrhea is life threatening (e.g. in malnourished infants) there is little evidence that antibiotics are beneficial except in the case of cholera. In cases in which there is strong clinical suspicion of cholera (or another infection that does require specific treatment) antibiotics should be started empirically while awaiting confirmation. Occasionally acute watery diarrhea may be the presenting symptom of an enteric infection which develops into persistent diarrhea (e.g. giardiasis) or dysentery (shigellosis or *Campylobacter* infection). In these cases antibiotic therapy may be necessary when the diagnosis becomes clear.

DYSENTERY

Dysentery is a clinical syndrome of bloody, usually low volume, diarrhea often associated with abdominal pain and fever. It is caused by infection with invasive enteropathogens (see Table 47.2). Fluid and electrolyte loss is not as great as in watery

Table 47.2 Clinical syndromes of gastroenteritis and typical causative organisms

	Acute watery diarrhea	Bloody diarrhea	Persistent diarrhea
Viruses	Rotavirus Enteric adenoviruses Caliciviruses (including norovirus) Astroviruses		Recurrent infections with rotavirus
Bacteria	<i>Salmonella enterica</i> serotypes <i>Campylobacter jejuni</i> Enteropathogenic <i>Esch. coli</i> Enterotoxigenic <i>Esch. coli</i> Enteroinvasive <i>Esch. coli</i> <i>Vibrio cholerae</i> <i>V. parahaemolyticus</i> <i>Clostridium difficile</i> <i>Staphylococcus aureus</i> (toxin b) <i>Bacillus cereus</i>	<i>Salmonella enterica</i> serotypes <i>Campylobacter jejuni</i> <i>Shigella</i> spp. Enteroinvasive <i>Esch. coli</i> Enterohemorrhagic <i>Esch. coli</i> <i>Yersinia enterocolitica</i> <i>C. difficile</i>	<i>Mycobacterium tuberculosis</i> Recurrent or relapsing infections with other bacterial pathogens
Protozoa	<i>Giardia lamblia</i> <i>Cryptosporidium parvum</i> <i>Isospora belli</i> <i>Cyclospora cayetanensis</i> <i>Dientamoeba fragilis</i>	<i>Entamoeba histolytica</i> <i>Balantidium coli</i>	<i>Giardia lamblia</i> <i>Entamoeba histolytica</i> <i>Cryptosporidium parvum</i> <i>Isospora belli</i> <i>Cyclospora cayetanensis</i>
Miscellaneous		<i>Schistosoma mansoni</i> <i>Trichuris trichiura</i>	Postinfectious irritable bowel syndrome Disaccharidase deficiency

Table 47.3 Assessment of dehydration in acute diarrhea in children

Symptom/sign	No/minimal dehydration	Moderate dehydration	Severe dehydration
Mental state	Alert	Restless, irritable	Lethargic or unconscious; floppy infant
Eyes	Normal	Sunken	Very sunken, dry
Tears	Present	Absent	Absent
Tongue	Moist	Dry	Very dry
Thirst	Drinks normally	Drinks very eagerly	Unable to drink
Skin pinch	Goes back rapidly	Goes back slowly	Goes back very slowly
Probable fluid deficit	<2.5% body weight	2.5–10% body weight	>10% body weight
Management	Increased fluids	Oral rehydration	Intravenous fluids

diarrhea, although ORS may still be important, especially in children. Morbidity and mortality are often due to complications other than dehydration, including perforation, sepsis and hemolytic–uremic syndrome (HUS). In most cases of bacillary dysentery, antibiotics significantly reduce the severity and duration of illness, and in some instances decrease mortality.⁸ Antimicrobials should always be used in shigellosis and amebic dysentery, and may be helpful in other forms of bacillary dysentery. In developed countries the empirical therapy for dysentery (when amebiasis is not suspected) is either a fluoroquinolone or azithromycin. In developing countries bacillary dysentery is presumptively treated as shigellosis (p. 600). However, in dysentery caused by verotoxigenic *Esch. coli*, antibiotic treatment increases the risk of toxin-mediated HUS and antibiotics should be used with caution if this is suspected.¹¹

PERSISTENT DIARRHEA

Infective diarrhea that continues for more than 14 days is defined as persistent, and may occur with or without malabsorption. It may be continuous, but is frequently intermittent, varying from day to day. Persistent diarrhea is often associated with weight loss and malnutrition, and accounts for most diarrheal deaths in children. It may be due to recurrent or relapsing infection with common and usually self-limiting bacterial or viral pathogens, especially in malnourished individuals. In other cases, such as giardiasis, Whipple's disease and intestinal tuberculosis, chronic diarrhea is the normal presentation in the absence of specific treatment (see Table 47.2). Immunocompromised patients, especially those infected with HIV, are susceptible to a variety of pathogens causing persistent diarrhea.

It is important to identify the infecting organism as specific treatment is often required. If this is not possible, empirical treatment based on local patterns of infection in relevant patients should be used. This is particularly important in people with HIV/AIDS. If malnutrition is either contributing to or resulting from infection, nutritional supplements should be given. Antimotility agents may give symptomatic relief when the underlying cause cannot be diagnosed or treated.

In some cases persistent diarrhea may be triggered by an acute and self-limiting infection. A number of pathogens, including rotavirus, can cause villus damage and disaccharidase deficiency, leading to malabsorption. This is managed by temporary withdrawal of the malabsorbed nutrient. Postinfectious irritable bowel may follow infection with some gastrointestinal pathogens.

ENTERIC FEVER

Enteric fever is primarily a systemic illness, although the spread is feco-oral and the portal of entry gastrointestinal. The diagnosis is based on typical features and confirmed by isolation of the organism from blood or bone marrow. Treatment is with specific antimicrobial therapy (p. 600).

ANTIBIOTIC-ASSOCIATED DIARRHEA

Diarrhea associated with antibiotic use can present from 1 day to several weeks after taking the antibiotic. Symptoms can vary from mild watery diarrhea to a dysenteric syndrome with severe colitis. In many cases (especially at the milder end of the spectrum) diarrhea is due to a direct effect of the antibiotic on the gut (commonly associated with macrolides and clavulanic acid) or to changes in the normal intestinal microflora. However, in 10–25% of patients with antibiotic-associated diarrhea (and 50–75% of those with antibiotic-associated colitis),¹² the symptoms are attributable to *Clostridium difficile* infection (p. 602).

TRAVELERS' DIARRHEA

Travelers' diarrhea is defined as the passage of three or more unformed stools per day in a resident of an industrialized country traveling in or recently returned from a developing nation. Infection is usually food- or water-borne, and

younger travelers are most often affected (probably reflecting behavior patterns). Reported attack rates vary from country to country, but approach 50% for a 2-week stay in many tropical countries. It may be caused by a wide variety of pathogens, the most common being enterotoxigenic *Esch. coli*.¹³ The severity and duration of symptoms can be reduced by antibiotic treatment,^{14,15} but the illness is usually relatively mild and self-limiting. ORS should be used to prevent dehydration. The decision to treat with antibiotics should be based on individual circumstances, bearing in mind the cost, potential side effects and the possible effects on antimicrobial resistance.

SOLUTIONS FOR ORAL AND INTRAVENOUS REHYDRATION

The use of oral rehydration solutions is based on the observation that glucose and other carbohydrates enhance sodium absorption in the small intestine, even in the presence of secretory loss due to toxins. The recognition of this principle, and the widespread promotion of the use of ORS by the World Health Organization (WHO) and other organizations, has saved millions of lives over the past 20 years. The composition of currently recommended (lower osmolarity) WHO/UNICEF and other ORS are shown in Table 47.4.

Although the original standard WHO/UNICEF ORS was effective in replacing fluid loss, it did not have any impact on the duration and severity of diarrhea. Other forms of ORS have been developed in an attempt to address this. ORS based on cereal carbohydrate (usually rice) rather than glucose has been shown significantly to decrease stool volume and length of illness in cholera, both in adults and in

children.¹⁶ In other forms of acute diarrhea it is at least as good as glucose ORS in replacing fluid loss (even in infants under 6 months), but does not have such a marked impact on the course of the illness.^{16,17} Hypo-osmolar ORS has been shown to decrease stool fluid loss in children,¹⁸ although this effect has not been demonstrated in adults and may be affected by other factors such as concurrent breast feeding.¹⁹ Because of the significant benefits in children (who are at most risk from diarrhea) the WHO and UNICEF now recommend that the hypo-osmolar formulation should be the first choice ORS.⁹

Several other supplements have been added to ORS in an attempt to improve efficacy. The addition of lactobacilli has been shown to improve outcomes in children with rotavirus and non-rotavirus diarrhea, although this has not become standard practice.^{20,21} Supplementation of ORS with zinc significantly decreases fluid requirements in malnourished children with persistent diarrhea,^{22,23} but other nutritional supplements such as folic acid have not been shown to help.²⁴ It is important to keep the preparation and administration of ORS simple: community-based studies have shown that despite instruction a high proportion of mothers are unable to prepare even standard ORS correctly.²⁵

In severely dehydrated patients intravenous fluids may be needed for initial resuscitation. The fluid used should contain electrolytes to replace those lost, and bicarbonate or lactate to correct any acid–base imbalance. Examples of suitable commercial and generic solutions are shown in Table 47.4. If these are not available, isotonic (0.9%) saline can be used but it does not contain base or potassium. Simple dextrose solutions should not be used as they contain no electrolytes.⁸

Table 47.4 Solutions for oral and intravenous rehydration

Solution	Components (mmol/L)			Substance added (grams/L of water)
Oral				
WHO/UNICEF reduced osmolarity	Na Cl K Citrate Glucose	75 65 20 10 75	NaCl Trisodium citrate KCl Glucose (anhydrous)	2.6 2.9 1.5 13.5
Household (salt based)			Salt Sugar	2.5 (½ teaspoon) 30 (6 teaspoons)

Ringer's lactate	Na Cl K Lactate	130 109 4 28	Commercial preparation	
Dhaka solution	Na Cl Lactate K	133 98 48 13	NaCl NaHCO ₃ KCl	5 4 1

DRUGS IN SYNDROMIC MANAGEMENT

ANTIBIOTICS

Antibiotics are often prescribed for acute watery diarrhea in developed countries, even though the disease is usually mild and self-limiting (Table 47.5). Quinolones have been shown to decrease slightly the duration and severity of symptoms in adults in industrialized countries;¹⁰ there is little information on children (in whom viral diarrhea is much more common), or from the developing world. By decreasing fluid loss, antibiotic therapy should help to prevent dehydration, but there is no good evidence that the use of antimicrobials decreases mortality from dehydration or other complications of acute watery diarrhea. It may occasionally be justified on symptomatic grounds in adults with particularly severe or prolonged symptoms; in these cases either azithromycin 500 mg/day or ciprofloxacin 500 mg every 12 h for 3 days is the best choice. Any benefit from antibiotic therapy has to be balanced against cost, the risk of side effects and the possibility of inducing resistance.

Treatment with antibiotics is definitely indicated in shigellosis, which is the most common cause of dysentery in the developing world. The benefits are less marked in dysentery due to other organisms such as *Salmonella* and *Campylobacter*, which account for a large proportion of bloody diarrhea in industrialized countries. In general, in countries where shigellosis is relatively rare antibiotic therapy should be reserved for those with more serious or prolonged symptoms of bloody diarrhea; azithromycin or ciprofloxacin are again the drugs of choice. In developing countries adults and children should receive antibiotics for presumed shigellosis (p. 600).

Enteric fever should always be treated with antibiotics, and if clinical suspicion is high treatment should be started empirically while results are awaited.

A variety of different antibiotics have been shown to decrease the severity and duration of symptoms in travelers' diarrhea, including trimethoprim-sulfamethoxazole, erythromycin, azithromycin and quinolones.¹⁵ Ciprofloxacin is effective in a single dose of 750 mg, and is the best choice if antimicrobial therapy is needed. Antibiotic prophylaxis may be appropriate in some cases, especially in immunocompromised individuals. New options for prophylaxis are becoming available with the use of non-absorbed antibiotics such as rifaximin, and vaccines are under development.²⁶

ANTIMOTILITY AND ANTISECRETORY AGENTS

A number of antimotility agents are available for the symptomatic relief of diarrhea. The most widely used are codeine phosphate, loperamide, diphenoxylate and kaolin/opiate preparations: proprietary formulations of these are available over the counter in many countries. None is recommended for use in infants or young children with acute diarrhea because of the risk of precipitating respiratory depression or paralytic ileus. In adults antimotility agents may be useful for short-term relief of the symptoms of acute watery diarrhea (e.g. during a journey), although they can cause abdominal bloating. The use of these agents in dysentery is controversial. There is some evidence that they do provide symptomatic relief, but concerns exist about both increased risk of toxic dilatation and prolonged excretion of pathogens. If antimotility agents are used in more severe diarrhea and dysentery, they should be given in conjunction with appropriate antimicrobial therapy. Loperamide and codeine have a role in the management of chronic infective diarrhea, particularly in HIV-associated diarrhea where definitive treatment of the infection may be impossible.

Table 47.5 Antibiotics in the empirical treatment of acute gastroenteritis^a

Condition	Drug of choice	Alternatives	Indications	Benefits
Acute watery diarrhea	Ciprofloxacin 500 mg every 12 h (15 mg/kg every 12 h) or azithromycin 500 mg per day for 3 days	Clarithromycin 500 mg every 12 h Trimethoprim-sulfamethoxazole 960 mg every 12 h (30 mg/kg every 12 h)	Severe symptoms, prolonged illness, immunosuppressed patient	Relieves symptoms, shortens illness
Dysentery ^b	Ciprofloxacin 500 mg every 12 h (15 mg/kg every 12 h) or azithromycin 500 mg/day for 3 days	Ofloxacin 200 mg every 12 h (15 mg/kg in two divided doses) Ceftriaxone 2 g per day	Most patients	Relieves symptoms, shortens illness Decreases mortality in children
Travelers' diarrhea	Ciprofloxacin 750 mg single dose	Trimethoprim-sulfamethoxazole 960 mg every 12 h (30 mg/kg every 12 h) Azithromycin 1 g single dose	Rarely needed	Relieves symptoms, shortens illness

Treatment is for 5 days unless otherwise stated.

^aThe doses indicated are for adults; when provided, children's doses are given in parentheses (not to exceed adult dose). Fluoroquinolones are not licensed for children under 12 years old, although they are widely used and appear safe.

^bAntibiotics should be used with caution if enterohemorrhagic *Esch. coli* is suspected.

MANAGEMENT OF SPECIFIC INFECTIONS

BACTERIAL INFECTIONS (Table 47.6)

Cholera

Cholera is characterized by watery diarrhea that is often profuse and may be life-threatening. It is caused by secretory enterotoxins (principally cholera toxin) produced by *Vibrio cholerae*. The main pathogenic strain of *V. cholerae* worldwide is O1 El Tor, which first appeared in South East Asia in 1961 (the start of the seventh pandemic), and is now endemic in Africa, Asia, and Central and South America. A smaller number of cases are caused by the O1 (classical) and O139 biotypes. The mainstay of treatment for cholera is rehydration, and with appropriate and effective rehydration therapy mortality can be reduced to less than 1%. Oral rehydration with ORS is usually adequate, but severely dehydrated individuals may need intravenous fluids. Several liters of intravenous fluid may be required initially, and fluids must be continued to keep up with ongoing loss. As in other forms of watery diarrhea, zinc supplementation is beneficial in children.²⁷

Antibiotics reduce the duration and volume of diarrhea, and may limit transmission by reducing the infectivity of the stools.²⁸ Treatment should be started as soon as possible in order to decrease the fluid requirement. The standard treatment in children is a 12-dose course of erythromycin. In adults doxycycline (300 mg single dose) remains the antibiotic of choice in most cases but resistance is becoming a major problem in many parts of the world.^{29,30} Plasmid-mediated multi-drug resistance is common, but unlike shigellosis, cholera does not tend to accrue resistance over time, and resistance patterns fluctuate rapidly even in the same region.³¹ For this reason in an outbreak situation samples should be obtained for sensitivity testing as soon as possible. *V. cholerae* is generally sensitive to fluoroquinolones, and a single dose of ciprofloxacin has been shown to be as effective as doxycycline (in adults)^{32,33} and erythromycin (in children)³⁴ in treating cholera. Recently, however, some resistance to fluoroquinolones has been reported.³⁵ Azithromycin, another possible alternative, is effective as single-dose therapy in children and adults, but is more expensive and less widely available than the other drugs.³⁶

Effective surveillance and improvements in hygiene and sanitation are the main factors in limiting the spread of cholera. Antibiotic prophylaxis should not be given to asymptomatic contacts: this practice promotes the development of resistance and is not cost-effective.³⁷ A number of cholera vaccines are available or under development.

Table 47.6 Antibiotic treatment of specific bacterial causes of acute gastroenteritis^a

Condition	Drug of choice	Alternatives	Indications	Benefits
Cholera	Ciprofloxacin 1 g single dose (20 mg/kg single dose) or doxycycline 300 mg single dose	Erythromycin 250 mg every 6 h (12.5 mg/kg every 6 h) for 3 days Azithromycin 1 g single dose (20 mg/kg single dose)	All patients	Relieves symptoms, shortens illness Reduces transmission
Enteric fever	Ciprofloxacin 500 mg every 12 h (15 mg/kg every 12 h) for 7 days	Ofloxacin 15mg/kg/day in 2 divided doses for 3 days Azithromycin 500 mg once daily (10 mg/kg once daily) for 5–7 days Chloramphenicol 500 mg every 6 h (12.5 mg/kg every 6 h) for 7 days Ceftriaxone 2 gm daily	All patients	Reduces morbidity and mortality
Non-typhoidal salmonellosis	Ciprofloxacin 500 mg every 12 h (15 mg/kg every 12 h)	Trimethoprim-sulfamethoxazole 960 mg every 12 h (30 mg/kg every 12 h) Azithromycin 500 mg/day	Prolonged illness; severe symptoms; immunosuppressed	Relieves symptoms, shortens illness May decrease complications in selected groups
Shigellosis	Ciprofloxacin 500 mg every 12 h (15 mg/kg every 12 h)	Ofloxacin 200 mg every 12 h (15 mg/kg in two divided doses only) Azithromycin 500 mg on day one then 250 mg/day for 4 days (10 mg/kg per day) Ceftriaxone 2 g per day	All patients	Relieves symptoms, shortens illness Decreases morbidity and mortality
Campylobacter	Azithromycin 500 mg/day (10 mg/kg per day)	Clarithromycin 500 mg every 12 h	Immunosuppressed; severe symptoms (rarely needed)	

Treatment is for 5 days unless otherwise stated. Therapy should be guided by local antimicrobial sensitivities where known.

^aThe doses indicated are for adults; when provided, children's doses are given in parentheses (not to exceed adult dose). Fluoroquinolones are not licensed for children under 12 years old.

ENTERIC FEVER

The enteric fever syndrome is an acute systemic illness characterized by fever, headache and abdominal discomfort. Typhoid, the typical form of enteric fever, is caused by *Salmonella enterica* serotype *Typhi*. A similar but generally less severe illness known as paratyphoid is due to infection with *Salmonella enterica* serotypes Paratyphi A, B or C. Untreated typhoid carries a mortality of up to 30%, but this can be reduced dramatically with appropriate therapy. After clinical recovery, 5–10% of patients will continue to excrete *S. Typhi* for several months: these are termed convalescent carriers. Between 1% and 4% will continue to carry the organism for more than a year: this is chronic carriage.

Chloramphenicol has long been the drug of choice in enteric fever, but from the late 1980s onwards isolates resistant not only to chloramphenicol but also to ampicillin and co-trimoxazole have been reported from many parts of the world^{38,39} (multiple antibiotic resistance is mediated by a transmissible plasmid).⁴⁰ As a result, quinolones are now widely used to treat typhoid and paratyphoid. Although many strains remain fully sensitive to all quinolones, decreased susceptibility has been reported in a number of countries.⁴¹ Such isolates, although apparently ciprofloxacin susceptible on disc testing, often show in-vitro resistance to nalidixic acid and are associated with increased clinical failure rates when treated with ciprofloxacin.⁴² Newer quinolones such as gatifloxacin appear to have better activity against these nalidixic acid resistant strains.⁴³

Wherever possible the treatment of enteric fever should be based on individual or local antibiotic susceptibility patterns. With decreased usage chloramphenicol resistance rates have actually fallen in India and Bangladesh, and many isolates are now once again sensitive to this drug^{44,45} (which is cheap and widely available). However, fluoroquinolones give better outcomes than chloramphenicol even in fully susceptible strains,⁴⁶ and are the drug of choice in most situations. Where there is no decreased fluoroquinolone sensitivity, ciprofloxacin gives a clinical cure rate of 98%, fever clearance time of 4 days, and relapse and chronic carriage rates of less than 2% (better in all respects than chloramphenicol).⁴² No one drug of this class has been shown to be better than others; ciprofloxacin is the most widely used, and short courses of both ofloxacin and fleroxacin have proved effective in children.^{47–49} Despite concerns about the use of these agents in children (because of the risk of damage to developing cartilage) there is now considerable evidence to suggest that ciprofloxacin is sufficiently safe to be used in the treatment of childhood typhoid.^{50,51} Studies using cephalosporins have produced variable results: one study showed good a cure rate with ceftriaxone⁵² but others have demonstrated less efficacy with ceftriaxone and with cefixime than with other drugs, especially in short-course regimens.^{48,53}

Several trials in adults and children have shown excellent results using a 5- or 7-day course of azithromycin.^{54–57} Studies directly comparing ciprofloxacin, azithromycin and ceftriax-

one have produced mixed results and are difficult to interpret because of variations in study design and populations.⁵⁸ Where there is known to be decreased susceptibility to quinolones, azithromycin appears to be the most effective agent,⁵⁹ but the use of this drug (and the cephalosporins) is limited by cost and availability. Another potential option in this situation is a quinolone such as gatifloxacin.⁴³

Most of these studies have been carried out in patients with mild or moderate typhoid. Patients with hypotension, impaired mental function or evidence of decreased organ perfusion have a worse prognosis, and the impact of newer antibiotics in this group has not been assessed. The role of steroids in severe typhoid remains controversial: one trial (with relatively small numbers) demonstrated increased survival in patients treated with high-dose dexamethasone,⁶⁰ but there is little corroborating evidence for this. Complications such as intestinal perforation and renal failure should be managed aggressively, with surgical intervention and intensive care support where necessary.

Chronic carriage of *S. Typhi* may be difficult to eradicate, especially in the presence of gallbladder disease or urinary schistosomiasis. Prolonged courses of amoxicillin or trimethoprim-sulfamethoxazole are sometimes effective, and quinolones appear to have a higher success rate.^{61,62} Treating underlying gallbladder or parasitic disease may help, but cholecystectomy is not justified on public health grounds alone.

SHIGELLOSIS

Infection with *Shigella* species can cause either watery diarrhea (clinically indistinguishable from other causes of acute watery diarrhea) or, more typically, dysentery. Four species can cause enteritis in humans: *Shigella dysenteriae* produces the most severe dysentery and may also secrete a toxin which can induce hemolytic-uremic syndrome. Antibiotic treatment of shigella dysentery leads to a reduction in the severity and duration of symptoms, as well as a decrease in mortality in children.⁸ In theory the use of antibiotics in toxigenic *S. dysenteriae* could lead to an increased risk of hemolytic-uremic syndrome (as has been demonstrated in infections with verotoxigenic *Esch. coli*), but this remains to be confirmed.

Shigella spp. can rapidly develop resistance to antimicrobials, due to their ability to acquire plasmid-borne resistance genes from other species such as *Esch. coli*.⁶³ Multiresistance is common, and some of the older and cheaper antibiotics such as ampicillin and trimethoprim-sulfamethoxazole are now ineffective in many developing and developed countries.^{64,65} Most isolates remain sensitive to quinolones, although it is now recognized that quinolone resistance too can be acquired through horizontal plasmid transfer,⁶⁶ and clinical fluoroquinolone resistance is being reported.^{67,68} The group 1 quinolone nalidixic acid has been used extensively for the treatment of shigellosis in the past. However, resistance to this drug develops rapidly and predisposes to more extensive quinolone resistance.⁶⁹ Nalidixic acid dosing regimens are more complicated than those of more

modern quinolones, it is no longer the cheapest option, and its use in shigellosis is no longer recommended.⁷⁰

A number of studies have demonstrated the clinical efficacy of ciprofloxacin, norfloxacin and ofloxacin in both adults and children.^{71,72} Short courses of quinolones (e.g. ofloxacin 15 mg/kg in two divided doses in children) appear to be effective in many cases, making their use more economically viable. Ceftibuten, cefixime and ceftriaxone have all been shown to be effective in various regimens,^{73,74} as has azithromycin (500 mg, followed by 250 mg/day for 4 days),⁷⁵ but the data on these drugs are less complete and their use is limited by cost and availability. Ideally, the choice of antibiotic for shigellosis should be guided by current local resistance patterns. In the absence of these, a fluoroquinolone is the drug of choice in most areas,⁷⁰ with ciprofloxacin being the cheapest and most widely available.

Although dehydration is not usually a major feature of shigella dysentery ORS should be given, especially to children.

NON-TYPHOIDAL SALMONELLOSIS

Salmonella serotypes other than Typhi and Paratyphi most commonly cause self-limiting gastroenteritis, which is usually watery but may be dysenteric. Bacteremia is documented in about 5% of cases: this may be transient and benign, but can lead to serious complications such as metastatic infection. Clinical trials suggest that fluoroquinolones may reduce the duration and severity of gastrointestinal symptoms in salmonella infection, but the effect is small (1–2 days reduction).¹⁰ In general, antibiotics are not recommended for people with mild or moderate salmonella enteritis: even the presence of bacteremia in an otherwise healthy person is not a definite indication. Treatment is justified in patients with severe or prolonged symptoms, in neonates, and for those at increased risk of invasive disease (in particular the immunocompromised and patients with significant underlying disease). Some authorities recommend a short (48–72 h) ‘pre-emptive’ course of antibiotics in those who have other risk factors for metastatic disease (e.g. elderly people and people with known atherosclerotic lesions or aortic aneurysm),⁷⁶ while others suggest a 10- to 14-day course in the same group:⁷⁷ the clinical efficacy of either approach is unproven.

If antibiotic treatment is indicated, then fluoroquinolones are the best choice. Ceftriaxone, azithromycin and aztreonam are also effective; trimethoprim–sulfamethoxazole may be used although resistance is increasing. A number of studies have looked at the effect of quinolone treatment on fecal excretion of *Salmonella* spp., which typically persists for several weeks after infection. Treated patients usually have negative stool cultures immediately after treatment, but overall antibiotics have little effect on the time taken to clear the organism.⁷⁸ Even this limited response may be effective in interrupting spread of the disease in institutional outbreaks.⁷⁹ The management of symptomatic salmonella bacteremia (which is common in HIV-positive patients in developing countries) is difficult: antibiotics may help, but eradication often proves

impossible. Metastatic salmonella infection, which typically affects atheromatous endothelium, also requires prolonged antibiotic therapy, often in conjunction with surgery.

ESCHERICHIA COLI INFECTION

Esch. coli infection of the gut with enterotoxigenic (ETEC), enteropathogenic (EPEC), enteroinvasive (EIEC), enterohemorrhagic (EHEC) or enteroaggregative (EAggEC) strains can cause human disease, but these pathogens are not routinely identified in most microbiological laboratories. Consequently information about these infections is limited, and there are few therapeutic trials.

Verotoxin-secreting strains of EHEC (principally O157:H7) can cause hemolytic–uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP), especially in children, and have therefore been the focus of much attention in industrialized countries. Several large food-borne outbreaks of *Esch. coli* O157 have been reported; most patients had a mild self-limiting bloody diarrhea, but 2.5–14% of children (and occasional adults) developed HUS.^{11,80} Antibiotic treatment appears to increase the risk of HUS, presumably by increasing toxin release from dying bacteria,¹¹ and antibiotics should generally be avoided in *Esch. coli* O157 enteritis. EHEC has also been reported as a cause of gastroenteritis in adults and children in Africa.⁸¹

ETEC, which can produce both heat-stable and heat-labile toxins, is an important cause of acute watery diarrhea in children and adults throughout the world.^{81,82} It has been responsible for large food- and water-borne outbreaks, and is the most commonly confirmed cause of travelers’ diarrhea.^{83,84} Widespread antibiotic resistance has been reported, with isolates from many parts of the world showing resistance to multiple drugs, including trimethoprim–sulfamethoxazole and amoxicillin.⁸³ The majority of ETEC remain sensitive to fluoroquinolones, but a survey in Thailand showed 1% of isolates to be ciprofloxacin resistant; 15% of isolates in the same study were azithromycin resistant.⁸⁵ The illness caused by ETEC is usually mild and self-limiting; however, if treatment is deemed necessary, then a fluoroquinolone should be used if available.

EIEC causes bacillary dysentery indistinguishable from shigellosis. It is rarely isolated and most cases are probably treated empirically as shigellosis. If EIEC is cultured, treatment should be guided by sensitivities.

EPEC is now recognized as a cause of acute watery diarrhea in infants and children worldwide, although it appears to be more common in developing countries.^{81,86,87} Relatively little is known about antibiotic sensitivities of EPEC: resistance to trimethoprim–sulfamethoxazole has been reported, but it is generally sensitive to quinolones.^{87,88} Antibiotic treatment is rarely indicated.

EAggEC can be isolated from healthy people, but it also appears to be responsible for episodes of travelers’ diarrhea,⁸⁹ persistent diarrhea in children^{87,90} and HIV-associated

diarrhea.⁹¹ The symptoms of both travelers' diarrhea and HIV-related chronic diarrhea caused by EAEC can be alleviated by ciprofloxacin,^{89,91} although in the former case this is not usually necessary. The epidemiology and treatment of EAEC diarrhea in developing countries remains unclear.

CAMPYLOBACTER INFECTION

Infection with *Campylobacter jejuni* can cause acute watery diarrhea or, less commonly, dysentery. The illness is usually relatively mild and self-limiting, although there may occasionally be more severe dysenteric or systemic features. *Campylobacter coli* causes a similar but generally less severe illness. *Campylobacter* spp., which are widespread in livestock animals, have considerable potential to develop antibiotic resistance. This is usually plasmid mediated and has been associated with the use of antibiotics in both humans and animals. Resistance to fluoroquinolones has become a major problem in many countries, with up to 70–80% of human isolates being resistant in some areas (notably Spain and Thailand).⁹² This has been linked to the veterinary use of these drugs,⁹³ but resistance has also been shown to develop in humans during a course of treatment.⁹⁴ Macrolide resistance is also increasing.⁹²

Most cases of campylobacter enteritis resolve without specific treatment. More severe cases are likely to be treated empirically, but if campylobacter is suspected then azithromycin is the best choice. If a *Campylobacter* species is grown and significant symptoms persist (especially in patients with HIV/AIDS), then antibiotic treatment should be guided by in-vitro sensitivities.

YERSINIA INFECTION

Yersinia enterocolitica is a relatively unusual cause of enteric infection in all ages. The spectrum of illness is very variable, and includes severe dysentery, septicemia and extraintestinal manifestations such as lymphadenopathy and reactive arthritis. More severe cases should be treated with antibiotics: fluoroquinolones appear to be the most effective agents, although data are limited.⁹⁵

NON-CHOLERA VIBRIO, AEROMONAS AND PLESIOMONAS SPECIES

These organisms are being isolated with increasing frequency from patients with gastroenteritis, although whether this represents a genuine increase in prevalence or simply better laboratory techniques is unclear. *Vibrio parahaemolyticus* has caused major food- and water-borne outbreaks in Asia,⁹⁶ while *Aeromonas* and *Plesiomonas* species are common causes of diarrhea in children and travelers in some parts of the world.^{77,84,97}

All three usually cause self-limiting watery diarrhea. Almost all of these organisms are sensitive to fluoroquinolones in vitro; there is widespread and variable resistance to other antibiotics.⁹⁸ Clinical data are very limited.

TOXIN-SECRETING BACTERIA

Some bacteria, notably *Clostridium perfringens*, *Bacillus cereus* and strains of *Staphylococcus aureus*, can produce heat-stable neurotoxins that affect the autonomic nervous system to cause diarrhea and vomiting. If toxin is ingested in contaminated food, symptoms start within a few hours. Although diarrhea may be profuse, the illness is usually short lived (24–48 h) and no specific treatment is required. Bacterial toxins are a common cause of food poisoning in Europe and the USA; the prevalence in developing countries is unknown. Ingestion of preformed toxins of *Clostridium botulinum* (especially from inadequately processed canned food) is a rarer but potentially fatal form of food poisoning.

CLOSTRIDIUM DIFFICILE

C. difficile has been recognized as a cause of antibiotic-associated diarrhea and of pseudomembranous colitis since the 1970s. In the last decade, however, it has attracted increased attention as a major cause of morbidity and mortality, especially in the healthcare setting. The overall incidence has increased, and mortality has risen since the emergence of the hypervirulent 027 ribotype in 2000.⁹⁹ The epidemiology of *C. difficile* as a healthcare-associated infection (HCAI) is well documented in the developed world, but there is a paucity of information on the prevalence and behavior in developing countries.

A spore-forming bacterium, *C. difficile* is widespread in the environment. It is occasionally found in asymptomatic individuals (especially neonates), but is usually prevented from colonizing the human gut by the presence of normal intestinal microflora. If the normal commensals are eradicated by antibiotic treatment, *C. difficile* is able to move into the vacant niche: this is especially likely in the immunocompromised and the elderly. The propensity for antibiotics to precipitate *C. difficile*-associated diarrhea (CDAD) depends on: (1) the effect of the antibiotic on the normal bowel flora, and (2) the resistance of *C. difficile* itself to the drug. Although almost any antibiotic can be associated with CDAD, cephalosporins, clindamycin and aminopenicillins have been the most frequently implicated in the past. More recently fluoroquinolones have emerged as an important predisposing factor because of increasing *C. difficile* resistance to quinolones.^{100,101}

Although antibiotics are important in the acquisition of *C. difficile* infection, there are complex organism and host factors involved in the development and course of CDAD. Once

the gut is colonized the organism produces cytopathic toxins (of which CDT A and B are the most important). These are responsible for the symptoms, which can range from mild watery diarrhea to potentially fatal pseudomembranous colitis.

The most obvious first step in managing CDAD is to stop or simplify antibiotic therapy. However, symptoms often do not start for days or weeks after the offending course, and if the patient is still on antibiotics it is often not clinically appropriate to stop them. The majority of patients with symptomatic *C. difficile* infection will require specific antimicrobial treatment. Metronidazole remains the most widely used agent, although the use of vancomycin is increasing. In mild or moderate CDAD the two drugs have similar efficacy, with cure rates of >90% (although recurrence is common). Some recent studies have shown poorer results with metronidazole; this may be related to the emergence of metronidazole-resistant *C. difficile*, although this relationship is unproven.^{12,102} In more severe disease vancomycin is more effective, with a better cure rate and faster time to cure,¹⁰³ and there is some evidence that higher doses (2 g per day) may be better still.⁹⁹ However, these benefits have to be weighed against the potential for increasing the rate of vancomycin resistance in other pathogens. Suggested treatment regimens are shown in Table 47.7.

Data on intravenous vancomycin and metronidazole in CDAD are limited. There is some evidence supporting the use of intravenous metronidazole in patients who are unable to take oral therapy;¹² vancomycin enemas have also been used in this situation. Relapse following treatment is common: this is usually due to reinfection with the same or a different strain rather than failure to clear the original infection. It is common

Table 47.7 Suggested management path for CDAD

	Antimicrobial treatment	Alternative/additional treatment
First episode General measures		Stop antibiotics if possible Fluid and electrolyte replacement Isolate; strict hygiene
Mild	Metronidazole 400 mg p.o. or 500 mg p.o. every 8 h ^a	Vancomycin 125 mg p.o. every 6 h
Severe ^{b,c}	Vancomycin 125 mg p.o. every 6 h ^d	Metronidazole 500 mg i.v. every 8 h ^e Vancomycin enema ^f
Recurrence	Metronidazole 400 mg or 500 mg p.o. every 8 h ^a	Vancomycin 250 mg p.o. every 6 h
Second recurrence	Vancomycin 500 mg p.o. every 6 h	<i>Saccharomyces boulardii</i> probiotic ^f Methylprednisolone ^g Immunoglobulins ^g

^aSwitch to vancomycin after 72 h if condition worsens.

^bCriteria for severe CDAD⁹⁸ include white blood cell count >15 × 10⁹, >50% rise in serum concentration of creatinine, severe diarrhea, temperature >38.3°C, albumin <25 mg/dL.

^cConsider surgery for megacolon or severe colitis.

^dMay be increased to 250 mg.

^eIf unable to take by mouth.

^fCaution in immunocompromised.

^gConsider in severe or refractory cases.

practice to treat relapses with an antibiotic other than that originally used, but there are no data to support this.

Other drugs have been used to treat CDAD. Teicoplanin and fusidic acid have been shown to have similar efficacy to metronidazole and vancomycin, but neither seems to offer significant advantages. Nitazoxanide (an antiprotozoal drug) and rifaximin (used for prophylaxis of travelers' diarrhea) have been used successfully for treating CDAD; neither is approved for this indication, but further assessment is underway. A number of new antimicrobials with activity against *C. difficile* are under development.^{104,105}

Other potential therapeutic measures include antimotility agents, probiotics, immunoglobulins and steroids. Antimotility agents have traditionally been contraindicated in CDAD, but recent evidence suggests that they may sometimes be helpful.¹⁰⁶ Further clinical trial data are needed before they can be recommended. The evidence on probiotics is extensive and confusing. For secondary prophylaxis in patients at high risk of recurrent disease, *Saccharomyces boulardii* may be protective.¹⁰⁷ There is not yet sufficient evidence that primary prophylaxis with probiotics has a role. Probiotics should be used with caution in immunocompromised patients as there is a risk of bacteremia and metastatic infection. Methylprednisolone and pooled human immunoglobulin have each been used with variable success to treat refractory CDAD.¹² These may be tried in intractable cases, although there is no real evidence of their efficacy. Severe CDAD is life-threatening, and surgical intervention (with colectomy) should be considered if there is no response to medical treatment. All severe cases should have regular surgical assessment, especially if there is significant cecal dilatation.¹⁰⁸

C. difficile is principally a healthcare-associated infection, and preventive measures include good antimicrobial stewardship, scrupulous attention to hand washing and hygiene, and contact isolation of affected patients.¹⁰⁹

WHIPPLE'S DISEASE

Whipple's disease (caused by infection with *Tropheryma whipplei*) is a multisystem disorder, but the most commonly affected site is the small intestine. It is extremely rare, with an estimated incidence of less than 1 per million. Antibiotic treatment may be curative, but relapse after treatment is common, especially in the central nervous system (CNS). There have been no randomized prospective trials comparing different drug therapy. A reasonable regimen is to give 2 weeks of intravenous therapy with either benzylpenicillin (2.4 g per day) and streptomycin (15 mg/kg per day) or ceftriaxone (2 g per day), followed by 1 year of trimethoprim-sulfamethoxazole 960 mg every 12 h.¹⁰⁹ Resistance to trimethoprim has been reported, and if possible isolates should be tested for resistance genotypes.¹¹⁰ Longer courses may be needed for CNS infection, and lumbar puncture should be performed in all cases to exclude CNS involvement.¹⁰⁹

INTESTINAL MYCOBACTERIAL INFECTION

Intestinal tuberculosis should be treated with standard antituberculosis chemotherapy (Ch. 58).

SMALL BOWEL OVERGROWTH

Colonization of the small intestine with exogenous bacteria may occur in patients with structural abnormalities of the small bowel (such as strictures or diverticula), bypassed surgical loops, or in conditions associated with hypomotility such as scleroderma. Bacterial overgrowth may lead to diarrhea and malabsorption. Clinical improvement is usually seen after treatment with metronidazole, tetracycline or a fluoroquinolone, but repeated courses are often required if the underlying abnormality remains.

HELICOBACTER PYLORI

Infection with *H. pylori* is common throughout the world. It is characterized by a mild chronic active gastritis, but this is usually asymptomatic. However, *H. pylori* gastritis is implicated in the pathogenesis of duodenal and gastric ulcers, mucosa-associated lymphoid tissue (MALT) lymphomas and some gastric adenocarcinomas.¹¹¹ Eradication of *H. pylori* virtually abolishes duodenal ulcer relapse, and all patients with peptic ulcer disease in association with *H. pylori* infection should receive antibiotics. Eradication therapy should also be used in the treatment of gastric lymphomas. Non-ulcer dyspepsia is commonly associated with *H. pylori* infection, but the evidence for a causal connection is limited. Some patients do get symptomatic improvement after clearance of *H. pylori*, but expert opinion is divided on who should be treated.^{111,112}

Several different therapeutic regimens have been used for treating *H. pylori* infection, including various combinations of antibiotics, proton pump inhibitors (PPI), H₂-receptor antagonists and bismuth compounds. The recommended first-line therapy in Europe remains PPI, plus clarithromycin (500 mg every 12 h), plus either metronidazole (400–500 mg every 12 h) or amoxicillin (1 g every 12 h) for 7–14 days.¹¹² The longer course is more effective, but not necessarily more cost-effective. The success rate of this regimen has fallen from >90% to <80%, largely due to increasing clarithromycin resistance. Various alternative treatment strategies have been proposed, both as primary therapy and as second line or rescue therapy. These include bismuth-based quadruple therapy, regimens substituting either fluoroquinolones or rifabutin for clarithromycin, and sequential treatment with different combinations.¹¹¹ The European Helicobacter Study Group continue to recommend bismuth-based treatment for people who fail to respond to first-line therapy¹¹² (PPI, bismuth, metronidazole 400–500 mg every

8 h, and tetracycline 500 mg every 6 h. A number of bismuth salts are available commercially, and dosage will depend on which preparation is in use locally.) This recommendation may change as more data on new regimens become available.¹¹¹

In children, *H. pylori* is associated with gastric and duodenal ulcer disease, as well as chronic gastritis. Eradication of the infection leads to long-term resolution of these conditions. However, there is a lack of data on treatment regimens and no clear consensus on optimal management.¹¹³

VIRAL INFECTIONS

Viral gastroenteritis is extremely common throughout the world, especially in children. It can be caused by several different organisms, notably rotavirus, enteric adenovirus (types 40 and 41), Caliciviridae and Astroviridae. Norovirus, a genus of closely related RNA viruses in the calicivirus family, is highly transmissible and is responsible for large outbreaks of gastroenteritis both in the community and in healthcare institutions.

All these viruses cause self-limiting watery diarrhea and require only supportive treatment and rehydration. Occasionally mucosal damage or disaccharidase deficiency caused by the infection may result in more prolonged diarrhea. Viral gastroenteritis, often in association with malnutrition, is a major cause of morbidity and mortality in children in the developing world.

Some viruses, notably cytomegalovirus and herpes simplex, can cause severe ulcerating infection of the gastrointestinal tract in patients with HIV/AIDS or other immunosuppressing conditions.

PROTOZOAL INFECTIONS

GIARDIASIS

Infection with *Giardia lamblia (intestinalis)* can produce a variety of responses including acute watery diarrhea, persistent diarrhea (often associated with nausea, anorexia and belching) and asymptomatic colonization. Most people recover spontaneously and treatment is often unnecessary. Treatment of symptomatic patients probably accelerates parasitological and clinical cure, and is definitely indicated in patients with a more protracted illness. There is little point in treating people with asymptomatic infection in endemic areas, as reinfection rates are high, but those living in non-endemic areas should be treated. The most commonly used drugs are metronidazole and tinidazole.¹¹⁴ Treatment regimens are discussed in more detail in Chapter 63.

AMEBIASIS

Infection with *Entamoeba histolytica* can be divided into three clinical pictures: asymptomatic cyst passage, dysentery and liver abscess. The management of asymptomatic carriage has

been complicated by the recognition that there are at least two species of ameba, *E. histolytica* and *E. dispar*, which are indistinguishable by microscopy of the cysts. Only the former is potentially pathogenic. The importance of a third species, *E. moshkovskii*, remains uncertain.¹¹⁵ In endemic areas attempts to eradicate cyst carriage are of limited value due to the high rate of reinfection. In non-endemic areas people with proven *E. histolytica* in the gut should be treated, because of the potential pathogenicity and the risk of transmission. However, tests to distinguish *E. histolytica* from *E. dispar* are still not widely available, and treatment of asymptomatic cyst carriers based on microscopy alone is not recommended (unless there is other reason to suspect *E. histolytica*).¹¹⁶ The drug of choice for treating cyst carriage is diloxanide furoate, a non-absorbed luminal amebicide; paromomycin is also effective.

Proven amebic dysentery and amebic liver abscess should always be treated. The best agents are nitroimidazoles, either metronidazole or tinidazole, although nitazoxanide is an alternative for amebic dysentery. In non-endemic areas systemic treatment should always be followed with a luminal amebicide. Appropriate regimens are described in Chapter 63.

OTHER PROTOZOAL INFECTIONS

The treatment of cryptosporidiosis, microsporidiosis, isosporiasis and infection with *Cyclospora cayetanensis* is described in Chapter 63.

Carriage of *Balantidium coli* is usually asymptomatic, but it can cause a syndrome similar to amebic dysentery. Tetracycline and metronidazole are effective, although there are no good clinical trials to guide therapy.¹¹⁷

Dientamoeba fragilis is often found in association with other gut parasites, but there is evidence that isolated *D. fragilis* infection can cause gastrointestinal symptoms.¹¹⁸ Treatment with tetracycline or metronidazole may be effective.

The role of *Blastocystis hominis* in human disease remains uncertain. It may occasionally be associated with clinical features (possibly related to a particular genetic subtype of the parasite),¹¹⁹ but in general the presence of this organism should not be accepted as a cause of symptoms.

CHAPTER

48 Hepatitis

Janice Main and Howard C. Thomas

Acute and chronic viral hepatitis continue to cause significant morbidity and mortality worldwide. While many viruses cause hepatitis this chapter concentrates on the hepatotropic viruses, particularly those associated with chronic hepatitis.

HEPATITIS A VIRUS INFECTION

Hepatitis A virus (HAV) is a member of the Picornaviridae family and a major cause of acute hepatitis. HAV is transmitted by the feco-oral route. Although most cases of acute HAV infection are subclinical, life-threatening fulminant hepatitis can occur and is particularly seen in older patients in the setting of significant alcohol consumption or pre-existing chronic liver disease such as chronic hepatitis B or C or non-alcoholic fatty liver disease (NAFLD).

There are anecdotal reports of interferon- β being used in severe cases¹ but this is an experimental approach and referral to a transplant center is recommended for those with life-threatening disease.

PREVENTION

A major advance in the prevention of HAV infection has been the development of a safe and effective vaccine.² Prior to this the only approach was the administration of 'normal human immunoglobulin', also known as gamma globulin, as passive prophylaxis. The efficacy of this depended on the presence of protective anti-HAV antibodies in the pool of blood donors, but the seroprevalence of IgG anti-HAV has declined with improved sanitation in many countries and failures of prophylaxis have occurred. There are also increasing concerns regarding the safety of immunoglobulin products with potential risk of new variant Creutzfeldt-Jakob disease.

HAV vaccine has also been combined with hepatitis B vaccine and, in a preparation particularly targeted towards travelers, with typhoid vaccine.

Different countries have used varying strategies for the administration of HAV vaccine. Some have included the vaccine as part of the normal childhood vaccination program and others have recommended a more targeted approach. The vaccine is recommended for those who travel to areas of poor sanitation, for those with underlying liver disease such as chronic hepatitis B or C and those involved in food preparation where the infection could be passed on to many individuals.

HEPATITIS B VIRUS INFECTION

EPIDEMIOLOGY

Hepatitis B virus (HBV) can be transmitted sexually, by blood, blood products or vertically (mother to child). There are an estimated 350 million cases of chronic HBV worldwide. In some areas of South East Asia approximately 20% of the population have chronic HBV infection, with many infected vertically. Already vaccination programs are reducing the prevalence in some countries, but it will be many years before the disease can be eradicated. In the Western world chronic hepatitis B (CHB) is mainly seen in high-risk individuals such as men who have sex with men (MSM) or intravenous drug users (IDU).

NATURAL HISTORY

HBV is a small (3.2 kb), partially double-stranded DNA virus and a member of the hepadnavirus group.

The incubation period is 2–6 months and although many cases are subclinical, fulminant hepatitis can occur.

Chronic HBV infection is defined by ongoing viral replication 6 months or more after the initial infection. Chronic infection is seen in approximately 5% of healthy adults, with higher rates in those with underlying immunodeficiency.

With perinatal infection the risk of chronicity is much higher (95%), and it is thought that this may be related to the immaturity of the neonatal immune system, circulating hepatitis B e antigen (HBeAg) inducing immune tolerance and possibly host genetic factors.³

More severe disease is seen in men and it is estimated that 40% of infected men, if untreated, will die because of the subsequent complications which include the development of cirrhosis, liver failure and the development of hepatocellular carcinoma (HCC).^{4,5}

WILD-TYPE VIRUS AND VIRAL VARIANTS

Patients infected with wild-type HBV have circulating hepatitis B surface antigen (HBsAg) and HBeAg. HBV variants are increasingly recognized and many have implications for diagnosis, management and vaccination programs. For example, a subgroup of patients who are HBsAg positive and HBeAg negative, with anti-HBe antibodies, have active viral replication with HBV DNA levels of more than 10^5 genomes/mL in the blood and active liver damage with raised transaminase levels and inflammation and often fibrosis on liver biopsy. Viral sequencing in these patients revealed a mutation in the pre-core gene⁶ which resulted in a stop codon which limited production of HBeAg. These viral variants are known as pre-core variants or HBe-negative variants and can develop in patients with wild-type virus, during antiviral therapy or, alternatively, patients can be infected de novo with these variants.

GENOTYPES

There are several genotypes of HBV and these were originally thought mainly to be of epidemiological interest. It is also recognized that the response to treatment may additionally be determined by the genotype. Patients infected with genotype A, for example, are more likely to respond to interferon therapy by HBe antigen/antibody seroconversion than those with other genotypes.

ANIMAL MODELS

Hepadnavirus infections with similar outcomes are seen in several animal species, including woodchucks, Beechey ground squirrels and Pekin ducks.

ACUTE HEPATITIS B

The development of acute hepatic illness appears to coincide with the host immune response and the detection of anti-hepatitis core (anti-HBc) IgM antibodies. Although fatigue is

not uncommon for some months following infection, it does not necessarily correlate with ongoing viral replication. Large multicenter trials would be required to determine whether immunomodulatory or antiviral therapy could limit the acute illness and reduce the risk of chronicity. There are theoretical risks that the immune stimulant effects of interferons could be detrimental in this setting. This has not been seen in practice.⁷ Small studies support the use of nucleoside analogs, particularly lamivudine, in severe cases.⁸

CHRONIC HEPATITIS B

The risks of developing decompensated liver disease or HCC have been shown to be positively correlated with viremia levels of more than 10^5 genomes/mL. The aims of antiviral therapy are to clear or suppress the infection and to reduce the risks of developing life-threatening liver disease. Viral clearance also reduces the risk of viral transmission to others.

CANDIDATES FOR THERAPY

Chronic infection is defined as the presence of ongoing viral replication (HBV DNA in blood) for more than 6 months. Those infected with wild-type virus will be HBsAg and HBeAg positive and those with HBe-negative variants will be HBsAg positive, HBeAg negative and anti-HBe antibody positive. HBe antigen positive and negative patients with viremia levels of more than 10^5 genomes/mL with evidence of hepatic necroinflammatory activity and fibrosis are candidates for therapy.⁹

ASSESSING THE RESPONSE TO ANTIVIRAL THERAPY

In patients with wild-type infection, a response is defined as:

1. sustained clearance of HBV DNA
2. sustained clearance of HBeAg and the development of anti-HBe antibodies (known as HBeAg/anti-HBe seroconversion)
3. sustained clearance of HBsAg and the development of anti-HBs antibodies (this can occur many years after (1)).

In patients infected with HBe-negative variants, only (1) and (3) are applicable.

In a successfully treated patient the clearance of virus is associated with a biochemical response (normalization of the elevated transaminase value) and a histological response (decreased hepatic inflammation and fibrosis).

With the available treatments only a minority of patients achieve a sustained virological response after 1 year of therapy, and long-term suppressive therapy has become an increasingly popular strategy for patients most at risk of the life-threatening complications of chronic HBV infection.

TREATMENTS

Interferons

Interferon- α has been administered for chronic HBV infection since 1976 and is now licensed therapy in many countries. Standard interferon- α was given thrice weekly for 3–6 months but has now been phased out in preference to the more long-acting pegylated interferons (peginterferons) which are administered weekly for 6–12 months.

It is thought that the successful response to interferon therapy is from its combination of antiviral and immunostimulatory effects.

Interferons induce intracellular enzymes which inhibit viral protein synthesis. They stimulate the production of about 30 host proteins including 2',5'-oligoadenylate synthetase which leads to activation of ribonuclease enzymes that cleave viral mRNA. Protein kinases are also induced which can have an inhibitory effect on viral protein synthesis.

Hepatocytes have very little major histocompatibility complex (MHC) class I display and it is thought that this limits host immune recognition of infected cells. Interferons enhance the MHC class I display and it is thought that this encourages immune lysis of infected cells, which sometimes manifests as an elevation of the transaminase values in patients successfully treated with interferon. In patients with HIV and HBV infection, a similar phenomenon is seen with the immune restoration that follows effective antiretroviral therapy.¹⁰ This ‘transaminitis’ (Fig. 48.1) is generally asymptomatic; in those with advanced liver disease, however, a brisk hepatitic response can lead to hepatic decompensation. Particular care is therefore required when treating patients with cirrhosis with interferon-based regimens.

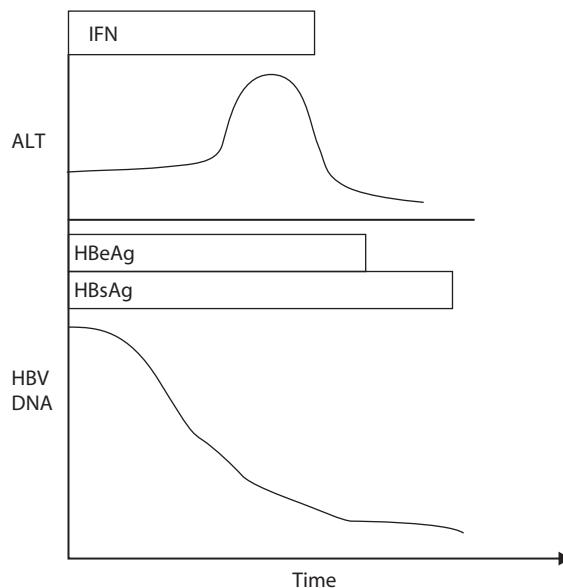

Fig. 48.1 Chronic hepatitis B; successful response to interferon (IFN). ALT, alanine transaminase.

In successfully treated patients with wild-type virus, an HBeAg/anti-HBe seroconversion occurs. Patients may continue to be HBsAg positive for some years but eventually this is often cleared.¹¹ Follow-up studies have shown an improvement in the level of inflammation and fibrosis in the liver and this has been associated with a reduced risk of HCC in these patients.¹²

The original studies were with standard interferon given thrice weekly subcutaneously and success rates of 25–40% were reported in those with adult acquired disease.^{13–16} Similar results have been seen with peginterferon.¹⁷

Lower sustained response rates (approximately 20%) are seen with treatment of patients with anti-HBe variants.¹⁸

Patients with an existing active immune response with high transaminase levels, or active inflammation on a liver biopsy and low HBV DNA levels, are more likely to respond to therapy than those with immunodeficiency such as HIV infection or vertically acquired disease.

The main adverse effects of interferon- α are listed in Box 48.1. In view of the potential myelotoxicity, careful monitoring of the blood count is advised, with dose alteration as required. Patients with advanced liver disease and leukopenia or thrombocytopenia at baseline require particularly careful monitoring. Influenza-like symptoms with malaise, fever and myalgia are particularly troublesome with the initiation of therapy. These can be minimized by administration of the interferon in the late evening and by prescribing paracetamol (acetaminophen) or non-steroidal anti-inflammatory drugs as required.

Depression is another major side effect and may limit therapy for some individuals. Patients with mild depressive symptomatology often find antidepressants helpful but expert psychiatric help is advised for those with more severe symptoms.

The immunostimulatory effects of interferon can also result in the exacerbation of underlying autoimmune conditions.

OTHER IMMUNOMODULATORY APPROACHES

Trials with thymic hormones, thymic peptides,¹⁹ levamisole and inosine pranobex have generally shown no benefit and the use of adjuvant vaccines remains experimental.

Box 48.1 Side effects of interferon- α

- Fever and chills (less with subsequent doses)
- Myalgia
- Fatigue
- Myelotoxicity (regular monitoring of full blood count required)
- Impaired concentration
- Altered mood (particularly depression – can be severe)
- Exacerbation or development of underlying autoimmune disease, e.g. hyperthyroidism or hypothyroidism
- Alopecia
- Arthralgia
- Hypersensitivity reactions (rare)
- Pulmonary infiltrates (very rare)

There are case reports of patients with CHB with hematological conditions who have been given bone marrow transplants from HBV immune donors and subsequently cleared HBV.²⁰ This has led to considerable interest in the potential for lymphocyte transfer or modulation of the host immune response by ex-vivo stimulation of host lymphocytes.

NUCLEOSIDE/NUCLEOTIDE ANALOGS (NUCs)

There are three classes of NUCs used as therapy for HBV infection.

L-Nucleosides

Lamivudine

Lamivudine (3'-thiacytidine, 3TC) was one of the first of the new generation of agents to be shown to have a significant effect on HBV replication.^{21–23} Its low toxicity, even with long-term use, is thought to relate to its minus enantiomer configuration.

After 1 year of therapy in one study 17% of patients cleared HBeAg and the response rate increased to 27% after a second year of therapy.²⁴ An incremental increase is seen with longer treatment periods and a success rate of up to 66% has been reported with 4 years of therapy.²⁵

Viral resistance was initially reported in the setting of liver transplantation^{26,27} and was noted to involve the YMDD motif (the equivalent of the 184 mutation in the HIV reverse transcriptase gene).

After 1 year of therapy approximately 20% of patients have resistant virus and this increases over time to around 70% at 5 years.

Although the YMDD variant is thought to be less replication competent,²⁸ there have been ‘flares’ in hepatitis^{29,30} reported with its emergence.

Although lamivudine in combination with interferon or other NUCs has not been shown to result in increased clearance rates, the emergence of resistance appears to be decreased by combination therapy.³¹

Lamivudine monotherapy appears effective for viral prophylaxis in patients at risk of HBV reactivation who are about to receive immunosuppressive therapy for co-existent morbidities.³² Lamivudine monotherapy is also occasionally used in pregnant mothers with high levels of viremia to reduce the risk of mother-to-baby transmission,³³ but otherwise, having been recognized as having a low genetic barrier, it is now rarely used as monotherapy.

Emtricitabine

As an antiviral agent, emtricitabine (FTC) appears very similar to lamivudine.^{34,35} Abnormal dreams are reported by some patients. It is mainly prescribed in combination with tenofovir and as both agents also have activity against HIV, this has

proved very useful for the management of patients with HIV/HBV co-infection.

Telbivudine

Although telbivudine appeared more effective than lamivudine in a large controlled trial,³⁶ there were reports of elevated creatine kinase levels and concerns regarding peripheral neuropathy with more prolonged therapy.

Acyclic nucleoside phosphonates

Adefovir

Adefovir as monotherapy has been shown to be effective in patients with HBeAg positive and negative chronic hepatitis B.^{37,38} More prolonged therapy appears more advantageous in HBeAg-negative chronic hepatitis.³⁹ There have been concerns regarding nephrotoxicity.⁴⁰ It has activity against lamivudine-resistant HBV and has therefore been mainly used in combination with lamivudine as a ‘de novo’ therapy or as an ‘add-on’ agent for patients on lamivudine monotherapy^{41,42} and emerging resistance.

Tenofovir

Tenofovir is more potent than adefovir.⁴³ It is increasingly used in patients with HBV infection as it has potent anti-HBV activity and low rates of resistance compared to lamivudine monotherapy. Reports suggest that patients with the anti-HBe variant may be more at risk of resistance than those infected with wild-type virus.⁴⁴ There are some concerns regarding the potential for nephrotoxicity, with reports of elevated creatinine, renal tubular dysfunction and risks of osteomalacia,^{44–48} and monitoring (creatinine, calcium and phosphate levels) is recommended. It is only with longer-term follow-up that the risk of this will be clarified.

Deoxyguanosine analogs

Entecavir

Entecavir has potent activity against HBV^{49,50} and low rates of resistance have been reported.⁵¹ It appears more potent than adefovir.⁵² It has been suggested that with low toxicity, high potency and low rates of resistance it is useful as a first-line agent as minimal monitoring is required in the outpatient clinic. It is less useful for patients with lamivudine-resistant virus⁵³ and also has limited efficacy in patients with a partial response to adefovir therapy.⁵⁴ There were concerns in animal studies regarding development of tumors but this has not been observed in humans.

PLANNING THERAPY FOR THE PATIENT

Overall it is possible to offer a sustained HBeAg/anti-HBe seroconversion rate of 30–40% of immunocompetent adults with adult acquired disease. Treatment can be stopped 6 months after HBe clearance.

Many patients, however, have only minimal liver disease and the risks of therapy with side effects of drugs and emergence of resistance have to be weighed against the clinical benefit and the healthcare costs.

Studies such as the REVEAL study^{55,56} have been helpful in determining which patients are most likely to benefit from therapy and this is acknowledged in guidelines.

This study showed that a worse disease outcome is seen in those with higher levels of HBV replication. Guidelines generally recommend targeting therapy to those with active viral replication and evidence of progressive liver disease.^{57,58} The potential risks and benefits of therapy have to be carefully assessed for the individual patient and guidelines are being frequently updated⁵⁹ with the development of new agents and the results of more long-term studies. Interferon is often recommended as a first-line therapy, particularly in those with a reasonable chance of response (genotype A, high transaminase level, low HBV DNA levels) as it is a 'one-off' therapy.

In a subgroup of patients treated with NUCs it is possible to discontinue therapy after a finite course of therapy; however, NUCs are increasingly being used as long-term suppressive therapy. The potency and high genetic barrier of tenofovir and entecavir have encouraged their use as monotherapy. These approaches should not be embarked on lightly as anti-viral treatment requires monitoring, is expensive and there are risks of potentially fatal flares of hepatitis if the patient discontinues medication.

PREVENTION

Safe and effective vaccines have now been developed against HBV.⁶⁰ Passive prophylaxis with HBV immune globulin continues to be used to help prevent vertical transmission and in the setting of transplantation if nucleoside NUCs are ineffective.

HEPATITIS C VIRUS INFECTION

Hepatitis C virus (HCV), a member of the Flaviviridae family, was discovered in 1989,⁶¹ although its existence was suspected for many years as some patients who had been exposed to blood products developed acute or chronic hepatitis but had negative tests for HAV or HBV infection. The terms 'post-transfusion' or 'parenterally transmitted' non-A, non-B hepatitis evolved and on retrospective testing the majority were found to be caused by HCV.

EPIDEMIOLOGY

HCV is mainly transmitted via blood. The screening of blood products has limited new cases but the infection remains common in those with a background of exposure to blood products before screening was introduced and in those with

a history of intravenous drug use. Mother-to-baby transmission can occur but, in contrast to HBV, sexual transmission among heterosexuals is rare. An outbreak of HCV infection among HIV-positive men has, however, raised the possibility that sexual transmission is a potential route of transmission in men who have sex with men (MSM).⁶²

In many patients there is no clear source of infection. It is estimated that there are 170 million people with hepatitis C worldwide.⁶³ The seroprevalence is low (0.07%)⁶⁴ in UK blood donors but thought to be 0.7% in the general UK population.⁶⁵

Higher seroprevalence rates are reported elsewhere. In some areas of Egypt, for example, 25% of the adult population have HCV infection.⁶⁶

There are six main genotypes of HCV:⁶⁷ genotypes 1, 2 and 3 are the predominant genotypes in Europe and the USA,⁶⁸ with genotype 4 predominating in Egypt.⁶⁹

NATURAL HISTORY

The incubation period of HCV infection is 6–12 weeks. Acute hepatitis is generally subclinical and therefore often undiagnosed unless the patient is being monitored following a needlestick injury. Chronic infection follows in 60–80% of patients which can, over decades, lead to the development of cirrhosis and HCC.^{70,71} More rapid progression is associated with male gender, older age at time of infection, heavy alcohol consumption⁷² and immunosuppression such as HIV infection.⁷³

It is also recognized that many patients with often only mild liver disease complain of significant fatigue and it has been postulated that HCV may cause CNS infection and/or dysfunction.⁷⁴

TREATMENT

ACUTE HEPATITIS

Although acute HCV is often undiagnosed, a number of studies have assessed the benefits of antiviral therapy with interferon monotherapy⁷⁵ or in combination with ribavirin. One study showed a response rate of more than 95% with standard interferon monotherapy.⁷⁶ Even in the setting of HIV infection, response rates of 60%⁷⁷ are recorded, apparently undetermined by the viral genotype.⁷⁸ These rates are much higher than those seen in established chronic infection.

Overall, early diagnosis and treatment are beneficial and this is important when dealing with a patient or with a healthcare worker, for example, who has sustained a needlestick injury from an infected patient.

The optimal regimen and, indeed, timing have yet to be determined but most clinicians would recommend treatment within 3 months, particularly if monitoring has shown no decline in HCV RNA levels.

CHRONIC HEPATITIS

Chronic hepatitis is when infection has been present for 6 months or more. Spontaneous clearance thereafter is highly unusual. Just as with HBV infection, the main aims of therapy are to clear the infection and to reduce the risks of fatal liver disease. There is no vaccine for HCV infection so treatment is also important in limiting potential spread of the disease.

The initial studies were before the discovery of HCV and the response limited to the transaminase levels and the liver biopsy appearances. Molecular virological advances have led to increased use of HCV RNA levels in determining the response to antiviral therapy.

Some patients when treated with antiviral therapy show no response or only a partial decline in the level of HCV RNA. Some patients who respond initially, subsequently 'breakthrough', and some patients show a favorable response and then relapse following cessation of therapy.

A sustained virological response (SVR) is defined as a negative HCV RNA test 6 months after cessation of therapy (Fig. 48.2). Relapse thereafter is highly unusual.

Detailed monitoring of the viral load during the first few weeks of therapy helps tailor the antiviral regimen.

The rapid virological response (RVR) is the response of the HCV RNA level to undetectable levels after 4 weeks of therapy, and the early virological response (EVR) is the response to negativity at 12 weeks. It is generally recommended, for example, that patients who fail to demonstrate an EVR should discontinue therapy as it is very unlikely that they will achieve an SVR.

Interferon- α

Interferon- α has been used in trials since 1986⁷⁹ and is licensed in many countries. Initially it was given as monotherapy thrice weekly, and SVR rates of 10–20% were seen

with this approach. With the introduction of peginterferons and combination therapy with ribavirin, however, overall SVR rates of 45–55% are now seen.^{80,81} SVR rates are 70–80% in patients with genotype 2 or 3 infection and 40–50% in patients with genotype 1 infection. The Hadziyannis study⁸¹ demonstrated that 48 weeks of therapy and full dose ribavirin was required to treat genotype 1 infection (SVR 52%), whereas 24 weeks of therapy and low dose ribavirin was sufficient for patients with genotypes 2 or 3 infection. The main side effects of interferon are listed in the Box 48.1 (p. 610).

Ribavirin

Ribavirin is a guanosine analog with broad-spectrum anti-viral activity. In initial monotherapy studies a reduction was seen in transaminase levels during therapy⁸² but subsequent studies showed very little effect on HCV replication⁸³ and its mode of action in hepatitis C therapy is therefore unclear. It is given orally in combination with interferon for HCV infection. Side effects (Box 48.2) include anemia (mainly secondary to hemolysis), skin rash, pruritus and, more rarely, hypersensitivity. There are concerns regarding its potential for teratogenicity and prospective patients and their partners should be carefully counseled regarding this. It is recommended that both men and women avoid conception whilst on therapy and for several months thereafter in view of the long half-life.

Combination therapy

Peginterferon and ribavirin combination therapy has been generally shown to be cost-effective. Older patients in particular should be carefully assessed prior to commencing therapy as they may risk cardiac decompensation if they develop significant anemia with ribavirin-associated hemolysis. Low

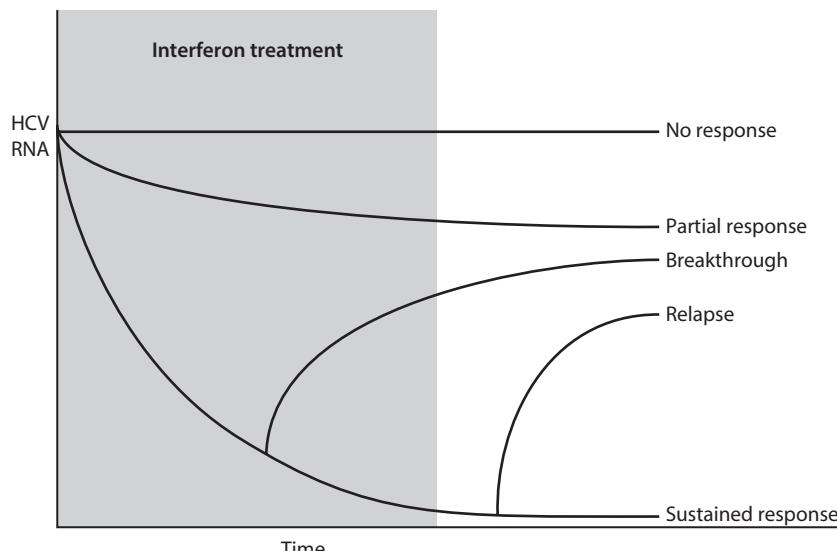

Fig. 48.2 Schematic representation of the influence of interferon treatment on hepatitis C virus RNA levels.

Box 48.2 Side effects of ribavirin

- Hemolysis – caution in patients with cardiac problems
- Risk of teratogenicity – males and females to avoid conception
- Rash – continue therapy if transient or mild
- Pruritus – may limit continuation of therapy
- Acute hypersensitivity – rare

response rates in genotype 1 infection suggest that it is not cost-effective to treat older patients with genotype 1 infection and mild liver damage⁸⁴ or cirrhosis.⁸⁵

Newer agents

Protease, polymerase and helicase inhibitors are being developed.

Telaprevir, for example, is a peptidomimetic. It resembles the HCV polypeptide which is cleaved by HCV protease. With monotherapy significant reductions were seen in HCV RNA levels⁸⁶ but viral resistance was observed early in the treatment course. Treatment courses (12–24 weeks) of telaprevir in combination with peginterferon and ribavirin (24–48 weeks) appear promising, with SVR rates of 61–67% in patients with genotype 1 infection.^{87,88} Rashes, pruritus, nausea and diarrhea were more common in patients given the triple therapy and this may limit longer treatment regimens with triple therapy.

Boceprevir is a protease inhibitor with activity against genotype 1 HCV,⁸⁹ and trials are underway with the drug in combination therapy with peginterferon and ribavirin.

PLANNING THERAPY FOR THE PATIENT

Initially antiviral therapy was considered only for patients with more severe liver disease as determined by liver biopsy. The improved success rates with more effective combination therapy and analysis of viral load responses have encouraged more patients to embark on antiviral therapy. The standard guidelines recommend 24 weeks of peginterferon and ribavirin for patients with genotype 2 or 3 infection.⁹⁰

A 48-week treatment course is recommended for patients with genotype 1 infection but treatment should only be continued beyond the first 12 weeks if there is a favorable response ($2 \log_{10}$ or more reduction in HCV RNA or undetectable HCV RNA). This early virological response is helpful in stopping ineffective therapy at an early stage. Those patients with genotype 1 infection who have undetectable levels of HCV RNA at 4 weeks (rapid virological response) may only require 24 weeks of therapy.

CHAPTER

49 Skin and soft-tissue infections

Anita K. Satyaprakash, Parisa Ravanfar and Stephen K. Tyring

The skin and underlying soft tissues form a formidable defensive barrier against infection despite the fact that the skin's surface is normally colonized by a variety of organisms. Disruption of the integrity of the integument, immunocompromised conditions, or spread of an organism via the circulation can lead to a variety of skin and soft-tissue infections. Diagnosis may rely solely upon the appearance of the skin lesions or on simple diagnostic tests such as cultures or skin biopsies. Isolation of the causative organism may be difficult, in many cases due to contamination by normal commensal skin flora. Treatment with systemic antiviral or antibacterial agents offers excellent tissue penetration and rapid recovery. Topical antimicrobial therapy is limited by lack of adequate tissue penetration and skin hypersensitivity; however, the advantage of topical therapy is its lack of systemic toxicity and ease of application.

CHILDHOOD EXANTHEMS

Viral exanthems are common in children. In some cases the morphology of the rash and associated findings may allow for a specific diagnosis and treatment, although many cases are non-specific and not pathognomonic for a specific virus. There are now more than 50 specific agents known to cause viral exanthems. The classic six childhood exanthems are not all caused by viruses (Table 49.1).

Most childhood exanthems cause a rather non-specific generalized rash that occurs in a predictable pattern. Most are benign and self-limiting viral diseases with no specific treatment except for supportive care; however, when these diseases

Table 49.1 Classic childhood exanthems

First disease	Rubeola (measles)
Second disease	Scarlet fever
Third disease	Rubella
Fourth disease	Filatov–Duke's disease
Fifth disease	Erythema infectiosum
Sixth disease	Exanthem subitum (roseola infantum)

occur during pregnancy and affect the fetus, they can have serious sequelae. For example, rubella (German measles) is a benign disease but the effects of congenital rubella can be very serious. If a pregnant woman is afflicted in the first trimester, the incidence of fetal damage approaches 50%.¹ Likewise, if erythema infectiosum (fifth disease; caused by parvovirus B19 infection) is acquired during pregnancy, the risk of spontaneous abortion or hydrops fetalis in a surviving offspring is increased. Some viral exanthems are known for the unique skin lesions they produce; measles (rubeola) causes the characteristic Koplik's spots and erythema infectiosum is known for the erythematous 'slapped cheek' appearance.

Treatment for viral exanthems is supportive, although childhood vaccination remains the most effective means of prevention in the case of measles and rubella.

ENTEROVIRAL INFECTIONS

Enteroviral infections such as hand, foot and mouth disease, herpangina, and echovirus 9 are the leading cause of childhood exanthems in the summer and fall. Enteroviruses enter through the gastrointestinal tract and are thought to account for two-thirds of all exanthems in August, September and October in the USA. More than 30 have been identified to cause exanthems. Enteroviral infections are spread by the oral–oral or fecal–oral route, and the typical incubation period is 3–5 days. The cutaneous manifestations are quite pleomorphic and include rubelliform, morbilliform, roseola-like, scarlatiniform, urticarial, pustular, petechial, purpuric and hemangioma-like eruptions. A specific enteroviral diagnosis is not possible for most exanthems. Hand, foot and mouth disease is characterized by vesicular lesions in the mouth and on the extremities associated with a mild fever. Herpangina is a specific infectious disease characterized by sudden onset of fever, headache and neck pain, and gray–white papulovesicular lesions on the anterior pillars, soft palate, uvula and tonsils. No specific treatment is available; only supportive care is recommended for enteroviral infections.

HERPESVIRUSES

HERPES SIMPLEX (HSV)

HSV-1 and HSV-2 are double-stranded DNA viruses. Both types are characterized by a primary infection, which may or may not be symptomatic, followed by the establishment of a latent infection in the spinal ganglion.

HSV-1 commonly causes herpes labialis, also known as cold sores. Primary infection is more severe than recurrences, and may be associated with fever and lymphadenopathy. Infection usually recurs on or near the vermillion border of the lip and is triggered by sunlight, emotional stress, trauma to the lips, fatigue or fever. Recurrence is heralded by a typical prodrome of itching or burning at the site, followed by the classic appearance of an erythematous macule, followed by a papule, vesicle and finally a crust.

Genital herpes is most commonly caused by HSV-2, generally acquired through sexual contact; however, HSV-1 has been increasingly associated with genital herpes. Over 50% of persons with asymptomatic HSV-2 actively shed the virus; 70–80% of cases of genital herpes are thought to be spread by asymptomatic viral shedding.² Like herpes labialis, a prodrome occurs in 40–50% of episodes.

Both oral and genital herpes infections appear as vesicles on an inflamed base. The vesicles erode quickly or become pustular before crusting over. Healing usually occurs in about 9 days for recurrent lesions and up to 3 weeks for primary infections.

Herpetic lesions such as herpetic whitlow are caused by primary or recurrent HSV infection on the fingers due to digital contact with infected oral or genital tissues.

Herpes gladiatorum, caused by direct skin-to-skin contact, is seen among wrestlers and rugby players and may affect the head, trunk and extremities.

Eczema herpeticum is a widespread cutaneous infection with HSV, which occurs in patients with skin disorders such as atopic dermatitis, Darier's disease and pemphigus. It is frequently superinfected with bacteria and is associated with fever, lymphadenopathy and malaise.

DIAGNOSIS

Diagnosis of herpes can be made by identifying multinucleated balloon keratinocytes on a Tzanck smear taken from the floor of an early vesicle stained with Wright or Giemsa stain. Culture is the gold standard for diagnosis, and serology via ELISA or Western blot can be used to distinguish between HSV-1 and HSV-2.

TREATMENT

HSV-1 and HSV-2 infections can be treated with oral aciclovir, famciclovir or valaciclovir, and are treated differently

depending on whether the patient presents with a first episode of infection, recurrence of infection or a need for suppressive therapy (more than six recurrences yearly). Table 49.2 lists the recommended treatment regimens for both herpes labialis and genital herpes. Both famciclovir and valaciclovir, which are equally effective, are more conveniently dosed and better absorbed than the prototype aciclovir (acyclovir).

Penciclovir and aciclovir creams are approved for herpes labialis; however, their effectiveness is limited by poor tissue penetration and by the frequent inconvenient dosing regimen.

VARICELLA ZOSTER VIRUS (HHV-3)

Varicella (chickenpox) and herpes zoster (shingles) are both caused by a single member of the herpesvirus family (human herpesvirus-3; HHV-3). Varicella results from a primary infection in a susceptible person, whereas zoster is a reactivation in persons who have had varicella. Varicella is highly contagious and usually transmitted via the respiratory route or by direct contact. The clinical manifestations of primary varicella include an occasional prodrome; in children, low-grade fever and malaise may proceed or occur simultaneously with the onset of the rash. In adults, a headache, myalgia, nausea, vomiting and anorexia can precede the rash. The rash is characterized by small erythematous macules that initially appear on the face and trunk, spread to the proximal upper limbs, and somewhat spare the distal lower limbs. The skin lesions rapidly evolve in crops over 12–14 h. The rash progresses in a predictable manner: first papules, next vesicles and, finally, crusts. Vesicles may have slightly hemorrhagic bases and have the characteristic

Table 49.2 Oral treatment regimens for herpes infections

Clinical disease	Treatment
Herpes labialis First episode	Aciclovir 400 mg every 8 h for 7–10 days (children and adults) Famciclovir 500 mg every 12 h for 7 days (adults) Valaciclovir 1 g every 12 h for 7 days (adults)
Recurrences	Aciclovir 400 mg every 8 h for 5 days Famciclovir 1.5 g once Valaciclovir 2 g every 12 h for 1 day
Suppressive therapy	Aciclovir 400 mg every 12 h Famciclovir 500 mg every 12 h Valaciclovir 500 mg once daily
Genital herpes First episode	Aciclovir 400 mg every 8 h for 7–10 days Aciclovir 200 mg five times daily for 7–10 days Famciclovir 250 mg every 8 h for 7–10 days Valaciclovir 1 g every 12 h for 7–10 days
Recurrences	Aciclovir 400 mg every 8 h for 5 days Aciclovir 800 mg every 8 h for 2 days Aciclovir 800 mg every 12 h for 5 days Famciclovir 125 mg every 12 h for 5 days Famciclovir 1 g every 12 h for 1 day Valaciclovir 500 mg every 12 h for 3 days
Suppressive therapy	Aciclovir 400 mg every 12 h Famciclovir 250 mg every 12 h Valaciclovir 500 mg once daily (≤9 outbreaks a year) Valaciclovir 1 g once daily (>9 outbreaks a year)

appearance of 'dewdrops on a rose petal'. Infection tends to be more severe in older children and adults.

For primary varicella in healthy children, treatment has traditionally been symptomatic, using only calamine lotion, cool compresses, tepid baths and non-aspirin antipyretics. Healthy children with primary varicella virus infection may also be treated with oral aciclovir.

Treatment of primary varicella in older children, adults and immunocompromised patients is mandatory. If the patient is an adult or of adult size, the dosage of acyclovir is 800 mg five times a day for 7 days; in smaller children the recommendation is 10 mg/kg four times a day for 5 days. Although neither famciclovir nor valaciclovir has been approved for treatment of primary varicella, zoster-equivalent doses are effective.

Herpes zoster is an acute inflammatory unilateral dermatosis having both dermatological and neurological manifestations. It is estimated to afflict 15–20% of the population, with incidence rising with increasing age.³ Immune senescence, resulting in a decline in T-cell-mediated immunity, is suspected to contribute to the reactivation of the varicella zoster virus lying dormant in the spinal cord dorsal root ganglia.⁴ The patient may experience prodromal symptoms of low-grade fever, pain, numbness, pruritus and paresthesia several days before cutaneous involvement. These signs foreshadow the appearance of the classic rash, most often described as unilateral grouped vesicles on an erythematous and edematous base along a dermatomal distribution. Frequently, there are a few scattered non-dermatomal lesions, and rarely a generalized eruption may occur. Complete cutaneous healing is expected in 3–4 weeks and patients are considered contagious until the lesions are crusted.

Varicella and herpes zoster are generally diagnosed clinically. The Tzanck smear is positive in 80–100% of zoster cases. The current recommendation for treatment of herpes zoster is famciclovir 500 mg every 8 h for 7 days or valaciclovir 1 g every 8 h for 7 days. These medications are more conveniently dosed and achieve higher plasma concentrations than oral aciclovir, for which the recommended dosing is 800 mg five times daily for 7 days.

EPSTEIN-BARR VIRUS (HHV-4)

Epstein-Barr virus (EBV) is a double-stranded DNA virus with an envelope and is a member of the herpesvirus family (HHV-4). Humans acquire infection through contact with salivary secretions. EBV persists for life as a latent infection in B cells. It is the etiological agent of infectious mononucleosis, and is associated with oral hairy leukoplakia and B-cell lymphoma in patients with AIDS, Burkitt's lymphoma, nasopharyngeal carcinoma, Hodgkin's disease and some T-cell lymphomas.

The triad of fever, sore throat and lymphadenopathy characterizes infectious mononucleosis.⁵ The monospot test is used to diagnose EBV. Mononucleosis is often self-limiting and management consists of rest and antipyretics. Severe cases may result in splenomegaly and subsequent splenic rupture after trauma.

Oral hairy leukoplakia is a non-malignant hyperplasia of the epithelial cells due to active replication of EBV, most commonly seen in HIV-positive individuals.^{6,7} Lesions are usually present on the lateral tongue and appear slightly raised and white with a corrugated or hairy appearance. Oral hairy leukoplakia resolves with oral aciclovir, but will recur 2 weeks to 2 months after stopping therapy.

CYTOMEGALOVIRUS (HHV-5)

Cytomegalovirus (CMV) is an enveloped, double-stranded DNA virus of the herpes family, also known as HHV-5. It is ubiquitous, with nearly everyone infected by adulthood. After primary infection, which is usually asymptomatic and sub-clinical, the virus remains present for life in a latent stage. Immunocompromised patients and neonates are at the highest risk of danger from CMV infection. Transmission occurs via intimate contact with body fluids such as saliva, vaginal secretions, semen, breast milk, feces or blood. Cutaneous lesions associated with CMV are rare and non-specific, and usually occur only in immunocompromised states. The most specific manifestation of cutaneous CMV is ulceration of the perianal area.

Treatment is generally not needed in immunocompetent individuals. Immunocompromised patients may be treated with ganciclovir, valganciclovir, foscarnet or cidofovir. Fomivirsen is also approved for treatment of CMV retinitis.

HUMAN HERPESVIRUS 6 (ROSEOLA)

Roseola (also known as exanthem subitum) is a very common childhood exanthem in which HHV-6 has been shown to play a causal role. Roseola is characterized by a prodrome of high fever (102–105°F) for 3–5 days, followed by an abrupt decrease in fever and sudden appearance of an exanthem (hence 'subitum') that occurs almost exclusively in children under 2 years old. Ganciclovir and foscarnet may be helpful in cases with severe complications, but are not approved for this purpose in the USA. Primary infections confer lasting immunity.

HUMAN HERPESVIRUS 7

This virus is also known to cause roseola, but much less commonly than HHV-6. It is also thought to be the causative agent of pityriasis rosea, a benign skin disease characterized by the appearance of a large, scaly, oval 'herald patch' followed by smaller patches on the trunk and extremities. The rash is self-limiting, with resolution in 6–14 weeks. Although HHV-7 is susceptible to ganciclovir and foscarnet and minimally susceptible to aciclovir, these agents are not routinely used since only supportive care is needed in most cases.

HUMAN HERPESVIRUS 8 (KAPOSI'S SARCOMA)

Kaposi's sarcoma is a malignancy associated with HHV-8 infection.⁸ It presents as violaceous, red–dark-brown firm macules or papules, irregularly oval-shaped and parallel to skin tension lines. Systemic therapy should be restricted to patients with disseminated disease or with massive involvement of visceral organs. In HIV-positive patients therapy should be postponed until the patient has had time to respond to highly active anti-retroviral therapy (HAART), as the lesions may improve with HAART only. Therapies for Kaposi's sarcoma include radiotherapy, interferon- α , cidofovir, conventional chemotherapy, and topical and systemic retinoids.⁹

POXVIRUSES

SMALLPOX

Smallpox is caused by a DNA virus known as variola. The last known case occurred in October 1977 and worldwide eradication was announced in 1979. Smallpox had a 25–30% mortality rate and was generally managed with supportive care; no treatment was ever found during its prevalence.

CONTAGIOUS ECTHYMA (CONTAGIOUS PUSTULAR DERMATITIS, ORF)

Contagious ecthyma is a member of the *Parapox* genus. It is acquired from infected sheep or goats with crusted lesions on the lips. The lesions appear as flat or dome-shaped bullae with minimal fluid and a central umbilicated crust. They bleed easily and heal without scarring. During a period of approximately 35 days the lesions pass through six clinical stages, each lasting about 6 days.¹⁰ The diagnosis is based on history and physical examination, viral culture on sheep cells, fluorescent antibody tests, electron microscopy and complement fixation test.¹¹ No treatment is usually necessary as the lesions resolve in 4–6 weeks. Liquid nitrogen or shave excision may be used to speed recovery; antibiotics are indicated for superinfection.

MILKER'S NODULE

Milker's nodule (caused by the paravaccinia virus) is similar to orf. The virus is endemic in cattle and is transmitted by direct contact with them.¹² Lesions have been described as passing through six clinical stages similar to the orf virus. Milker's nodule resolves without therapy.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is caused by a double-stranded DNA virus of the poxvirus group. It affects mainly children,

sexually active adults and immunocompromised individuals, and is spread by direct inoculation between humans. The lesions are small, discrete waxy, flesh-colored, dome-shaped papules with a central umbilication that are 3–6 mm in size. In patients with AIDS, several systemic fungal infections commonly mimic molluscum contagiosum, including cryptococcosis, histoplasmosis and *Penicillium marneffei* infection.

Histologically, molluscum bodies are present. The stratum corneum disintegrates in the center of the lesion, releasing the molluscum bodies and creating a central crater.

Treatment options include cryosurgery, curettage, incision and expression of the molluscum body; cantharidin, topical podophyllotoxin cream, salicylic acid preparations, imiquimod and topical cidofovir.

HUMAN PAPILLOMAVIRUSES

Warts are caused by papillomaviruses, members of the family Papillomaviridae. Papillomaviruses are double-stranded DNA viruses that do not have an envelope and thus can remain infectious for long periods of time after drying. More than 100 different types of human papillomavirus (HPV) have been identified by their separate DNA genotypes as detected by polymerase chain reaction.¹³ Incubation period is 2–9 months (average 3 months). Table 49.3 lists the various HPV types and their common lesions.

Table 49.3 Human papillomaviruses and their common lesions

Human papillomaviruses type	Wart type
HPV-1, HPV-2, HPV-4	Palmoplantar warts
HPV-2, HPV-4, HPV-27, HPV-29	Common warts
HPV-3, HPV-10, HPV-28, HPV-49	Flat warts
HPV-6, HPV-11	Condyloma (low risk of carcinoma)
HPV-16, HPV-18, HPV-31, HPV-33–35, HPV-40, HPV-51–60	Squamous cell carcinoma (high risk of carcinoma)
HPV-6, HPV-11	Laryngeal papillomas
HPV-30	Laryngeal carcinoma
HPV-13, HPV-32	Oral focal epithelial hyperplasia (Heck's disease)
HPV-16, HPV-18, HPV-31, HPV-33–35, HPV-39, HPV-40, HPV-51–60	Bowenoid papulosis
HPV-7	Butcher's warts
HPV-5, HPV-8, HPV-9, HPV-12, HPV-14, HPV-15, HPV-17, HPV-19–26, HPV-36, HPV-47, HPV-50	Epidermodysplasia verruciformis
HPV-6, HPV-11	Giant condyloma of Buschke and Loewenstein

Palmoplantar warts usually occur on the palms, soles and the lateral aspects of the fingers and toes. They can be painful on pressure and look similar to a callus, but are differentiated by their loss of skin lines and multiple black dots (which represent punctate hemorrhages from thrombosed dermal capillaries). Common warts (*verruca vulgaris*) can occur on any skin surface and are described as scaly, rough, spiny papules. Flat warts (*verruca plana*) are most common on the face, lower legs and dorsal hands.

Epidermodysplasia verruciformis (EV) represents a unique susceptibility to cutaneous HPV infection, especially types that are not generally responsible for human infection, such as HPV-5, -8, -9, -12, -14, -15, -17, -19, -25, -36, -38, -47 and -50.¹⁴ Approximately 50% of cases are inherited, usually with an autosomal recessive pattern. Recent findings have shown mutations in the EVER1 and EVER2 genes to be associated with this disease. Patients suffer from extensive infection with warts that resemble *verruca plana*.¹⁵

Condyloma acuminatum commonly occurs on the penis, vulva and anal region. The lesions appear as soft verrucous papules that coalesce into cauliflower-like masses.

Giant condyloma acuminata of Buschke and Loewenstein has been associated with HPV-6 and HPV-11 DNA, and is regarded as a low-grade verrucous carcinoma that resembles a large aggregate of condyloma acuminata. It is most common on the glans penis, vulva and anal region.

Bowenoid papulosis is described as multiple, small, reddish-brown flat-topped papules of the genitalia of men and women. Squamous cell carcinoma may arise in a Bowenoid papule, and is most commonly associated with HPV-16.

Oral focal epithelial hyperplasia (Heck's disease) is a rare condition described in Native Americans and Eskimos. Heck's disease is a chronic disease associated with HPV-13 and HPV-32. Lesions commonly present on the oral mucosa of the lower lip, buccal and gingival mucosa.

Therapy depends on the type of lesion seen clinically:

- For common and palmoplantar warts, daily topical salicylic acid preparations, cryotherapy, curettage, electrodesiccation, cantharidin, intralesional bleomycin and CO₂ laser ablation are routine therapies.
- Genital warts respond to imiquimod, sinecatechin cream, cryotherapy, trichloroacetic acid 50–80%, electrosurgery, excision, laser ablation and interferon- α intralesionally. Imiquimod induces interferon- α and is the most effective treatment with the lowest recurrence rate. Podophyllin is contraindicated because it contains mutagens which are potential carcinogens.
- Flat warts may respond to topical treatment with the vitamin A derivative tretinoin or 5-fluorouracil, cryotherapy and imiquimod.
- Epidermodysplasia verruciformis may also respond to systemic retinoids.
- Radiation of verrucas is contraindicated due to its association with the development of malignancy.

GRAM-POSITIVE ORGANISMS

STAPHYLOCOCCAL INFECTIONS

IMPETIGO

Both bullous and non-bullous forms of impetigo exist; however, non-bullous impetigo caused by *Staphylococcus aureus* accounts for the majority of cases. A prodrome of itching and pain heralds the appearance of a vesicle or pustule, after which the classic honey-colored crusted plaque with surrounding erythema appears.

Treatment with topical mupirocin or bacitracin every 8 h for 7–10 days or retapamulin every 12 h for 5 days is generally sufficient for localized involvement, although a course of oral antibiotics with a penicillinase-resistant semisynthetic penicillin may be needed (Table 49.4). Oral dicloxacillin

Table 49.4 Common penicillin doses (for adults) used in skin and soft-tissue infections

Penicillin	Route	Dose
Natural penicillins		
Aqueous penicillin G	i.v.	8–24 MU every 2–6 h
Procaine benzylpenicillin G	i.m.	0.6–1.2 MU once
Benzathine penicillin G	i.m.	1.2–2.4 MU once
Procaine + benzathine penicillin	i.m.	2.4 MU once
Penicillin V	oral	250–500 mg every 6 h
Penicillin-resistant penicillins		
Dicloxacillin	oral	125–500 mg every 6 h before meals
Cloxacillin	oral	250–500 mg every 6 h
Flucloxacillin	oral	250–500 mg every 6 h before meals
	i.m.	250–500 mg every 6 h
	i.v.	250–1 g every 6 h
Nafcillin	i.m.	500 mg every 4 h
	i.v.	500–2000 mg every 4–6 h
Oxacillin	oral	500–1000 mg every 6 h
	i.m., i.v.	250–2000 mg every 4–6 h
Aminopenicillins		
Amoxicillin	oral	250–500 mg every 8 h
	i.m.	500–1000 mg every 6 h
	i.v.	1–2 g every 4–6 h
Ampicillin	oral	250–1000 mg every 6 h
	i.m.	500–1000 mg every 6 h
	i.v.	1–2 g every 4 h
Ampicillin–sulbactam	i.v.	1.5–3 g every 6 h
Amoxicillin–clavulanate	oral	250/125 mg every 8 h
		500/125 mg every 12 h
		875/125 mg every 12 h
Antipseudomonal penicillins		
Piperacillin–tazobactam	i.v.	3.375 g every 6 h
		4.5 g every 8 h
Ticarcillin–clavulanate	i.v.	3.1–3.2 g every 4–6 h
Ticarcillin	i.v.	3 g every 4 h or 4 g every 6 h
Mezlocillin	i.v., i.m.	3 g every 4 h or 4 g every 6 h
Piperacillin	i.m., i.v.	6–24 g per day in divided doses

MU, megaunit (1 megaunit = 600 mg).

125–500 mg every 6 h, flucloxacillin 250–500 mg every 6 h or oxacillin 500–1000 mg every 4–6 h (Table 49.4) are recommended. A first-generation cephalosporin such as oral cefalexin 250–500 mg every 6 h (Table 49.5) may also be used. Alternatives include ampicillin plus clindamycin and either azithromycin, erythromycin or clarithromycin (Tables 49.4 and 49.6).

ECTHYMA

Impetigo can evolve into ecthyma if left untreated. Either *Staph. aureus* or *Streptococcus pyogenes* causes ecthyma (Table 49.7). The lesions of ecthyma penetrate the epidermis, creating a yellow–gray crusted ulcer up to 3 cm in diameter. The lesions most commonly affect the lower extremities in neglected debilitated patients with poor hygiene. Healing can take

Table 49.5 Common cephalosporin doses (for adults) used in skin and soft-tissue infections

Cephalosporin	Route	Dose
First generation		
Cefalexin	oral	250–500 mg every 6 h
Cefadroxil	oral	1–2 g per day
Cefamandole	i.v., i.m.	500–1000 mg every 4–8 h
Cefazolin	i.m., i.v.	500–2000 mg every 8 h
Second generation		
Cefaclor	oral	250–1000 mg every 8 h
Cefuroxime	i.m., i.v.	750–1500 mg every 8 h
Loracarbef	oral	400 mg every 12 h
Cefoxitin	i.v.	2 g every 6 h
Cefotetan	i.v.	2 g every 12 h
Third generation		
Cefotaxime	i.v., i.m.	1–2 g every 6–12 h
Ceftriaxone	i.m., i.v.	1–2 g per day
Cefixime	oral	400 mg/day or 200 mg every 12 h
Ceftazidime	i.m., i.v.	1–2 g every 8–12 h
Cefoperazone	i.v., i.m.	2–4 g every 12 h
Cefpodoxime	oral	200 mg every 12 h
Fourth generation		
Cefepime	i.v.	500–2000 mg every 12 h

Table 49.6 Common macrolide doses (for adults) used in skin and soft-tissue infections

Macrolide	Route	Dose
Erythromycin base	oral	250–500 mg every 6 h
Erythromycin ethyl succinate	oral	400 mg every 6 h
Erythromycin estolate	oral	250 mg every 6 h
Erythromycin lactobionate	i.v.	15–20 mg/kg every 6 h (maximum dose, 1 g every 6 h; 4 g per day)
Azithromycin	oral	500 mg for one day followed by 250 mg/day for 4 days or 1–2 g single dose
	i.v.	500 mg/day
Clarithromycin	oral	250–500 mg every 12 h

several weeks, despite antibiotic therapy. Topical antibiotics plus the same oral antibiotic regimens as used in impetigo, coupled with warm compresses 3–4 times daily, are recommended.

FOLLICULITIS

Folliculitis is most commonly caused by *Staph. aureus* (Table 49.7). The two common types of folliculitis are superficial and deep. The superficial types are referred to as follicular or Bockhart's impetigo and commonly are located on the beard area, axilla, buttocks and extremities. The deep form of folliculitis typically occurs in the beard areas and involves peri-follicular inflammation. Treatment with topical mupirocin, clindamycin 1% or erythromycin 2% along with an antibacterial wash or soap is usually sufficient; systemic treatment with antibiotics is reserved for deep extensive cases. Left untreated, folliculitis can evolve into a furuncle or carbuncle.

FURUNCLES AND CARBUNCLES

A furuncle, also known as a boil, is a deep, firm, erythematous painful inflammatory nodule, which occurs around hair follicles and gradually enlarges to form a fluctuant abscess. *Staph. aureus* is the etiological agent (Table 49.7), and increasing numbers of infections are found to be due to methicillin-resistant *Staph. aureus* (MRSA), which may be hospital or community acquired. Following rupture of a furuncle, pus is expressed along with a core of necrotic material and the lesion begins to heal. Several furuncles can coalesce into a deeper network of more extensive lesions and form a carbuncle.

Carbuncles are usually more erythematous and indurated than furuncles. Carbuncles and furuncles can evolve into more serious diseases such as cellulitis and bacteremic spread.

Treatment is aimed at incision and drainage of the pus. If a carbuncle or furuncle is complicated by fever or cellulitis, treatment with a semisynthetic penicillin is indicated: oral dicloxacillin, flucloxacillin, cefalexin, clindamycin or erythromycin, or intravenous nafcillin/oxacillin 2 g every 6 h (Table 49.4). Alternatively, intravenous cefazolin 1–2 g every 8 h or vancomycin 1 g every 12 h may be used. When MRSA infection is suspected, oral tetracyclines, trimethoprim-sulfamethoxazole, clindamycin or linezolid (400 mg every 12 h) may be used.

PARONYCHIA

Paronychia are infections caused predominately by *Staph. aureus* entering a break in the skin around the fingernails in persons exposed to hand trauma or chronic moisture¹⁶ (Table 49.7). Other organisms causing paronychia include *Streptococcus*, *Candida*, *Pseudomonas* spp., oral anaerobes

Table 49.7 Skin and soft-tissue infections, causative organisms and primary and secondary treatment regimens

Disease	Causative organism	Primary treatment	Secondary treatment
Acne	<i>Propionibacterium acnes</i>	Doxycycline Minocycline Tetracycline	Erythromycin base Clindamycin
Actinomycosis	<i>Actinomyces israelii</i> , <i>Actinomyces gerencseriae</i>	Penicillin V	Clindamycin
Anthrax	<i>Bacillus anthracis</i>	Penicillin G (aqueous) Ciprofloxacin Levofloxacin	Erythromycin base Doxycycline
Bacillary angiomatosis	<i>Bartonella henselae</i> , <i>Bartonella quintana</i>	Erythromycin base	Doxycycline
Blistering distal dactylitis	<i>Staphylococcus aureus</i> , <i>Streptococcus pyogenes</i>	Dicloxacillin Penicillin V	Cephalosporin (2nd generation) Erythromycin base Clindamycin
Boils (carbuncles, furuncles)	<i>Staphylococcus aureus</i>	Dicloxacillin	Cephalosporin (2nd generation) Erythromycin base Clindamycin Levofloxacin
Cat bite	<i>Pasteurella multocida</i> , <i>Staphylococcal aureus</i>	Amoxicillin-clavulanate	Doxycycline Cefuroxime Penicillin G (aqueous) Penicillin V
Cat-scratch disease	<i>Bartonella henselae</i>	Ciprofloxacin	Trimethoprim-sulfamethoxazole
Cellulitis	<i>Streptococcus pyogenes</i> , <i>Staphylococcus aureus</i>	Nafcillin Oxacillin Dicloxacillin Cefazolin	Cephalosporin (2nd generation) Erythromycin base Azithromycin or clarithromycin Clindamycin Levofloxacin Linezolid
Clostridium cellulitis	<i>Clostridium perfringens</i>	Penicillin G (aqueous)	Clindamycin Metronidazole Tetracycline Chloramphenicol Imipenem
Diphtheria	<i>Corynebacterium diphtheriae</i>	Erythromycin base	Penicillin V Benzylpenicillin
Dog bites	<i>Pasteurella multocida</i> , Viridans group streptococci, <i>Staphylococcus aureus</i>	Amoxicillin-clavulanate	Clindamycin plus: 1. fluoroquinolone (adults) 2. trimethoprim-sulfamethoxazole (children)
Ecthyma	<i>Staphylococcus aureus</i>	Dicloxacillin	Cephalosporin (2nd generation) Erythromycin Clindamycin
Ehrlichiosis	<i>Ehrlichia</i> spp.	Doxycycline	Chloramphenicol
Erysipelas	<i>Streptococcus pyogenes</i>	Penicillin G (benzathine) Nafcillin Oxacillin Dicloxacillin	Erythromycin base Azithromycin Clarithromycin Cephalosporin (2nd generation)
Erysipeloid	<i>Erysipelothrix rhusiopathiae</i>	Penicillin G (aqueous) Ampicillin	Erythromycin base Fluoroquinolones Cephalosporin (4th generation) Clindamycin
Erythema gangrenosum	<i>Pseudomonas aeruginosa</i>	Ceftazidime Amikacin	Piperacillin Tobramycin Ciprofloxacin
Erythrasma	<i>Corynebacterium minutissimum</i>	Erythromycin base	Topical benzoyl peroxide Topical clindamycin

(Continued)

Table 49.7 Skin and soft-tissue infections, causative organisms and primary and secondary treatment regimens—cont'd

Disease	Causative organism	Primary treatment	Secondary treatment
Folliculitis	<i>Staphylococcus aureus</i>	Topical mupirocin	Dicloxacillin Penicillin V Oxacillin Penicillin G (benzathine) Erythromycin base
Gangrenous cellulitis (necrotizing fasciitis)	<i>Peptostreptococcus</i> spp. <i>Bacteroides</i> spp. <i>Enterobacter</i> spp. <i>Proteus</i> spp.	Ampicillin–sulbactam Imipenem–cilastatin Ticarcillin–clavulanate	Cephalosporin (3rd generation) Clindamycin Metronidazole + aminoglycoside
Gangrenous cellulitis (streptococcal gangrene)	<i>Streptococcus</i> group A/B/C/G	Penicillin G (aqueous) Penicillin V	Erythromycin base Cephalosporin Vancomycin Clarithromycin Azithromycin Clindamycin
Gas gangrene	<i>Clostridium perfringens</i>	Penicillin G (aqueous) Clindamycin	Doxycycline Erythromycin base Chloramphenicol Cefazolin Cefoxitin
Human bites	<i>Viridans group streptococci</i> <i>Staphylococcus epidermidis</i> <i>Bacteroides</i> spp. <i>Corynebacterium</i> spp. <i>Eikenella corrodens</i>	Amoxicillin–clavulanate	Amoxicillin–sulbactam Cefoxitin Ticarcillin–clavulanate Piperacillin–tazobactam Clindamycin + ciprofloxacin or trimethoprim–sulfamethoxazole
Impetigo	<i>Staphylococcus aureus</i> , <i>Streptococcus pyogenes</i>	Dicloxacillin Penicillin V Oxacillin Penicillin G (benzathine)	Cephalosporin (2nd or 3rd generation) Erythromycin base Clindamycin Azithromycin Clarithromycin Mupirocin
Kawasaki syndrome	<i>Staphylococcus aureus</i> superantigens	Intravenous immunoglobulin + aspirin	None
Listeriosis	<i>Listeria monocytogenes</i>	Ampicillin Penicillin G (aqueous)	Trimethoprim–sulfamethoxazole
Lyme disease (erythema migrans)	<i>Borrelia burgdorferi</i>	Ceftriaxone Ceftizoxime Doxycycline Amoxicillin	Penicillin G (aqueous) Azithromycin Clarithromycin
Meningococcemia	<i>Neisseria meningitidis</i>	Penicillin G (aqueous)	Ceftriaxone Chloramphenicol Minocycline
Nocardiosis	<i>Nocardia asteroides</i>	Trimethoprim–sulfamethoxazole	Minocycline
Paronychia	<i>Staphylococcus aureus</i>	Clindamycin	Erythromycin
Plague	<i>Yersinia pestis</i>	Gentamicin Streptomycin	Doxycycline Chloramphenicol Fluoroquinolones
Pseudomonal infection	<i>Pseudomonas aeruginosa</i>	Meropenem Cefepime Piperacillin–tazobactam plus amikacin	Gentamicin Tobramycin
Rat bite fever	<i>Streptobacillus moniliformis</i>	Penicillin G (aqueous) Doxycycline	Erythromycin base Chloramphenicol
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	Doxycycline	Chloramphenicol Fluoroquinolones

Table 49.7 Skin and soft-tissue infections, causative organisms and primary and secondary treatment regimens—cont'd

Disease	Causative organism	Primary treatment	Secondary treatment
Rosacea	Unknown	Minocycline Doxycycline Tetracycline Erythromycin Metronidazole (topical 1%) Ampicillin	Trimethoprim-sulfamethoxazole Metronidazole (oral) Dapsone
Saltwater contaminated wound	<i>Vibrio vulnificus</i> , <i>Vibrio damsela</i>	Ceftazidime + doxycycline	Cefotaxime Ciprofloxacin
Scarlet fever	<i>Streptococcus pyogenes</i>	Penicillin (all)	Cephalosporins (all) Macrolides (all)
Staphylococcal scalded skin syndrome	<i>Staphylococcus aureus</i> exotoxin	Nafcillin	Oxacillin
Toxic shock syndrome	<i>Staphylococcus aureus</i> exotoxin	Nafcillin or Oxacillin + intravenous immunoglobulins	Cephalosporin (1st generation)
Tularemia	<i>Francisella tularensis</i>	Streptomycin	Gentamicin Doxycycline Chloramphenicol
Wound infection postoperative	<i>Staphylococcus aureus</i> , <i>Streptococcus</i> , Enterobacteriaceae	Cephalosporin (2nd generation) Amoxicillin-clavulanate	Doxycycline Cephalosporin (2nd and 3rd generation) Levofloxacin Linezolid

Note: Flucloxacillin can be substituted for nafcillin, oxacillin or dicloxacillin in countries in which it is available.

and dermatophytes. Paronychia usually presents as red-hot, tender, proximal and lateral nail-fold inflammation.

Treatment of bacterial paronychia includes both topical and oral antibiotic therapy plus incision and drainage of any abscess formation. Oral amoxicillin-clavulanate (375–625 mg every 8 h) or clindamycin (300 mg every 6 h) are the suggested regimens (Table 49.6). Fungal paronychia may be treated with topical antifungal preparations or oral ketoconazole (200 mg/day).

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Staphylococcal scalded skin syndrome is a severe skin exfoliation caused by a staphylococcal exotoxin (Table 49.7). Children under the age of 5 years are most commonly affected due to their immature immune systems; however, immunocompromised adults can also be afflicted.

The generalized syndrome can begin with an upper respiratory tract, eye or ear infection.¹⁷ Areas around the mouth and axilla initially become tender and slightly erythematous; this heralds the appearance of the generalized blisters that evolve into large flaccid bullae. Next, large sheets of epidermis are shed, leaving an erythematous, denuded base exposed. Uniquely, the mucous membranes are spared. Healing of the lesions can be expected in 5–7 days. Culture and biopsy confirm diagnosis.

Treatment with an intravenous penicillinase-resistant antibiotic and subsequent substitution with an oral agent

within a few days is appropriate (Table 49.4). Diligent management of electrolytes and supportive skin care will speed recovery; however, despite all efforts the mortality rate is approximately 2–3% (rates are higher in adults than in children). Care must be taken to avoid epidemics in neonatal care units by eradicating *Staph. aureus* from healthcare workers who are nasal carriers and by implementing strict handwashing policies.

The recommended penicillinase-resistant antibiotic is intravenous nafcillin, oxacillin or flucloxacillin (2 g every 4 h in adults; 150 mg/kg every 6 h in children). Treatment should last 5–7 days (Table 49.4).

STAPHYLOCOCCAL TOXIC-SHOCK SYNDROME

Staphylococcal toxic-shock syndrome, like staphylococcal scalded skin syndrome, is an illness that results from an exotoxin produced by *Staph. aureus* (Table 49.7). In addition, it is a multisystem disease involving at least three organ systems, with hypotension, fever, and a rash resembling that of scarlet fever followed by skin desquamation.

Menstruating women using tampons for a prolonged period of time account for up to 90% of cases. The conjunctiva may become infected; the oral mucosa and vagina may appear intensely erythematous. Palmar and plantar desquamation occurs between 1 and 2 weeks later.

Initial treatment is aimed at controlling the hypotension and shock with fluid replacement. The tampon must be

removed and intravenous penicillinase-resistant antibiotics started. If therapy is instituted early, intravenous γ -globulins and fresh-frozen plasma containing immunoglobulins will expedite recovery.¹⁶ Treatment with intravenous clindamycin 600–900 mg every 8 h is recommended. Intravenous nafcillin, oxacillin or flucloxacillin 2 g every 4 h or a first-generation cephalosporin such as cefazolin 1–2 g every 8 h may also be used (Tables 49.4 and 49.5).

KAWASAKI SYNDROME

Kawasaki syndrome is an acute multisystem vasculitis of infancy and childhood associated with high fever, mucocutaneous inflammation and the development of coronary artery abnormalities.¹⁸ The etiology of Kawasaki syndrome is unknown; however, it is suspected that *Staph. aureus* superantigens may trigger the disease (Table 49.7).

Treatment should begin with intravenous immunoglobulin 2 g/kg over 12 h, plus oral aspirin 80–100 mg/kg per day in four divided doses, followed by aspirin 3–5 mg/kg per day for 6–8 weeks. If the patient remains febrile after the first dose of immunoglobulin, a second dose may be administered.

STREPTOCOCCAL INFECTIONS

IMPETIGO

Streptococcal impetigo is often indistinguishable from the staphylococcal variant (Table 49.7). Patients may be infected with both staphylococcal and streptococcal impetigo. Treatment of the streptococcal form with mupirocin ointment is effective, but more severe forms of group A streptococcal impetigo should be treated with oral or intramuscular penicillin. Oral penicillin V 250–500 mg/day is the recommended regimen (Table 49.4). If an intramuscular dose of penicillin is preferred, then benzathine penicillin G(0.6–1.2 million units) is advocated (Table 49.4). An alternative oral antibiotic is a second-generation cephalosporin (Table 49.5). Second-line treatment consists of a macrolide antibiotic or a third-generation cephalosporin (Tables 49.5 and 49.6).

BLISTERING DISTAL DACTYLITIS

Blistering distal dactylitis is caused most commonly by *Str. pyogenes* (Table 49.7). Mostly children and adolescents are affected.¹⁹ The lesion is described as a seropurulent blister on an erythematous base that develops on the distal palmar or plantar aspect of the fingers and toes. Treatment with oral penicillin or erythromycin base is appropriate (Tables 49.4 and 49.6).

ERYSIPelas

Erysipelas is a form of superficial cellulitis with lymphatic vessel involvement, caused mainly by group A β -hemolytic streptococci (Table 49.7). The lesions may be precursors to a more invasive cellulitis. The painful lesions are well demarcated and the plaques appear very erythematous and edematous, with an advancing raised border.²⁰ The diagnosis is usually clinical; however, Gram stain and culture will confirm the organism. It is important to differentiate between the more superficial erysipelas and the deeper cellulitis so that appropriate treatment can be instituted.

Treatment is with either oral or intramuscular penicillin; erythromycin base can be used in the penicillin-allergic patient (Tables 49.4 and 49.6). A penicillin-resistant semisynthetic penicillin such as oral dicloxacillin or flucloxacillin 500 mg every 6 h or, for a more severe infection, intravenous nafcillin, oxacillin or flucloxacillin 2 g every 4 h is preferred. Second-line agents include macrolide antibiotics, first-generation cephalosporins or ampicillin and clindamycin (Tables 49.5 and 49.6). Improvement can be expected in 24–28 h with antibiotic therapy.

CELLULITIS

Cellulitis is caused most commonly by *Staph. aureus* and group A streptococci (Table 49.7). Other pathogens involved include group B streptococci, cryptococci, pneumococci and Gram-negative bacilli. Unlike erysipelas, the deep dermis and subcutaneous soft tissues are affected, and the margins are indistinct, not raised and are indurated. However, like erysipelas, cellulitis is very painful. Diagnosis is clinical and confirmed with Gram stain and culture.

Treatment must be implemented rapidly to avoid any complications such as superinfections, bacteremia, necrotizing fasciitis and amputations. Treatment can be customized depending on the offending pathogen (if cultures are available). Realistically, when patients present with cellulitis, cultures are not immediately available and therefore empirical treatment with an intravenous penicillinase-resistant penicillin should be initiated to treat both staphylococcal and streptococcal infections. Intravenous nafcillin or oxacillin 2 g every 4 h is appropriate (Table 49.4). Subsequent culture results can help guide specific therapy. For moderately complicated infections oral levofloxacin 500–750 mg every 12 h is acceptable (Table 49.8). Treatment with intravenous vancomycin (1 g every 12 h) or linezolid is preferred for methicillin-resistant cases of cellulitis.²¹ Linezolid is available in intravenous and oral preparations and is 100% orally bioavailable so patients may be switched from intravenous preparations to oral preparations without dose changes. Linezolid is available in 600 mg tablets, an oral suspension containing 100 mg/mL and an intravenous solution. The recommended oral dose for uncomplicated skin infections is 400 mg every 12 h.²¹ Immobilization and elevation of the affected limb will aid in reducing edema and pain.

Table 49.8 Common fluoroquinolones doses (for adults) used in skin and soft-tissue infections

Fluoroquinolones	Route	Dose
Nalidixic acid	oral	1 g every 6 h
Ciprofloxacin	oral	250–750 mg every 12 h
	i.v.	200–400 mg every 12 h
Ofloxacin	oral, i.v.	200–400 mg every 12 h
Levofloxacin	oral, i.v.	200–750 mg once daily or every 12 h
Trovafloxacin/ alatrofloxacin	oral	100–200 mg once daily
	i.v.	300 mg once daily
Sparfloxacin	oral	400 mg first day, followed by 200 mg once daily
Gatifloxacin	i.v., oral	400 mg once daily
Moxifloxacin	oral	400 mg once daily

Frequent dressing changes with sterile saline will keep the lesion clean. Oral analgesics may be necessary for pain management.

GANGRENOUS CELLULITIS

Necrotizing fasciitis is a type of gangrenous cellulitis. The various forms of necrotizing fasciitis include a non-streptococcal gangrene, streptococcal gangrene, synergistic necrotizing cellulitis and Fournier's gangrene. Gangrenous cellulitis usually begins on an extremity, the perineum, or postoperative wound or trauma site and initially appears as a cellulitis infection. As the infection evolves, gangrenous changes become apparent within 36–72 h. The area becomes purple, followed by formation of vesicles and bullae that quickly rupture, producing sharply demarcated areas of necrotic eschar and crepitus that destroy all soft tissues, including vessels and nerves. A foul-smelling discharge and palpable gas in the tissues can sometimes be detected.

Streptococcal gangrene is caused principally by group A streptococci.

Non-streptococcal gangrene is a type of necrotizing fasciitis caused by pathogens other than group A streptococci, such as anaerobes plus at least one facultative species.²⁰ These same pathogens can also cause Fournier's gangrene, which involves the scrotum and penis.²²

Another type of highly lethal necrotizing fasciitis is the polymicrobial synergistic necrotizing cellulitis, which involves necrosis of all layers of soft tissues and commonly involves the perineum. The diagnosis is based on Gram stain, culture and clinical findings. Treatment with broad-spectrum antibiotics (with aerobic, anaerobic and antipseudomonal coverage) plus wide surgical debridement of the gangrenous tissue is recommended. Despite therapy, mortality remains high.

SCARLET FEVER

Scarlet fever is usually caused by a pharyngeal infection with group A streptococci and subsequent elaboration of a pyrogenic exotoxin occurring in children under 10 years of age (Table 49.7). Between 24 and 48 h after the appearance of the fever and pharyngitis, the unique cutaneous manifestations of scarlet fever, including the characteristic diffuse erythematous 'sandpaper' like rash, and 'strawberry' red tongue appear. Diagnosis is confirmed by the presence of a positive group A streptococcal throat culture.

Following treatment with penicillin the symptoms improve quickly; however, a desquamation may persist for a few weeks. If untreated, uncomplicated infection may last 4–5 days.

CORYNEBACTERIUM MINUTISSIMUM

ERYTHRASMA

Erythrasma caused by *Corynebacterium minutissimum* is a common disease, occurring more often in men and with a predilection for the intertriginous areas (Table 49.7). The organism possesses keratolytic properties and lesions cause thick lamellated plaques on affected areas. The toe web spaces are commonly affected; a Wood's lamp examination revealing a striking bright coral red-pink fluorescence will confirm the diagnosis, as will a culture. Recommended treatment for widespread involvement is oral erythromycin (250 mg every 6 h or 500 mg every 12 h for 14 days) and, for more localized involvement, benzoyl peroxide (Table 49.7).

BACILLUS ANTHRACIS (ANTHRAX)

Anthrax is caused by infection with *Bacillus anthracis*, an aerobic, encapsulated, square rod (Table 49.7). Although primarily a disease of animals, humans can be infected by contact with infected carcasses during animal product handling. Other means of infection include aerosolized spores, which may cause pulmonary infection. A painless malignant pustule occurring on an exposed surface of the body is the hallmark of cutaneous anthrax.

Treatment of choice is aqueous penicillin G 20 million units a day intravenously in four divided doses (Table 49.4). For aerosolized anthrax, fluoroquinolones and doxycycline are effective alternatives (Table 49.8).

ERYSIPLOTHRIX RHUSIOPATHIAE (ERYSIPEROID)

E. rhusiopathiae is a rod-shaped Gram-positive organism (Table 49.7), which occurs most commonly in people handling raw fish, poultry or other meat products. The organism is inoculated through a break in the skin.²³

The macular and plaque-like lesions appear violaceous with sharply defined borders. A culture may confirm the presence of *E. rhusiopathiae*; however, the clinical history is usually enough to suggest the diagnosis.

Treatment with oral or intramuscular penicillin 2–3 million units (1.2–1.8 g) per day for 7–10 days is recommended (Table 49.4). In the penicillin-allergic patient, a fourth-generation cephalosporin, imipenem or ciprofloxacin would be adequate; however, most isolates are resistant to vancomycin²⁴ (Tables 49.5 and 49.8).

BARTONELLA HENSELAE (CAT-SCRATCH DISEASE)

Cat-scratch disease caused by *B. henselae* is the most common cause of localized chronic lymphadenopathy in children and young adults (Table 49.7).²⁵ Infection is typically benign and is caused by a bite or scratch from a cat. The initial inoculation may start as a papule and evolve into a vesicle and subsequent crust within 5 days.²⁶ The gold standard for diagnosis is the cat-scratch disease skin test.

Treatment with antibiotics remains controversial, because most cases of this disease spontaneously resolve. *B. henselae* is sensitive to fluoroquinolones, macrolides, tetracyclines, and third- or fourth-generation cephalosporins (Tables 49.6, 49.8 and 49.9). A recommended regimen would be oral azithromycin 500 mg for 1 day followed by 250 mg for 4 additional days (Table 49.6); oral ciprofloxacin 500–750 mg every 12 h is also effective (Table 49.8).

BARTONELLA QUINTANA (BACILLARY ANGIOMATOSIS)

Either *B. henselae* or *B. quintana* may cause bacillary angiomatosis (Table 49.7). Bacillary angiomatosis typically affects severely immunocompromised patients, such as advanced cases of HIV with CD4⁺ lymphocytes <50 cells/mm³.²⁷ Symptoms of bacillary angiomatosis include fever, lymphadenopathy, abdominal pain, and the classic grouped dark-red and violaceous papules and nodules that are friable and painful. The lesions of bacillary angiomatosis appear similar to Kaposi's sarcoma and pyogenic granulomas, and should be distinguished from these conditions.

Erythromycin (500 mg every 6 h) is the drug of choice; oral macrolide antibiotics (clarithromycin 500 mg every

Table 49.9 Common tetracycline doses (for adults) used in skin and soft-tissue infections

Tetracycline	Route	Dose
Short-acting tetracyclines Tetracycline	oral	250–500 mg every 6 h
Long-acting tetracyclines Doxycycline	oral, i.v.	200 mg initially then 50–100 mg every 12 h
Minocycline	oral, i.v.	200 mg initially then 100 mg every 12–24 h

12 h or azithromycin 250 mg/day) may also be used (Table 49.6). Ciprofloxacin (oral 500–750 mg every 12 h) (Table 49.8) and oral doxycycline (100 mg every 12 h) are also recommended (Table 49.9). Treatment must continue for up to 6 months.

PROPIONIBACTERIUM ACNES (ACNE)

Acne is an inflammatory condition caused by the accumulation of free fatty acids in the follicles of the skin, produced by the action of bacterial lipolytic enzymes on triglycerides (Table 49.7). Acne begins with the formation of a comedone, sometimes papules, pustules and nodules. The ensuing inflammation is a result of the presence of *P. acnes* which is the target of the inflammatory response. The accumulation of sebum in the follicles of the face, chest, shoulders and back produces nutrients on which *P. acnes* thrives.

The disruption in keratinization is a fundamental component of acne for which therapy is directed. Topical agents include use of products containing benzoyl peroxide, salicylic acid, vitamin A derivatives, the synthetic retinoids adapalene and tazarotene, and dapsoe. Topical antibacterial agents such as clindamycin and erythromycin are effective (Table 49.10). Another cream intended to affect the keratinization process is azelaic acid. Cleansing is of limited value because soaps will not remove bacteria or lipids from inside the follicle. Intralesional steroid injection of larger nodular lesions will decrease inflammation and avoid potential scar formation. Daily oral tetracycline, erythromycin, clindamycin, doxycycline and minocycline decrease the concentration of free fatty acids and suppress *P. acnes* (Tables 49.6 and 49.9). Oral contraceptives containing estrogen will decrease sebum production and therefore decrease acne lesions. Isotretinoin, a synthetic oral retinoid that produces profound decreases in sebum production, has several side effects, including pronounced dryness of the skin and mucous membranes. A dose of 0.5–1.0 mg/day is recommended for a 20-week treatment. Baseline complete blood cell counts, liver function tests and triglyceride levels should be checked and repeated at 3–4 weeks and 6–8 weeks of therapy. As isotretinoin is teratogenic, women of childbearing age should start contraception 1 month before therapy.

CLOSTRIDIUM PERFRINGENS (CLOSTRIDIUM CELLULITIS)

Clostridium perfringens infection can cause a crepitant cellulitis of the subcutaneous tissue, possibly muscle, following traumatic tissue injury associated with soil contamination (Table 49.7). The crepitus present is caused by gas in the underlying tissues (gas gangrene). Pure clostridial infections do not emit foul odors; however, mixed and non-clostridial infections will produce foul-smelling hydrogen compounds through incomplete oxidation produced by anaerobic organisms.²⁸

Table 49.10 Topical antimicrobial agents

Antibiotic/strength	Indications	Bacterial coverage	Available forms
Azelaic acid 20%	Acne	Gram-positive	Cream
Bacitracin	Impetigo, furunculosis	Gram-positive	Ointment
Chloramphenicol 1%	Minor skin infections	Gram-positive and negative	Cream
Clindamycin 1%	Acne	Gram-positive	Solution, gel, ppledget, lotion
Clioquinol	Tinea pedis	Broad spectrum	Cream, ointment
Demeclocycline	Skin infections	Gram-positive	Cream
Erythromycin 1.5–2%	Acne	Gram-positive and negative	Solution, gel, ppledget, ointment solution
Fusidic acid	Skin infections	Gram-positive	Cream, ointment, impregnated gauze
Gentamicin 0.01%	Prophylaxis of malignant otitis externa	Gram-negative	Cream, ointment
Gramicidin	Skin infections	Gram-positive	Ointment
Metronidazole 0.75%	Rosacea	Anaerobes	Gel, cream
Mupirocin 2%	Impetigo, antimicrobial prophylaxis, and eliminating <i>Staph. aureus</i> nasal carriage	Gram-positive	Ointment
Neomycin	Abrasions, burns	Gram-negative	Ointment
Neomycin + polymyxin	Abrasions	Gram-negative	Cream
Neomycin + polymyxin + bacitracin	Abrasions	Gram-positive and negative	Ointment
Nitrofurazone 0.2%	Burns	Gram-positive and negative	Cream, solution
Paromomycin	Cutaneous leishmaniasis	Broad-spectrum antibacterial and antiparasitic	
Polymyxin B	Infected atopic, nummular, stasis dermatitis and swimmer's ear	Gram-negative	Ointment
Retapamulin 1%	<i>Staph. aureus</i>	Gram-positive	Ointment
Silver sulfadiazine	Burns	Broad spectrum	Cream
Tetracycline	Acne	Gram-positive and negative	Ointment, solution

The pain of a clostridium cellulitis is often mild and infection appears superficial, although tissue damage may be extensive. Treatment requires surgery and adjunct penicillin G, with possibly clindamycin and hyperbaric oxygen therapy (Table 49.4).

LISTERIA MONOCYTOGENES (LISTERIOSIS)

Listeria monocytogenes is found in the feces of wild animals, birds and soil; however, infection cannot usually be associated with exposure to any of the common sources (Table 49.7). Treatment is with either ampicillin or penicillin (Table 49.4). For adults the dosage of aqueous penicillin G is 12–24 million units (7.2–14.4 g) intravenously daily in divided doses every 2–4 h; the dose of ampicillin is 12 g intravenously in divided doses every 3–4 h (Table 49.4). In non-pregnant adults allergic to penicillin, trimethoprim–sulfamethoxazole is an alternative.²⁹

ACTINOMYCSES (ACTINOMYCOSIS)

Either *Actinomyces israelii* or *Actinomyces gerencseriae* can cause actinomycosis (Table 49.7). Infection typically involves the cervicofacial anatomy following a traumatic procedure such as a dental extraction. Infection can result in a painful indurated soft-tissue swelling around the oral mucosa known as 'woody fibrosis'. As the lesion enlarges at the angle of the jaw it is referred to as 'lumpy jaw'. Direct extension to adjacent thoracic structures may occur.

Diagnosis is based on clinical suspicion and detection of the organism on Gram stain, culture, exudates or biopsy.

Treatment is with intravenous aqueous penicillin G 10–20 million units (6–12 g) per day in divided doses every 4 h for 4–6 weeks (Table 49.4) or intravenous ampicillin 50 mg/kg per day in divided doses every 12 h for 4–6 weeks, followed by amoxicillin 500 mg/day for 6–12 additional months to prevent relapse (Table 49.4).

GRAM-NEGATIVE ORGANISMS

NEISSERIA MENINGITIDIS (MENINGOCOCCEMIA)

Neisseria meningitidis is an obligate aerobic, encapsulated Gram-negative coccus (Table 49.7). Humans are the only known host. Asymptomatic exposure to *N. meningitidis* can elicit protective bactericidal antibodies; thus immunity increases with age.³⁰ A brief upper respiratory tract infection and subsequent nausea, vomiting, myalgia, fever, meningismus, stupor, hypotension and hemorrhagic rash can precede acute meningococcemia. The hemorrhagic rash is a result of the pathogen damaging the small dermal blood vessels. The rash may transiently appear macular and papular with an erythematous hue with evolving purpura, and sometimes there are large red–black geographic-appearing areas of tissue infarction with a gray center.

Polymorphonuclear leukocytosis is observed in the peripheral blood and cerebrospinal fluid. The organism may be seen on Gram stain and is easily cultured in cases of meningococcemia.

Untreated infection with *N. meningitidis* is fatal. Adults should be given aqueous penicillin G, 4 million units (2.4 g) intravenously every 4 h for 7 days after the temperature has returned to normal (Table 49.4); in the penicillin-allergic patient, chloramphenicol 1 g intravenously every 6 h is the recommended regimen. In parts of the world where meningococcal resistance to penicillin has been isolated (e.g. Spain or the UK), a third-generation cephalosporin should be used³¹ (Table 49.5). The recommended prophylactic dose of rifampicin (rifampin) is 600 mg orally every 12 h for 2 days.³² In cases of rifampicin resistance, a fluoroquinolone is an effective oral single-dose substitute (Table 49.8). Ceftriaxone is an alternative parenteral single dose for children and adults^{31,33} (Table 49.5). Immunization with polysaccharide vaccines is safe and effective in preventing disease in adults and children over the age of 2 years.^{32,34}

PSEUDOMONAS AERUGINOSA

Pseudomonas aeruginosa is an obligate aerobic Gram-negative bacillus (Table 49.7). Some strains produce the characteristic blue pigment pyocyanin or the yellow-green pigment fluorescein, which will fluoresce under Wood's ultraviolet lamp. An odor of grapes, characteristic of trimethylamine, is typical of pseudomonal infection.³⁵ Healthy people infected with *Pseudomonas* will typically be affected in areas exposed to increased humidity and moisture, such as the toe webs, fingernails (green nail syndrome) and the ear canal (swimmer's ear). People utilizing public swimming pools or hot tubs (hot tub folliculitis) can also be affected.³⁶ Local infections will improve with topical therapy and drying of the affected area. Superficial skin infections such as toe web infections respond

to acetic acid, silver nitrate and gentian violet each applied 2–3 times per day. Paronychia responds well to 4% thymol in chloroform, surgical drainage and nail trimming. For external ear infection, acetic acid in 50% alcohol, 0.1% polymyxin in acetic acid, or glucocorticoids with neomycin are effective. Systemic infection is rare in the immunocompetent host.

Patients with *Pseudomonas* infections are typically immunocompromised and may be afflicted with gangrenous cellulitis or possibly ecthyma gangrenosum. Ecthyma gangrenosum lesions are painless and begin with an area of erythema surrounding a gray region of infarcted tissue. The lesions evolve to become black necrotic eschars. Treatment for systemic infections requires intravenous antibiotic therapy; meropenem, ceftazidime and piperacillin–tazobactam plus amikacin are recommended as first-line agents. The aminoglycosides gentamicin and tobramycin are also recommended (Table 49.11).

BORRELIA BURGDORFERI (LYME BORRELIOSES)

Lyme disease is caused by a tick vector that transmits the offending Gram-negative bacterial spirochete *Borrelia burgdorferi* to humans (Table 49.7). Lyme borreliosis is common throughout the northern hemisphere. Lyme disease can be classified into three stages: the first stage is called the early localized stage, the second the early disseminated and the last stage the late or chronic stage of Lyme disease.

The hallmark cutaneous manifestation of Lyme disease, erythema migrans, begins at the site of a tick bite. Initially, the lesion appears as a confluent erythematous macule or patch; however, as the lesion spreads centrifugally the center of the lesion fades, leaving an annular area of erythema. The rash may be asymptomatic; however, systemic symptoms such as lymphadenopathy, headache, fever, malaise, myalgia, arthralgia and gastrointestinal symptoms may be present.

Diagnosis is based on the history of exposure to a tick bite plus the appearance and evolution of the characteristic rash and serology.

Amoxicillin (1 g every 8 h) or doxycycline (200 mg every 12 h) for 14 days, as well as intravenous ceftriaxone or ceftizoxime, have all been suggested for treatment (Tables 49.4–49.6 and 49.9).

Table 49.11 Adult doses of aminoglycosides for treatment of skin and soft-tissue infections

Aminoglycoside	Route	Dose
Amikacin	i.m., i.v.	15 mg/kg daily every 8–12 h
Gentamicin	i.m., i.v.	1.7–5.0 mg/kg daily every 8 h
Spectinomycin	i.m.	2 g once
Tobramycin	i.m., i.v.	3–5 mg/kg daily every 8 h
Streptomycin	i.m., i.v.	15 mg/kg daily or 25–30 mg/kg 2–3 times per week

YERSINIA PESTIS (PLAQUE)

The plague is an infection in humans caused by *Yersinia pestis*, which is endemic in wild rodents and spread to humans via flea bites (see Ch. 61). Bubonic plague is the most common form of plague in the USA. Treatment is with intravenous gentamicin 2 mg/kg loading dose then 1.7 mg/kg every 8 h, or intramuscular streptomycin 1 g every 12 h for 10 days³⁷ (Table 49.11). Chloramphenicol, doxycycline and fluoroquinolones are alternative treatments and preferred if streptomycin-resistant strains are present (Table 49.9).

FRANCISSELLA TULARENSIS (TULAREMIA)

Tularemia is an infection of humans that typically follows direct inoculation by animals or by insect vectors with *Francisella tularensis* (see Ch. 61). Treatment is with streptomycin 1–2 g per day for 7–10 afebrile days. Gentamicin, tetracycline and chloramphenicol are alternatives (Tables 49.9 and 49.11).

STREPTOBACILLUS MONILIFORMIS (RAT BITE FEVER)

Rat bite fever is acquired from rodents and is characterized by fever, polyarthralgia, and a rash³⁸ (Ch. 61). Treatment is with intravenous penicillin G 4 million units every 4 h; therapy can be switched to oral amoxicillin 1 g every 8 h for total treatment course of 14 days. Doxycycline, erythromycin and chloramphenicol are alternatives in the penicillin-allergic patient³⁷ (Tables 49.6 and 49.9).

PASTEURELLA MULTOCIDA

Pasteurella multocida infection typically follows an animal bite (Ch. 61); *P. multocida* can be isolated from the upper respiratory tract of healthy dogs, cats, rats and mice. Treatment of choice is intravenous penicillin G 2–4 million units every 4 h or oral penicillin V 500–750 mg every 6 h (Table 49.4). For the penicillin-allergic patient, amoxicillin, doxycycline, chloramphenicol and trimethoprim–sulfamethoxazole (Table 49.9) are alternatives. Fourth-generation cephalosporins are also effective (Table 49.5); alternatively, oral clindamycin 150–300 mg every 6 h plus a fluoroquinolone may be effective (Table 49.8).

VIBRIO VULNIFICUS

Vibrio vulnificus is the most pathogenic of the *Vibrio* species. The soft-tissue infection and septicemia caused by *V. vulnificus* is fatal 50% of the time (Table 49.7). *V. vulnificus* produces a toxin and lytic enzymes that contribute to its pathogenicity. Gastroenteritis and saltwater wound injuries are common clinical findings. Septicemia following consumption of raw oysters can develop within 24 h.

Treatment of septicemia initially involves fluid replacement for shock followed by treatment with ceftazidime 2 g intravenously every 8 h plus doxycycline 100 mg (intravenously or orally) every 12 h (Tables 49.5 and 49.9). Alternative regimens include cefotaxime 2 g intravenously every 8 h or ciprofloxacin (oral 750 mg every 12 h or intravenous 400 mg every 12 h) (Tables 49.5 and 49.8). Surgical debridement of necrotic lesions is indicated.³⁷

RICKETTSIA RICKETTSII

Rickettsiae are obligate intracellular parasites transmitted to humans by arthropod vectors. The most common rickettsial disease in the USA is Rocky Mountain spotted fever. Others include typhus, trench fever and Q fever. Rocky Mountain spotted fever can range from virtually asymptomatic disease to fulminant, fatal disease.³⁹ The disease begins with abrupt fever, chills, headache, myalgias and arthralgias, followed by a characteristic rash. The rash is a result of diffuse vasculitis that often begins first on the wrist, ankles and forearms, progresses to involve the palms and soles, and then spreads centrally to involve the trunk, arms, thighs and face. The lesions initially appear as blanchable macules and papules, which become hemorrhagic with time. Treatment is with oral or intravenous doxycycline 200 mg every 12 h for 3 days and then 100 mg once daily for 4 days or for 2 days after the temperature returns to normal (Table 49.9). An alternative is oral or intravenous quinolones or chloramphenicol for 7 days or 2 days after the temperature reaches normal.

PARASITES

SCABIES

Scabies is caused by the mite *Sarcoptes scabiei* var. *humanus*. The scabies mite is transmitted by skin-to-skin contact between sexual partners or family members. Infestation is usually bilateral and commonly involves the finger web spaces, wrists, elbows, and genital and axillary folds. Diagnosis is made by identifying the mite, eggs or fecal pellets.

Treatment is permethrin 5% cream, applied to the entire body from the neck down, paying special attention to the commonly infested areas. The cream must be washed off approximately 10 h after application. A second application may be used a week later if necessary. Lindane 1% (discontinued in several countries, but still available in the USA) is equally effective, and since low levels of systemic absorption may occur, central nervous system toxicity has been reported. Permethrin and lindane must not be used on children under 2 years of age. Sulfur 6% in petrolatum, applied nightly for three nights and washed off in the morning, is safe and effective for infants (and pregnant mothers). Symptomatic therapy of pruritus that may persist for weeks after effective therapy

should include oral and topical antihistamines, and low to mid-potency topical steroids.

In serious cases, systemic treatment with ivermectin 18 mg as a single dose may be effective.⁴⁰

PEDICULOSIS (LICE)

Lice are blood-sucking insects. Their bites are painless and a person would be unaware of infestation if it were not for the body's immune system recognizing the foreign saliva and anticoagulant produced by the bite of the insect feeding on the underlying dermis. Head lice (*Pediculus humanus* var. *capitis*) are typically isolated to the scalp. Crab lice or pubic lice (*Phthirus pubis*) are typically sexually transmitted. Body lice (*Pediculus humanus*) are found on people with poor hygiene.

Head lice are treated with synthetic pyrethrins: permethrin 5% shampoo applied to a previously shampooed and rinsed hair and scalp, allowed to set for 10 minutes and then rinsed off with water. Alternatives include synergized pyrethrins applied in a similar manner. A second application of the medication 7–10 days later will kill any surviving eggs or nymphs that were not killed with the first treatment.

Crab lice are treated similarly with either synergized pyrethrins or lindane shampoo. The pubic area and the surrounding abdomen and thighs should be treated, especially if the patient is hairy. All undergarments and linens should be washed in hot water and dried on a high heat dryer cycle.

Body lice should be treated with a single application of permethrin 5% cream, exactly as one would treat scabies. Clothing and bed linens should be discarded or washed thoroughly in hot water.

OTHER INFECTIONS

- **Fungal infections** are discussed in detail in Chapter 60.
- **Mycobacterial infections** are discussed in detail in Chapter 58.

Jeffrey Tessier and W. Michael Scheld

Bacterial meningitis remains an important cause of mortality and morbidity despite the widespread availability of effective antimicrobials.¹ Bacterial meningitis was nearly always a fatal disease in the pre-antimicrobial era. However, following the introduction of penicillin, mortality fell to 15–30%. Today, despite the availability of potent antimicrobials, the overall mortality from bacterial meningitis in adults has not decreased, averaging 25% over the past three decades.² In children, major progress was achieved in the 1990s following the successful implementation of immunization against *Haemophilus influenzae* type b. However, in the neonate bacterial meningitis remains a serious disease; while the incidence has changed little in the past 30 years, the mortality rate has declined in industrialized countries from almost 50% in the 1970s to ~10% in 2001.³ Nevertheless, neurological sequelae remain problematic in spite of improvements in treatment.

BACTERIAL MENINGITIS

Epidemiological data are largely derived from developed countries, in which the most common infecting organisms are *Streptococcus pneumoniae*, *Neisseria meningitidis*, Group B streptococci, *Escherichia coli* and *Listeria monocytogenes*. In contrast, Gram-negative bacilli such as *Klebsiella pneumoniae* and *Pseudomonas aeruginosa* are important but occasional pathogens, both in the context of nosocomial and community-acquired meningitis. In the latter, the elderly and those individuals with chronic diseases such as diabetes mellitus, cirrhosis and malignancy are at risk from Gram-negative meningitis. *Str. pneumoniae* is numerically now the most important cause of community-acquired meningitis; strains resistant to penicillin and cephalosporins are increasingly recognized worldwide and have led to significant changes in management. Despite the widespread use of the conjugated 7-valent pneumococcal vaccine among children in developed countries, the pneumococcus continues to be the most common cause of pediatric bacterial meningitis in these settings, with at least half of the cases caused by serotypes not included in the PCV7 vaccine (especially 19A).⁴

The etiology of bacterial meningitis varies by age and region of the world. One million cases of bacterial meningitis are estimated to occur worldwide; of these, ~200 000 people die annually. Case-fatality rates vary by age and the causative organism, ranging from 3% to 19% in developed countries, and rates of 37–60% have been reported from developing countries.⁵ Up to 54% of survivors are left with disability due to bacterial meningitis, especially following meningitis caused by *Str. pneumoniae* or *Str. suis*. These include deafness, mental retardation and other neurological sequelae.^{6,7}

The etiology of bacterial meningitis has changed substantially since the introduction of conjugate *Haemophilus influenzae* (Hib) vaccine in the early 1990s. In addition, the frequency of neonatal group B streptococcal meningitis has declined in some countries because of the implementation of screening and treatment protocols in obstetric patients.⁸ *Str. pneumoniae* is a well-recognized cause of meningitis following fracture of the skull. Nosocomial cases of bacterial meningitis are commonly associated with neurosurgery and are caused by Gram-positive (coagulase-negative staphylococci, *Staphylococcus aureus*) and Gram-negative bacteria (Enterobacteriaceae, *Ps. aeruginosa*). Mixed infections, sometimes involving anaerobic organisms, are also found (Table 50.1).

Community-acquired bacterial meningitis exhibits seasonal variation. The lowest incidence is in the summer months while pneumococcal infections are most common in the winter and meningococcal infections in the spring. Epidemic meningococcal infections are uncommon in developed countries but still occur in parts of Africa, India and other emerging nations.

PRINCIPLES OF DIAGNOSIS AND TREATMENT

Early diagnosis of bacterial meningitis is essential for successful treatment. The age of the patient is of some value in indicating which of the common bacteria might be responsible. However, the only helpful physical sign is the characteristic

Table 50.1 Recommended empirical antimicrobials for patients with meningitis according to age

Empirical therapy	Frequent pathogens	Recommended antimicrobials			
Patients <3 months	Group B streptococci <i>Escherichia coli</i> <i>Listeria monocytogenes</i>	Cefotaxime 50 mg/kg every 12 h in <1 month age 50 mg/kg every 6 h in >1 month age			<i>plus</i> ampicillin 200 mg/kg per day
Patients 3 months to 50 years	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i>	Ceftriaxone 100 mg/kg per day (children), 2 g every 12 h (adult) or cefotaxime 300 mg/kg per day (children), 2 g every 6 h (adult) <i>plus</i> vancomycin 60 mg/kg per day (children) or 30–45 mg/kg per day (adult)			
Adults over 50 years	<i>Str. pneumoniae</i> <i>L. monocytogenes</i> Gram-negative bacilli	Ceftriaxone cefotaxime ampicillin vancomycin	2 g every 12 h 2 g every 6 h 2 g every 4 h 30–45 mg/kg total daily dose	<i>or</i> <i>plus</i> <i>plus</i>	
Immunocompromised adults	<i>L. monocytogenes</i> <i>Str. pneumoniae</i> Gram-negative bacilli (<i>Pseudomonas aeruginosa</i>)	Ceftazidime cefpipime ampicillin vancomycin	2 g every 8 h 2 g every 8 h 2 g every 4 h 30–45 mg/kg total daily dose	<i>or</i> <i>plus</i> <i>plus</i>	
Head trauma, postneurosurgery patient (adult dosing)	Enteric Gram-negative bacilli, <i>Staphylococci</i> , including <i>Staphylococcus aureus</i> and coagulase-negative staphylococci; <i>Pseudomonas aeruginosa</i>	Ceftazidime cefpipime meropenem vancomycin	1–2 g every 8–12 h 2 g every 8 h 2 g every 8 h 30–45 mg/kg total daily dose	<i>or</i> <i>or</i> <i>plus</i>	

rash found in some patients with severe meningococcal infection. Because of this paucity of clinical evidence, early bacteriological diagnosis is of the utmost importance, and identification of bacteria on a Gram-stained film of cerebrospinal fluid (CSF) should be regarded as a medical emergency. One of the most important factors contributing to delayed diagnosis and therapy is the decision to perform a head CT scan prior to lumbar puncture and therapy (Table 50.2). In patients with papilledema, age >60 years, an immunocompromised state, altered level of consciousness, focal neurological symptoms or a seizure, a CT scan should be obtained;⁹ a lumbar puncture should not be performed immediately due to the risk of herniation. If cranial imaging is deemed necessary, patients should have blood cultures drawn and empirical antimicrobials administered before CT evaluation. Administering 1 or 2 h of antimicrobial therapy before lumbar puncture does not decrease diagnostic sensitivity as long as CSF culture is performed in conjunction with additional CSF analysis and blood culture.¹⁰ A prospective study

of adults with pneumococcal meningitis admitted to an intensive care unit found that a delay in the administration of antimicrobials greater than 3 h from the time of presentation is a major predictor (odds ratio [OR] 14.12, CI 3.93–50.9) of mortality 3 months after diagnosis.¹¹ This and other data support the rapid diagnosis and administration of antimicrobial therapy when bacterial meningitis is suspected.

Other methods to supplement Gram stain and culture are now becoming more widely available. Rapid methods can be used to detect microbial antigens in CSF, blood or urine using specific sera against the common causal pathogens. These methods enable a rapid causal diagnosis to be made in some patients (especially those who have received antimicrobial treatment before lumbar puncture or when no bacteria can be seen in the Gram-stained CSF). Countercurrent immunolectrophoresis and other methods such as enzyme-linked immunosorbent assays have been supplanted by commercially prepared latex agglutination kits which are easy to use and give results in a few minutes, although they vary in their sensitivity

Table 50.2 Guidelines for the role of CT scans and lumbar puncture in suspected intracranial infection

Urgent CT scan indicated, lumbar puncture contraindicated	Urgent CT scan indicated, followed by lumbar puncture if CT satisfactory	Lumbar puncture contraindicated, urgent CT scan may not alter management, antimicrobials should not be delayed
<ol style="list-style-type: none"> Raised intracranial pressure <ol style="list-style-type: none"> focal neurological signs definite papilledema CT findings <ol style="list-style-type: none"> lateral shift of midline structures loss of suprachiasmatic or context of suspected basilar cisterns obliteration of fourth ventricle obliteration of superior cerebellar/quadrigeinal plate cisterns with sparing of ambient cisterns 	<ol style="list-style-type: none"> Altered level of consciousness, confusion, Glasgow Coma Scale <13 Seizures (recent or upon presentation) When abscess suspected in view of ear/sinus or other focus of infection ± a subacute onset Immunocompromised patient Age >60 years Papilledema Focal neurological findings 	Fulminant presentation ± purpuric rash ± coagulopathy ± hypotension

Lumbar puncture must be performed without preceding CT scan in the absence of all of the above.

and specificity.¹² Obtaining a CSF sample for polymerase chain reaction (PCR) assay between 24 and 72 h after admission is now standard practice in many centers and is reported to have increased the diagnostic rate and led to improved management.¹³ For patients treated with antimicrobials prior to lumbar puncture, the CSF culture may remain negative but the PCR may still reveal the causative pathogen. A recent Danish study described the development and use of a multiplex PCR to detect the eight most common pathogens causing meningitis in Denmark (*Str. pneumoniae*, *N. meningitidis*, *Esch. coli*, *L. monocytogenes*, group B streptococci, *Staph. aureus*, HSV-1/2 and VZV).¹⁴ When compared to the ‘gold standard’ of Gram stain microscopy and bacterial culture for the two most common pathogens, *Str. pneumoniae* and *N. meningitidis*, the PCR assay had excellent sensitivity (95% and 100%, respectively) and specificity (99.1% and 99.7%, respectively) while providing an accurate result in less than 1 workday.

No organism can be isolated from the CSF in some cases of purulent meningitis; the proportion varies between 12% and 25% in different series. The major reason for this is the pre-admission administration of an antimicrobial, which reduces the number of positive CSF Gram-stained films and cultures. One large study of pediatric patients with bacterial meningitis found that antimicrobial therapy >12–72 h prior to lumbar puncture was associated with higher CSF glucose levels and lower CSF protein levels, but not with changes in the CSF leukocyte or absolute neutrophil count compared to those receiving no pre-treatment or treatment <12 h prior to the lumbar puncture.¹⁵ The low CSF glucose concentration normally found in pyogenic meningitis tends to persist and in the presence of a predominantly lymphocytic reaction suggests tuberculous meningitis. A variety of studies have investigated the use of various biochemical markers as a means of differentiating between bacterial and viral meningitis; elevated CSF lysozyme, β-glucuronidase, complement C3, factor B

and serum procalcitonin levels have all been advocated as useful diagnostically, but none is used routinely for this purpose pending further data.^{16–19}

PHARMACOKINETIC FACTORS

FACTORS AFFECTING ANTIMICROBIAL PENETRATION INTO CSF

The factors affecting penetration of antimicrobials into CSF include molecular size and configuration, lipophilicity, plasma protein binding, the degree of meningeal inflammation, molecular charge and active efflux from the CSF.²⁰

Numerous studies have focused on the penetration of antimicrobials into CSF, brain tissues and brain abscess pus. Most measurements were performed with lumbar CSF and consist of a single determination in several individuals, either after a single dose or repeated bolus doses. The available data on CSF levels vary greatly from drug to drug (Table 50.3), but it is possible to make a clinical classification (Box 50.1) into four groups:

1. Therapeutic CSF concentrations may be reached by standard dosage and route of administration.
2. A high therapeutic ratio allows adequate CSF concentrations to be achieved by high intravenous or intramuscular doses; the CSF concentration is usually higher when the meninges are inflamed.
3. Drug toxicity precludes an increase in dose, and the CSF concentration may reach therapeutic levels only when meninges are inflamed.
4. Little or no drug is found in the CSF with or without meningitis; intrathecal administration may be needed.

Table 50.3 Penetration of some agents into human CSF in relation to MIC₉₀ for selected meningeal pathogens

Agent	Dose (route/frequency)	Concentration in CSF (mg/L)	CSF:serum ratio (%)	MIC ₉₀ against common meningeal pathogen					
				NM	HI	PSSP	PRSP	EC	PA
Pencillin G	1.5 × 10 ⁵ i.v./M	0.8	8	0.03	1–256	≤0.06	4	NA	NA

Box 50.1 Penetration of antimicrobial agents into CSF**1. Therapeutic CSF concentrations achieved by standard doses and routes of administration**

Chloramphenicol
Sulfonamides
Trimethoprim
Fluoroquinolones
Metronidazole
Doxycycline
Isoniazid
Rifampicin
Pyrazinamide
Ethionamide

2. Therapeutic CSF concentrations achieved by high intravenous or intramuscular doses, especially in meningitis

Penicillins
Cephalosporins

3. Therapeutic CSF concentrations may be achieved by standard doses and routes in meningitis

Clindamycin
Vancomycin
Tetracycline
Erythromycin
Ethambutol

4. Therapeutic CSF concentrations cannot be reliably achieved except where intrathecal route is possible

Aminoglycosides
Polymyxin
Fusidic acid

Logical decisions regarding antimicrobial dosing depend not only on knowledge of drug penetration but also on knowledge of the pharmacokinetic and pharmacodynamic properties of the antimicrobial.

Because of the general limitation in antimicrobial penetration into the CSF, the use of oral antimicrobials is discouraged since the dose and tissue levels tend to be considerably lower than with parenteral agents. An exception can be made for rifampicin (rifampin), given either as a synergistic drug or for eradication of mucosal carriage of *H. influenzae* or *N. meningitidis*.

Because of erratic distribution within the CSF, and failure of antimicrobials injected into lumbar theca to become distributed throughout the ventricular system, intrathecal therapy is discouraged by many physicians as risks outweigh the doubtful therapeutic advantage. There are, nevertheless, some situations in which intrathecal treatment is indicated, when the ventricular route must be used. Doses and preparations for intrathecal injection should be determined carefully.

**CONTRIBUTION OF EXPERIMENTAL STUDIES**

Although much information has been gathered about antimicrobial concentrations in serum and CSF in humans with

meningitis, ethical and practical limitations make it difficult to achieve a full picture of the conditions necessary for successful treatment. Many factors contribute to the poor results of treatment in neonatal meningitis and in Gram-negative bacillary meningitis in older age groups, but recent studies indicate that failure to achieve the appropriate concentration of the correct antimicrobial at relevant sites correlates with poor results. As elsewhere in the body, local foci of infection remain important and, in neonatal meningitis especially, persistent ventriculitis results in treatment failure. General principles apply here: the antimicrobial regimen used must be active and, in this situation, bactericidal against the causal organism at concentrations regularly achieved in CSF. Additional factors related to success or failure have been clarified in experimental animals, especially in a rabbit model of experimental meningitis, in which repeated estimations of bacterial counts and of antimicrobial concentrations can be made. McCracken has shown that, for some agents, the pharmacokinetic factors can be quite similar in the rabbit and the human infant.²¹ McCracken concludes that measurement of the ratio of CSF area under curve to serum area under curve (CSF AUC:serum AUC × 100) after single doses and the mean relative concentrations after 9 h infusions are good predictors for CSF penetration in infants and children. Both in rabbits and in children, best results are achieved if the bactericidal titer of the CSF for the relevant organism is at least 1:8, but the rate of decline in the CSF bacterial population is no greater even if this titer is much exceeded. Measurements of this type, both in experimental animals and in humans, are helpful in the initial evaluation of new putative agents for treating meningitis, but are impractical clinically once pharmacokinetic features of the drug have been well established.

SPECIFIC FEATURES OF ANTIMICROBIALS COMMONLY USED IN THE TREATMENT OF MENINGITIS
**BENZYL PENICILLIN AND AMPICILLIN**

As a general rule, most β-lactams, including penicillins, ampicillin and amoxicillin, penetrate into the CSF poorly. Their low toxicity, however, enables this disadvantage to be overcome by high systemic dosages which normally require intravenous therapy. Where conditions make this impracticable or hazardous, intramuscular injections can be used but the large injection volumes are painful. CSF concentrations appropriate for the treatment of penicillin-susceptible meningoococcal or pneumococcal meningitis can be achieved with a dosage of 150 mg/kg (250 000 units/kg) daily divided into 4-hourly intravenous doses.²² The same general points apply to ampicillin and its congeners. The range of doses in controlled trials has varied from 150 to 400 mg/kg per day. The highest doses are unnecessary, and a standard dose of 200 mg/kg per day is

recommended. Notably, none of the oral forms of penicillin or ampicillin is suitable for treating meningitis. CSF penetration diminishes even further as meningeal inflammation begins to resolve. The short half-lives of these compounds make it unwise to prolong the dose interval beyond 4–6 h.

Neurological toxicity from penicillin presents a danger only when excessively high blood or CSF concentrations are reached. This sometimes occurs when very large doses are given intravenously in the presence of renal failure, but was especially associated with incorrectly high intrathecal dosage at a time when this form of administration was commonly used.

CEPHALOSPORINS

The extended-spectrum cephalosporins (cefotaxime, ceftriaxone and cefepime) are characterized by excellent antibacterial activity against common meningitis-causing bacteria, and are currently the drugs of choice for the empirical therapy of bacterial meningitis. Cephalosporins, like other antimicrobials, are not known to be metabolized in the CSF; thus, their concentrations in CSF depend on the balance between penetration and elimination. In most clinical trials, the penetration of cephalosporins through the blood-brain barrier is expressed as the ratio of CSF to blood concentration at a particular time-point (Table 50.3, p. 635). Because of the slow entry of cephalosporins secondary to low lipophilicity, their concentration-time curves in CSF lag behind those in blood.²³ Furthermore, the most important determinant predicting efficacy in meningitis is the relationship between the antimicrobial concentration in CSF and the minimum bactericidal concentration (MBC) of the common organisms causing meningitis. The wide variability and occasional low CSF concentrations are worth noting because higher dosages are well tolerated and therapeutic concentrations in the CSF can still be achieved. Goldwater measured the concentration of ceftriaxone or cefotaxime in the CSF of children with bacterial meningitis caused by *Str. pneumoniae*, *H. influenzae* or *N. meningitidis*.²⁴ Though there was significant variability in the CSF concentrations of these antimicrobials, the concentrations exceeded the minimum inhibitory concentrations (MICs) for these organisms by 45- to 8750-fold. During the 1980s many controlled trials evaluated different cephalosporins in treating meningitis. The largest groups studied were children with *H. influenzae* meningitis. In most trials the compound under investigation was compared with ampicillin and chloramphenicol in combination, the prevailing standard of treatment for community-acquired childhood meningitis at the time. These trials gave results generally similar to, but not better than, the standard regimen. Of the many compounds available, cefotaxime and ceftriaxone have been especially well studied.

In addition to clinical comparisons with the standard regimens, many trials included measurements of the rate of decline of bacterial counts in the CSF, and time to negative CSF cultures, which were again generally comparable in the

two groups. In one trial comparing twice-daily ceftriaxone with chloramphenicol and ampicillin, repeat lumbar puncture 10–18 h after the start of treatment showed similar reductions of bacterial counts, but the median bactericidal titer in the CSF was 1:1024 in the ceftriaxone group, compared with 1:4 in the conventional therapy group.²⁵ Ceftriaxone concentrations in the CSF were 3–24% (mean 11.8%) of the serum concentration. These generally good results emboldened investigators to study once-daily ceftriaxone dosing, allowing the possibility of outpatient treatment in patients who were well enough after the initial diagnostic assessment and initiation of treatment. Again, results were satisfactory;²⁶ diarrhea, the main adverse effect, was not severe enough to necessitate a change of treatment. Duration of treatment has also been studied, with Lin et al²⁷ showing that the results with 7 days of ceftriaxone were as good as those after 10 days. Roine et al²⁸ found that 4 days of ceftriaxone therapy proved to be almost as safe as a 7-day course, especially in patients with rapid initial recovery from bacterial meningitis.

Cefotaxime has also been studied extensively and shown to be effective in the common forms of bacterial meningitis, usually at a dose of 50 mg/kg every 6 h. Cefotaxime may be administered at a dose of 300 mg/kg per day (maximum dose, 24 g per day) in treating resistant pneumococci.²⁹ A large study of 285 children prospectively randomized to receive cefotaxime or meropenem showed similar progress in the two groups.³⁰

The increasing importance of drug resistance in *H. influenzae* infection, and the possible antagonism between ampicillin and chloramphenicol, led Finnish investigators to conduct an important multicenter comparison in 220 children with meningitis (146 with *H. influenzae*) of chloramphenicol, ampicillin (initially with chloramphenicol), cefotaxime or ceftriaxone.³¹ Results were similar in the four treatment groups, but all four bacteriological failures were with chloramphenicol and treatment had to be changed more frequently in this group. Use of ampicillin was limited by the problem of resistance. Results were equivalent between groups receiving either cephalosporin. Cefotaxime has fewer adverse effects, but the cost of both drugs limits their potential in developing countries.

Although cefotaxime and ceftriaxone are the most widely used cephalosporins for meningitis, other β-lactam compounds have also been studied in *Haemophilus* meningitis, including ceftazidime, ceftizoxime and aztreonam – again, usually in comparison with ampicillin and chloramphenicol. Other cephalosporins currently available or under development for clinical use are ceftobiprole, cefpirome, cefepime, cefoselis, cefclidin, cefozopran and cefluprenam. Cefepime is active against a broader spectrum of bacteria than earlier cephalosporins. This cephalosporin penetrates inflamed meninges to produce CSF concentrations ±20% of the serum concentrations.³² This concentration is two- to four-fold greater than that achieved by ceftriaxone or cefotaxime. In 1995, Saez-Llorens et al compared the use of cefepime and cefotaxime in 90 children with bacterial meningitis aged between 2 months and 15 years, randomized to receive cefepime 50 mg/kg every

8 h or cefotaxime 50 mg/kg every 6 h.³³ CSF concentrations of cefepime varied from 55 to 95 times greater than the MIC of the causative pathogens. Clinical response, CSF sterilization, complications and hospital stay were similar for the two treatment regimens, leading to the conclusion that cefepime is safe and therapeutically equivalent.³³ This study has been confirmed by the same group in 345 pediatric patients in two randomized trials that compared cefepime with either ceftriaxone or cefotaxime.³⁴ However, non-convulsive status epilepticus and reversible severe encephalopathy have been observed as unwanted side effects, especially if given in high doses or in patients with renal failure.³⁵

CARBAPENEMS

Carbapenems (meropenem, imipenem–cilastatin, ertapenem and doripenem) have a spectrum of antimicrobial activity that exceeds most other antimicrobial classes, which includes organisms resistant to many other antimicrobials, including other β -lactam agents. The mean CSF concentration of meropenem following a single dose of 40 mg/kg in patients with inflamed meninges who had received dexamethasone (which markedly reduces the CSF concentrations of β -lactam antimicrobials) has been reported to be 3.28 mg/L at 2.5–3.5 h after administration.³⁶

Meropenem has been extensively evaluated in treating bacterial meningitis in children but few studies have been comparative. Schmutzhard et al randomized 56 adults with bacterial meningitis to meropenem ($n = 28$), cefotaxime ($n = 17$) or ceftriaxone ($n = 11$).³⁷ The dose of meropenem was 40 mg/kg, up to a maximum of 2 g, every 8 h. The causative pathogens included meningococci, pneumococci, *Ps. aeruginosa* and *H. influenzae*. All bacterial isolates were eliminated, regardless of the drug used. Among evaluable patients at the end of treatment, all patients on meropenem, 9 of 12 on cefotaxime, and 8 of 10 on ceftriaxone were classified as cured.³⁷ Klugman and Dagan randomized 98 children with bacterial meningitis to meropenem 40 mg/kg every 8 h and 98 children to cefotaxime 75–100 mg/kg every 8 h.³⁸ Two cefotaxime-treated patients died while receiving therapy and one meropenem-treated patient died of trauma 26 days after therapy. None of the deaths was judged to be related to the study drug. In evaluable patients, cure without sequelae was reported in 54 of 75 (72%) patients on meropenem and 52 of 64 (81%) randomized to cefotaxime; 21 patients (28%) on meropenem and 10 on cefotaxime (16%) had neurological and/or audiological sequelae. Seizures after the start of therapy were seen in five patients randomized to meropenem and three given cefotaxime.³⁸ Meropenem would appear to be as effective as cefotaxime for this indication.

Imipenem–cilastatin has been evaluated for the treatment of bacterial meningitis in children.³⁹ Although highly effective at eradicating bacteria from the CSF, 33% of the children developed seizures after administration of this drug. As a consequence, the clinical trial was terminated; neurological

toxicity limits enthusiasm for the use of imipenem–cilastatin in the treatment of bacterial meningitis.

The latest carbapenems, ertapenem and doripenem, have not been evaluated for the treatment of bacterial meningitis. Ertapenem has a significantly longer half-life than the other carbapenems but lacks activity against *Ps. aeruginosa*, while doripenem has an antimicrobial spectrum similar to meropenem.

GLYCOPEPTIDES

Vancomycin is approximately 55% bound to serum proteins. It does not diffuse well into CSF, especially in the absence of inflamed meninges. Therapeutic concentrations can be achieved when higher dosages (15 mg/kg) are administered every 6 h or by continuous infusion.⁴⁰ Animal studies reveal that maximal bacterial killing rate is achieved with C_{max} :MBC ratios of 5:1 to 10:1; any further increases in vancomycin CSF concentration does not increase bacterial killing.⁴¹ Vancomycin in combination with a cephalosporin is recommended to treat pneumococcal meningitis caused by strains with diminished susceptibility to the cephalosporin, especially in children older than 1 month.^{42,43}

Although vancomycin (and teicoplanin) has not been systematically evaluated for the treatment of meningitis caused by methicillin-resistant *Staph. aureus* (MRSA), multiple case reports and series describe its successful use for this disease.^{44,45} While *Staph. aureus* is not a common cause of community-acquired bacterial meningitis, this pathogen must be considered in specific scenarios, such as intravenous drug use, post-neurosurgical patients, and patients at risk for *Staph. aureus* bacteremia (e.g. hemodialysis, long-term intravenous catheters). In these settings, empirical use of vancomycin pending antimicrobial susceptibility testing is warranted.

CHOICES OF EMPIRICAL ANTIMICROBIALS

All adults in whom a diagnosis of bacterial meningitis is suspected should receive antimicrobials as rapidly as possible, even if in the community while awaiting transport to the hospital. There is little published evidence to indicate that the diagnosis is obscured by preadmission antimicrobials. In view of the serious nature of this disease, it is strongly recommended that primary care physicians should give 2 g of ceftriaxone or cefotaxime intravenously without delay upon suspicion of possible bacterial meningitis.

For patients admitted to hospital with suspected bacterial meningitis, empirical antimicrobial therapy is indicated if the lumbar puncture is to be delayed or if the CSF findings are compatible with bacterial meningitis with or without a diagnostic Gram stain. Antimicrobial therapy should be started as soon as possible. Early antimicrobial administration does not hinder microbiological diagnosis when PCR testing is used. The concern that early antimicrobial administration

may aggravate the clinical condition by causing antimicrobial-induced endotoxin release^{46,47} has not been confirmed clinically.⁴⁸ In contrast, delayed antimicrobial therapy will simply result in an increase in bacterial biomass and the damaging effects of a more severe inflammatory response.

Because the CNS is an immunologically defective site, optimal therapy for bacterial meningitis depends on using antimicrobials with bactericidal activity in vivo. Empirical treatment must cover the full spectrum of possible causative pathogens, based on the patient's age, co-morbidities, and whether infection is community or hospital acquired (Table 50.1, p. 634). It is also important to note any history of drug allergy, recent travel, exposure to someone with meningitis, recent infections (especially respiratory and otic), use of antimicrobials, injection drug use, and the presence of a petechial or ecchymotic rash.

Currently a cephalosporin (usually cefotaxime or ceftriaxone) is recommended for the empirical treatment of community-acquired meningitis in adults and children older than 3 months. Empirical therapy for children younger than 3 months of age consists of ampicillin and cefotaxime (in preference to ceftriaxone, which can bind albumin and alter bilirubin metabolism), though often ampicillin plus gentamicin is used in resource-limited settings. Cefotaxime and ceftriaxone have emerged as the β -lactams of choice in the empirical treatment of meningitis in all other age groups. These drugs have potent activity against the major pathogens, with the notable exception of *Listeria*. They are clinically equivalent to, or better than, penicillin and ampicillin owing to their consistent CSF penetration. Their activity also includes most strains of penicillin-resistant *Str. pneumoniae*. Furthermore, synergistic activity has been reported between ceftriaxone and vancomycin in vitro and in experimental meningitis with strains for which the MIC of ceftriaxone was >4 mg/L.⁴⁹⁻⁵¹ These findings have led most authorities to recommend vancomycin and ceftriaxone as empirical therapy for patients with meningitis in areas with a high incidence of cephalosporin-resistant pneumococci.

ROLE OF CORTICOSTEROIDS IN MANAGING (NON-TUBERCULOUS) BACTERIAL MENINGITIS

A variety of host inflammatory factors involved in the complex pathophysiology of bacterial meningitis have been identified that may serve as targets for adjunctive therapy. Dexamethasone has been the most widely evaluated since benefit was observed in experimental bacterial meningitis. Early administration of corticosteroids such as dexamethasone in childhood meningitis, although showing no survival advantage, reduced the incidence of severe neurological complications and deafness in *H. influenzae* infection.⁵² A meta-analysis of five studies in children showed a relative risk of bilateral deafness of 4.1 and of late neurological sequelae of 3.9 in controls compared with children treated with steroids.⁵³ Concerns over the adjunctive use of steroids include gastrointestinal bleeding, secondary fever, difficulties in the clinical assessment of bacteriological cure due to quicker defervescence, and reduced penetration

of antimicrobials through the blood-brain barrier, particularly in penicillin-resistant pneumococcal meningitis.⁵⁴ Children with bacterial meningitis may be in septic shock and the role of steroids in septic shock and viral infections is unclear.⁵⁵ Sterilization of CSF by ampicillin and gentamicin in the presence of steroids also needs clarification. Not much is known about the use of dexamethasone in malnourished patients or those with HIV infection or other serious illness.

In 2002 a prospective, randomized clinical trial of dexamethasone therapy in adults with bacterial meningitis was published.⁵⁶ This trial randomized 301 adults to receive either placebo ($n = 144$) or 10 mg of dexamethasone every 6 h for 4 days ($n = 157$), with the dexamethasone administered before or with the first antimicrobial dose. Approximately one-third of the patients were infected with *Str. pneumoniae*, one-third with *N. meningitidis*, and the remainder with other bacteria or negative CSF cultures. The group receiving dexamethasone had a lower risk of an unfavorable clinical outcome (relative risk [RR] 0.59, CI 0.37–0.94, $p = 0.03$), based on the Glasgow Outcome Scale at 8 weeks, and a reduction in mortality (RR 0.48, CI 0.24–0.96, $p = 0.04$) compared to the placebo group. Subgroup analysis based on causative organism demonstrated particular benefit for those infected with *Str. pneumoniae*.

For pediatric meningitis, the evidence from recent meta-analyses confirms benefit from dexamethasone in *H. influenzae* type b meningitis and efficacy in pneumococcal meningitis only if given early (before or during initial parenteral antimicrobials). The American Academy of Pediatrics recommends that adjunctive therapy with dexamethasone should be considered for infants and children 6 weeks of age and older; the potential benefits and risks must be carefully weighed. An important concern is that the administration of steroids in combination with vancomycin may be disadvantageous. Vancomycin does not penetrate well into non-inflamed CSF and the addition of steroids has been shown to decrease CSF vancomycin concentrations in adults, but this concern may be moot as vancomycin should not be used alone to treat pneumococcal meningitis.⁵⁷ This effect has not been observed in children. Ricard et al measured vancomycin concentrations in the CSF of 14 adult patients with bacterial meningitis (13 with *Str. pneumoniae*, 1 with *N. meningitidis*) who were being treated with dexamethasone 10 mg every 6 h.⁵⁸ The vancomycin was dosed as a continuous infusion of 60 mg/kg per day after a loading dose of 15 mg/kg. The mean serum concentration was 25.2 mg/L with a mean CSF concentration of 7.2 mg/L (~29% of mean serum levels). This mean CSF concentration is above the MBCs for the vast majority of pneumococci, so it appears safe to use steroids during concomitant vancomycin administration with an extended-spectrum cephalosporin.

Two prospective, randomized, double-blind trials examining the use of adjunctive dexamethasone in the treatment of bacterial meningitis were published in 2007, one conducted among 465 adults in sub-Saharan Africa and one among 435 adolescents and adults in Vietnam. In the African study, the majority (90%) of patients were HIV infected. When compared to placebo, dexamethasone had no effect on 40-day mortality, the

main outcome measure of this trial.⁵⁹ Additionally, no difference was observed between dexamethasone- and placebo-treated patients in the secondary outcomes of disability or death, hearing impairment and adverse events. In the Vietnamese study, patients >14 years old with suspected bacterial meningitis were randomized to receive adjunctive dexamethasone or placebo, with the main outcome measures being death at 1 month and the risk of death or disability at 6 months.⁶⁰ Intention-to-treat analysis of all suspected bacterial meningitis cases indicated no difference between the dexamethasone- and placebo-treated groups with respect to death at 1 month or death/disability at 6 months. However, among the randomized patients with confirmed (by CSF culture) bacterial meningitis, dexamethasone significantly reduced the risk of death at 1 month (OR 0.43, 95% CI 0.20–0.94) and death/disability at 6 months (OR 0.56, 95% CI 0.32–0.98) compared to placebo.

A prospective, randomized, double-blind study comparing adjuvant dexamethasone or glycerol with placebo was performed among children (2 months to 16 years) with bacterial meningitis in Latin America.⁶¹ The study included 654 patients infected mainly with *H. influenzae* type b, *Str. pneumoniae* and *N. meningitidis*, and the primary endpoints were death or severe neurological sequelae (as a composite) or deafness. Dexamethasone (0.15 mg/kg every 6 h for 48 h, first dose 15 min prior to

ceftriaxone) was given to 166, glycerol (1.5 g/kg orally every 6 h, first dose 15 min prior to ceftriaxone) to 166, both dexamethasone and glycerol to 159, and placebo to 163. None of the adjuvant therapies affected death or deafness as individual outcomes, but the groups receiving either glycerol (OR 0.31, CI 0.13–0.76, $p = 0.01$) or dexamethasone plus glycerol (OR 0.39, CI 0.17–0.93, $p = 0.033$) had a reduced risk of severe neurological sequelae. Based on this trial, glycerol appears to be a safe adjunct to ceftriaxone therapy in pediatric bacterial meningitis and has the advantage of oral administration in many patients.

Agents other than dexamethasone that are capable of intervening with inflammatory mediators such as nitric oxide synthase inhibitors, peroxynitrite scavengers, endothelin antagonists and matrix metalloproteinase inhibitors are beneficial in experimental bacterial meningitis and await clinical trials in humans.

DURATION OF THERAPY

The duration of antimicrobial therapy in patients with bacterial meningitis has traditionally been 10–14 days for non-meningococcal isolates (Table 50.4). Further information is presented later when each pathogen is discussed.

Table 50.4 Recommended antimicrobial regimens for patients with culture proven meningitis

Organism	Antimicrobial therapy	Dosage in children >1 month age (mg/kg/day), dose interval	Dosage in adults	Duration of treatment (days)
<i>Streptococcus pneumoniae</i> Penicillin MIC <0.1 mg/L Penicillin MIC 0.1–1.0 mg/L	Penicillin G Cefotaxime or ceftriaxone ± vancomycin	300 000–400 000 U ^a every 4–6 h 225–300 mg every 6–8 h 100 mg every 12–24 h 60 mg every 6 h	2.4 g every 4 h 2 g every 6 h 2 g every 12 h 30–45 mg/kg per day in 2–3 divided doses or by continuous infusion	10–14
Penicillin MIC >1.0 mg/L	Cefotaxime or ceftriaxone ± vancomycin	300 mg every 6–8 h 100 mg every 12–24 h 60 mg every 6 h	2 g every 6 h (up to 24 g) 2 g every 12 h 30–45 mg/kg per day in 2–3 divided doses or by continuous infusion	
Ceftriaxone or cefotaxime MIC ≥1.0 mg/L	Cefotaxime or ceftriaxone plus vancomycin ± rifampicin	300 mg every 6–8 h 100 mg every 12–24 h 60 mg every 6 h rifampicin 20 mg every 12 h	2 g every 6 h (up to 24 g) 2 g every 12 h 30–45 mg/kg per day in 2–3 divided doses or by continuous infusion 300–600 mg every 12 h	
<i>Haemophilus influenzae</i> β-lactamase negative β-lactamase positive	Ampicillin Cefotaxime or ceftriaxone	300 mg every 6 h 225–300 mg every 6–8 h 100 mg every 12–24 h	2 g every 4 h 2 g every 6 h 2 g every 12 h	7
<i>Neisseria meningitidis</i>	Penicillin G	300 000–400 000 U ^a every 4–6 h (maximum dose, 12 MU per day)	2.4 g every 4 h	5–7
<i>Listeria monocytogenes</i>	Ampicillin plus aminoglycoside	300 mg every 6 h	2 g every 4 h	14–21
<i>Str. agalactiae</i>	Ampicillin ± aminoglycoside	Depends on aminoglycoside 300 mg every 6 h	Depends on aminoglycoside 2 g every 4 h	14–21
Enterobacteriaceae	Ceftriaxone or cefotaxime ± aminoglycoside	100 mg every 2–24 h 300 mg every 6–8 h	Depends on aminoglycoside 2 g every 12 h 2 g every 4 h	21
<i>Pseudomonas aeruginosa</i>	Ceftazidime (or ceftipime) + aminoglycoside	150 mg every 8 h	Depends on aminoglycoside 2 g every 8 h	21
		Depends on aminoglycoside	Depends on aminoglycoside	

^a300 000–400 000 U penicillin G = 180–240 mg. MU, million units.

PATHOGEN-DIRECTED THERAPY

MENINGOCOCCAL MENINGITIS

Although meningococcal meningitis is a serious illness and meningococcal shock syndrome one of the most rapidly fatal of all infections, the organism itself is easily eliminated by appropriate chemotherapy. The mainstay of treatment is benzylpenicillin, administered as described earlier, though the Infectious Diseases Society of America recommends a third-generation cephalosporin with penicillin as an alternative.⁶² Susceptibility testing is necessary because of the appearance of strains with reduced susceptibility to penicillin. In-vitro testing of 431 isolates of *N. meningitidis* (373 from the USA, 58 non-USA) demonstrated an elevated penicillin MIC ($\geq 0.12 \mu\text{g/mL}$) in 14.3%, though the MIC range for these organisms was ≤ 0.007 to $1 \mu\text{g/mL}$.⁶³ These levels of reduced susceptibility are not clinically important if the correct dosage is used.

Ampicillin is also suitable for meningococcal disease. When the microbial diagnosis of pyogenic meningitis is uncertain, the cephalosporins (discussed above) are fully active against meningococci. Ceftriaxone has the added advantage of eradicating nasopharyngeal carriage (see below) in the index case, which is not true of benzylpenicillin.

In sharp contrast to the situation with many other forms of meningitis, eradication of the organism can be achieved rapidly and prolonged treatment is unnecessary. Treatment is often continued for 7 days, but 5 days suffices to eradicate infection and even shorter treatments have been effective. Viladrich et al⁶⁴ treated 50 patients with meningococcal meningitis with intravenous penicillin for 4 days. Even shorter regimens, such as 2 days of ceftriaxone⁶⁵ or single-dose therapy with a parenteral preparation of long-acting chloramphenicol, have been successful.⁶⁶ A randomized, open-label trial compared a single dose of long-acting oily chloramphenicol (100 mg/kg intramuscularly, up to 3 g) with a single dose of ceftriaxone (100 mg/kg intramuscularly, up to 4 g) in African patients with epidemic meningococcal meningitis.⁶⁷ This trial demonstrated clinical equivalence between these regimens, supporting a role for single-dose ceftriaxone in this resource-limited setting.

If meningococcal disease is suspected, the patient should be given parenteral penicillin or a third-generation cephalosporin and admitted to hospital immediately. All suspected cases should be reported to the relevant public health authority. Although formerly widely used, nasal or throat swabs are no longer routine practice. Chemoprophylaxis should be offered promptly to all household and mouth-kissing contacts, to patients before discharge, and anyone who has had contact with a patient's nasopharyngeal secretions (healthcare workers whose mouth or nose has been directly and heavily exposed to respiratory droplets/secretions from a case of meningococcal disease around the time of hospital admission).⁶⁸ Contacts should be advised about possible early symptoms and of

the persisting risk, even if they have received prophylaxis. In epidemic situations the use of vaccine should be considered, although prevention of epidemics of meningococcal disease in developing countries will be difficult until long-lasting conjugate vaccines capable of interrupting transmission of *N. meningitidis* can be incorporated into routine infant immunization schedules.

Prophylaxis of meningococcal meningitis

Outbreaks of meningococcal meningitis in closed communities, especially military recruits, are well recognized, but spread within family groups may also occur, especially in conditions of overcrowding. Sulfadiazine has been very effective for chemoprophylaxis, but the emergence of sulfonamide-resistant strains has posed a problem and this agent is no longer used for this purpose. Rifampicin is much more effective than penicillin, ampicillin, tetracycline or erythromycin in controlling the carriage of sulfonamide-resistant strains. A number of trials in the early 1970s established the degree of efficacy of rifampicin (85–90%) in immediate reduction of the meningococcal carrier rate, but a substantial proportion of the residual strains isolated in the post-treatment period were rifampicin resistant; it is therefore possible that widespread use of rifampicin will be accompanied by an increase in strains resistant to this drug. The dosage of rifampicin is 600 mg every 12 h for four doses (10 mg/kg every 12 h for four doses for children). Moderate success in controlling meningococcal carriage has also been achieved with minocycline 200 mg followed by 100 mg every 12 h for 5 days. Total clearance of carriers was achieved using a combination of rifampicin and minocycline, but one-third of the patients given both drugs experienced unpleasant side effects. Sequential use of minocycline followed by rifampicin has also been employed. Single-dose oral ciprofloxacin, in a dose of either 500 or 750 mg, has proved notably effective, and is now the preferred agent for adult contacts. Cuevas et al conducted a randomized comparative study of rifampicin and ciprofloxacin for eradicating nasopharyngeal carriage of meningococci.⁶⁹ Ciprofloxacin proved a safe and effective alternative to rifampicin for eradication of meningococcal carriage in adults but remains contraindicated in children. Similarly, 46 persistent carriers were treated with 750 mg in a single oral dose in a placebo-controlled double-blind trial.⁷⁰ 20 of the 22 placebo recipients remained positive, whereas 20 of 23 recipients of active drug showed negative results on swabbing 7 and 21 days later. Adverse drug reactions occur rarely following a single dose of ciprofloxacin but have included hypersensitivity reactions. Single-dose injection treatment with ceftriaxone has also been successful in clearing nasopharyngeal carriage⁷¹ and this is the agent of choice in pregnant contacts. The adult dose is 250 mg as a single intramuscular injection; children under 12 years should receive half this dose. Furthermore, single doses of ofloxacin or azithromycin were found to be 97.2%⁷² and 95%⁷³ effective, respectively, in eradicating carriage of *N. meningitidis*.

Chemoprophylaxis may fail if given too late or given to the wrong person, or because of non-compliance. Rifampicin resistance, although rare, is another cause of failure.⁷⁴ The effect of chemoprophylaxis is further limited because it does not prevent reintroduction of the pathogenic strain from a carrier outside the group, and therefore late secondary cases may occur.

Based on the observation that approximately half of the secondary cases in families develop within 24 h in children under 15 years, the Norwegian health authorities have advised treating these possible co-primary cases with phenoxycephalothin for 1 week. Although this strategy has substantially reduced the number of co-primary fatalities in families, no controlled studies are available and this strategy has not been widely adopted elsewhere.

PNEUMOCOCCAL MENINGITIS

Initially, all *Str. pneumoniae* isolates were exquisitely susceptible to penicillin ($\text{MIC} \leq 0.06 \text{ mg/L}$), and this antimicrobial served as the drug of choice. Today, drug-resistant *Str. pneumoniae* is recognized worldwide. Several reports of treatment failures related to pneumococcal isolates with decreased susceptibility to penicillin were published in the 1970s. In these cases, pneumococci with penicillin MICs between 0.1 and 1.0 mg/L were associated with microbiological and/or clinical treatment failures in patients given penicillin. These cases led to the conclusion that penicillin at routine doses did not result in high enough levels in the CSF (peak $\sim 1.0 \text{ mg/L}$) to reliably treat meningitis caused by intermediately susceptible pneumococcal strains (penicillin MIC 0.1–1.0 mg/L). At that time, ampicillin and chloramphenicol were the standard empirical agents for suspected bacterial meningitis in children. Chloramphenicol was considered an acceptable alternative to complete therapy if a penicillin-resistant *Str. pneumoniae* isolate was recovered, which at that time was still an infrequent occurrence. However, by the early 1990s, as penicillin-resistant pneumococcal isolates became more common throughout the world, treatment failures associated with cefotaxime or ceftriaxone administration for pneumococcal meningitis were reported. Vancomycin has also been used, but the correct drug concentration is difficult to achieve and a number of failures have been recorded. It is suggested that vancomycin be used (in penicillin- and chloramphenicol-resistant pneumococcal meningitis) only when high-dose cephalosporins have failed.⁷⁵ Vancomycin may also have a place in combination with cephalosporins when diminished susceptibility to the cephalosporin has been demonstrated.⁷⁶ Although optimal therapy for infections caused by drug-resistant pneumococci is not known at present, several options are available. Where the majority of isolates remain sensitive to penicillin, this drug can continue to be used, although for empirical therapy ceftriaxone would be a more reliable choice. Where resistance rates are high, it seems prudent to treat all patients with purulent meningitis empirically with vancomycin

combined with either cefotaxime or ceftriaxone while awaiting CSF culture and antimicrobial susceptibility test results. The recommended dose of vancomycin in cases resistant to other drugs is 60 mg/kg per day. Alternative combination regimens for penicillin- and cephalosporin-resistant pneumococcal meningitis include rifampicin with either ceftriaxone or cefotaxime, rifampicin and vancomycin, and vancomycin and chloramphenicol. Both cefepime and meropenem have been evaluated in clinical trials for the treatment of bacterial meningitis. Randomized comparative studies assessed the efficacy of cefepime as empirical monotherapy in the treatment of bacterial meningitis. This drug represents an important therapeutic option for the empirical treatment of bacterial meningitis in children based on the good clinical response and bacteriological eradication rates observed in this study.³⁴ However, no penicillin-resistant pneumococci were identified in the study; the effectiveness of cefepime for treating pneumococcal meningitis due to resistant strains could not be assessed and thus remains unknown.

Although meropenem is an alternative to extended-spectrum cephalosporins, much more experience with the drug is required before it can be reliably recommended as an effective antimicrobial for the treatment of antimicrobial-resistant pneumococcal meningitis.

Daptomycin, a lipopeptide antimicrobial with excellent in-vitro activity against *Str. pneumoniae* (MIC_{90} range $<0.125\text{--}0.5 \text{ mg/L}$), may become a useful agent for the treatment of pneumococcal meningitis.^{77,78} Unlike β -lactams, daptomycin does not lyse pneumococci in experimental animal models of pneumococcal meningitis, despite having bactericidal activity in the CSF.^{79,80} Importantly, daptomycin does not cause release of pneumolysin from dead or dying pneumococci; pneumolysin is a critical virulence factor for pneumococci and has been shown to induce apoptosis in neurons.^{81,82} Daptomycin is more rapidly bactericidal than ceftriaxone in experimental pneumococcal meningitis and retains antimicrobial activity against penicillin- and quinolone-resistant pneumococci.⁸³ A rabbit model of experimental pneumococcal meningitis also demonstrated that a combination of daptomycin and ceftriaxone was more effective than vancomycin plus ceftriaxone after the addition of dexamethasone.⁸⁴ Clinical trials are needed to confirm the efficacy, safety and appropriate dosing of daptomycin in patients with pneumococcal meningitis.

In summary, the initial treatment of suspected pneumococcal meningitis should be altered especially in areas where resistant pneumococci have been encountered. Initial therapy with cefotaxime or ceftriaxone combined with vancomycin is recommended (Table 50.4), with administration of dexamethasone (10 mg every 6 h) before or with the initial antimicrobial agent. Once the results of susceptibility testing are available, modifications of therapy should be made. If the strain is susceptible to penicillin, vancomycin should be discontinued. Vancomycin plus cefotaxime or ceftriaxone should be used only if the organism is either intermediately or highly resistant to both penicillin and the cephalosporins. The addition of rifampicin or substitution of rifampicin for

vancomycin after 24–48 h could be considered if the organism is susceptible to rifampicin or if there is evidence to suggest an inadequate clinical or microbiological response. It is prudent to perform a repeat CSF examination and culture at 24–48 h, until more experience is gained in treating meningitis caused by penicillin-resistant pneumococci.

HAEMOPHILUS MENINGITIS

With the widespread addition of conjugate *H. influenzae* type b vaccine in developed countries, very few cases of meningitis from this organism now occur in childhood. *H. influenzae* meningitis, although very much less common overall, is now encountered more frequently in adults.

The treatment for *Haemophilus* meningitis over the years illustrates the progressive limitation of therapeutic choice that results from the spread of antimicrobial resistance. For many years chloramphenicol was unquestionably the drug of choice: it is bactericidal at concentrations that can readily be achieved in the CSF and is superior to ampicillin in that respect. Ampicillin appeared to be equally effective, and being free from possible hematological toxicity, it became the preferred drug, especially in the USA.

In 1974, the situation changed when resistant strains of *H. influenzae* type b emerged. Resistance of *H. influenzae* is most commonly due to plasmid-mediated β -lactamase production. Ampicillin resistance in *H. influenzae* has increased globally and ranges from 0% to 94%, depending on the geographical area. Resistance to chloramphenicol, though reported in the early 1970s, has remained rare, the incidence being about 0.5%. These changing resistance patterns have led to the widespread use of cephalosporins as initial treatment of *Haemophilus* meningitis. It is important to note that there is no evidence that cephalosporins give better results; the sole reason for their use is the presence of antimicrobial resistance. Treatment with chloramphenicol or ampicillin is entirely appropriate when isolates are susceptible, an especially important consideration in resource-poor countries. Practice in the USA, before ampicillin resistance became common, favored the initial use of chloramphenicol together with high-dose ampicillin. The antagonism between ampicillin (or penicillin) and chloramphenicol makes it likely that this form of combined treatment effectively relies on the chloramphenicol component,⁸⁵ and equivalent results are obtained whether chloramphenicol is used alone or in combination with penicillin.⁸⁶

A number of choices are available when cephalosporins are indicated for the treatment of *Haemophilus* meningitis. In many countries cefotaxime or ceftriaxone is chiefly used but, as indicated, many other extended-spectrum cephalosporins are equally suitable for *Haemophilus* meningitis. The generally low toxicity of β -lactams permits high parenteral dosage and this, together with their high intrinsic activity against common bacterial causes of meningitis, overcomes their poor

CSF penetration. CSF concentrations and CSF:serum ratios for these compounds are summarized in Table 50.3. The wide variability and occasional low concentrations in CSF are worth noting.

Protection of contacts

The risk of child contacts of patients with *Haemophilus* meningitis (and possibly other systemic *Haemophilus* infections) is of a similar order to that experienced by contacts of meningococcal disease. The overall risk is about 0.5% but nearer 2% in household contacts under 5 years of age. The high rate of nasopharyngeal carriage of the organism in contacts suggests the need for chemoprophylaxis. As with meningococcal infections, many agents that are effective in vitro or in vivo are ineffective in reducing nasopharyngeal carriage. Rifampicin, given in a dose of 20 mg/kg once daily for 4 days, has been shown to reduce carriage rates by 90% and the effect persists, to a lesser extent, for several weeks. Resistance to rifampicin has been documented, although most re-isolates are still susceptible. These findings provided the basis for a number of trials, which showed a significant reduction of risk in contacts given rifampicin. The importance of correct dosage emerged clearly; in one study, carriage was reduced by 97% in children given 20 mg/kg of rifampicin but only by 63% in those given half that dose (and by 28% in the placebo group). Current recommendations have been influenced by the success of vaccination against invasive *Haemophilus* disease. Rifampicin chemoprophylaxis is now offered to all contacts in households in which there are any unvaccinated or incompletely vaccinated children less than 4 years old. The index case should also be given rifampicin, because persistent nasopharyngeal carriage may re-emerge after the acute infection has been treated. Chemoprophylaxis is also given to adult and child contacts in preschool age groups if two or more cases of disease have occurred within 120 days.

Chemoprophylaxis does not obviate the need for careful observation of all contacts, because a workable policy for chemoprophylaxis cannot include all those at risk. Rifampicin may fail to eradicate carriage, and the risk of rifampicin resistance is as yet uncertain. Moreover, although the re-colonization rate is reduced, it does still occur. Failure of rifampicin prophylaxis has been reported a number of times. Rifampicin chemoprophylaxis, although marginally effective, will have negligible effect on the total number of patients with invasive *H. influenzae* disease and is much less important than vaccination as a control measure.

STAPHYLOCOCCAL MENINGITIS

Staphylococcus aureus meningitis is usually encountered as a component of a generalized hematogenous infection, commonly in the elderly or in patients with serious underlying disease⁸⁷ such as post-neurosurgical or post-trauma patients

and those with CSF shunts; other underlying conditions include diabetes mellitus, alcoholism, chronic renal failure requiring hemodialysis, injection drug use and malignancies. Other sources of community-acquired *Staph. aureus* meningitis include patients with sinusitis, osteomyelitis and pneumonia. Mortality rates have ranged from 14% to 77% in various series. The course of the illness is difficult to modify, even with appropriate therapy. Vancomycin is a suitable choice pending information from susceptibility tests. Meningitis caused by methicillin-sensitive *Staph. aureus* (MSSA) may be treated with a penicillinase-resistant penicillin (nafcillin, oxacillin, flucloxacillin). Results in the series quoted gave a suggestion that prognosis might be improved by the use of fusidic acid in conjunction with a penicillin. Meningitis due to MRSA should be treated with vancomycin; daptomycin may be an alternative, but linezolid or quinupristin–dalfopristin is not recommended. *Staph. epidermidis* is the most common cause of meningitis in patients with CSF shunts (discussed in detail in Ch. 42).

STREPTOCOCCUS SUIS MENINGITIS

Streptococcus suis meningitis has a strong occupational association with pigs or pork production. Arthritis, endocarditis and other septic manifestations have been reported, and deafness is a common sequel. Importantly, 6–31% of patients infected with *Str. suis* develop skin findings similar to purpura fulminans seen with meningococcemia.⁷ Kay et al, in a review that included 25 of their own cases,⁸⁸ indicated that *Str. suis* is susceptible to penicillin, ampicillin, cephalosporins, trimethoprim–sulfamethoxazole and vancomycin. Although 2–3 weeks' treatment with penicillin or ampicillin is usually satisfactory, relapses sometimes occur and require further treatment.

GRAM-NEGATIVE BACILLARY MENINGITIS

Meningitis caused by organisms such as *Esch. coli*, *Klebsiella* and *Proteus* spp. is mainly encountered in neonates. It has become less unusual in older patients and those with immunosuppression or other conditions such as chronic renal failure. Cephalosporins (notably ceftriaxone and cefotaxime) have revolutionized the approach to their management, with reported recovery rates of 78–94%. Ceftazidime is active in vitro against *Ps. aeruginosa* and has demonstrated clinical efficacy in infected patients. It is recommended that ceftazidime be combined with a parenteral aminoglycoside for the treatment of *Ps. aeruginosa* meningitis. Concomitant intraventricular aminoglycoside therapy should be considered in patients who fail to respond.⁸⁹ Other cephalosporins such as cefepime have been successful in the treatment of patients with Gram-negative enteric bacillary meningitis. However, although the MICs of these drugs for many Gram-negative bacilli found in

meningitis are low and greatly exceeded by attainable serum and CSF concentrations, MICs for some organisms such as *Enterobacter cloacae* and *Acinetobacter baumannii* may be relatively high and treatment may fail for this reason.

The fluoroquinolones (e.g. ciprofloxacin) have also been used to treat these infections but are contraindicated in infants and children because of concerns about cartilage damage. Fluoroquinolones are most useful against multiresistant Gram-negative organisms or when the response to conventional β-lactam therapy is slow.⁹⁰ The fluoroquinolones penetrate well into the CSF, producing CSF:serum ratios of 20–30% for ciprofloxacin and ofloxacin.⁹¹ Hence, they find occasional utility in the treatment of Gram-negative bacillary meningitis, especially for organisms resistant to standard regimens.⁹²

The carbapenems (e.g. meropenem) are logical choices for the treatment of Gram-negative bacterial meningitis, particularly for carbapenem-sensitive strains of extended-spectrum or AmpC β-lactamase-expressing organisms (e.g. *Esch. coli*, *K. pneumoniae*, *Enterobacter* spp.). These agents may also be used to treat meningitis caused by *A. baumannii*, though there has been a worldwide increase in carbapenem-resistant strains of this organism. Very few options exist for the treatment of meningitis caused by broadly resistant strains of *A. baumannii*. A comprehensive review of therapies for *Acinetobacter* meningitis suggested the combination of intravenous meropenem with an aminoglycoside (intrathecal or intraventricular, depending on the presence of ventriculitis) for those isolates susceptible to a carbapenem.⁹³ These authors suggest the use of an intravenous polymyxin (colistin methanesulphonate, polymyxin B) with an aminoglycoside (intrathecal or intraventricular, depending on the presence of ventriculitis) and optional rifampicin. As these infections are commonly nosocomially acquired in the post-neurosurgical setting, removal of all potentially infected hardware is also recommended.

NEONATAL MENINGITIS

Meningitis often complicates neonatal sepsis, and carries both a high mortality and risk of residual neurological damage. The organisms responsible are summarized in Table 50.1. Among these, *Esch. coli* and *Str. agalactiae* (group B streptococcus) predominate. Factors predisposing to neonatal meningitis are low birthweight, a complicated labor and maternal puerperal infection. Other causes include meningomyelocele or other neurological defects. Gram-negative bacilli causing meningitis often demonstrate a varied antimicrobial susceptibility pattern, and prompt laboratory guidance on positive CSF and blood cultures is essential.

Historically, neonatal meningitis was often treated empirically with a penicillin, usually ampicillin, and an aminoglycoside, usually gentamicin, as initial treatment. The poor penetration of aminoglycosides into CSF led to frequent supplementary administration of daily intrathecal injections of gentamicin. The erratic distribution of drug into the ventricular system following administration led to the introduction of

ventricular reservoirs, allowing repeated CSF sampling and drug administration. The achievement of adequate ventricular concentrations of antimicrobial is not merely a theoretical requirement. However, successive trials have also shown that addition of gentamicin by the lumbar intrathecal route to a parenteral regimen of ampicillin and gentamicin does not improve the outlook, and that intraventricular administration carries a substantial risk.

The most appropriate initial regimen, if no organism is seen on Gram stain of the CSF deposit, is a combination of ampicillin and an appropriate cephalosporin, usually cefotaxime or ceftriaxone. If Gram-negative bacilli are seen, the cephalosporin can be used as sole initial agent. The former regimen of ampicillin and gentamicin (or other aminoglycoside) is still widely employed, especially when health budgets are low. However, failure to achieve adequate concentrations in the CSF and increasing resistance among Gram-negative bacilli account for some treatment failures with persistent meningitis.

LISTERIA MONOCYTOGENES

Listeria monocytogenes meningitis is less uncommon than previously thought. When it occurs in the newborn, it appears to result from maternal genital tract infection. It is also encountered in adults and is especially associated with lymphoreticular disease, immune suppression (as in transplant patients), pregnancy, diabetes mellitus and alcoholism.⁹⁴ Some patients have no underlying disease.

Ampicillin or penicillin G should be used as therapy for meningitis caused by *L. monocytogenes*. Many add an aminoglycoside for proven infection due to documented in-vitro synergy, even though a controlled trial comparing ampicillin with ampicillin plus gentamicin has never been performed in humans. Ceftriaxone, cefotaxime and cefepime are inactive against *L. monocytogenes* and should not be used alone as an empirical regimen in neonates or when this organism is considered a likely pathogen.

Trimethoprim-sulfamethoxazole is increasingly used in patients who are allergic to penicillin, despite the in-vitro activity of chloramphenicol against *Listeria*, because the latter drug has an unacceptably high failure rate. Intraventricular vancomycin has been successful in one patient with recurrent *L. monocytogenes* meningitis. Meropenem, which is active in vitro and in experimental animal models of *Listeria* meningitis, may be a further useful alternative.⁹⁵

STREPTOCOCCUS AGALACTIAE

Neonatal infections caused by *Str. agalactiae* (group B streptococcus) have come to prominence in recent years, especially in the USA. Much is now known of their epidemiology and pathogenesis. Two syndromes are seen: an early septic variety

of rapid course and high mortality (50%) closely simulating the respiratory distress syndrome, and a meningitic syndrome developing somewhat later in the neonatal period. Group B streptococcal meningitis carries a high mortality (20%), as do other forms of neonatal meningitis. The median MICs of benzylpenicillin and ampicillin are 0.02 and 0.04 mg/L, respectively, with conventional inocula (10^5 colony forming units), but rise appreciably with larger inocula. Since the CSF may contain 10^6 – 10^8 bacteria/mL, treatment with high doses of penicillin, in excess of 150 mg/kg per day by intravenous injection, is recommended.

In most patients treated with high-dose penicillin or ampicillin alone, the CSF rapidly becomes and remains sterile. In some patients, however, poor response or relapse has been noted. One reason may be failure to eradicate the organisms from focal sites such as the ventricles or cardiac valves; another possibility is infection by a penicillin-tolerant strain, showing a high MBC:MIC ratio. These difficulties, together with the demonstration of synergy in vitro and in animal models between penicillin and aminoglycosides against group B streptococci, suggest the initial use of benzylpenicillin in high dosage with an aminoglycoside. The latter drug may be withdrawn if clinical progress and further laboratory data on the causal organism are satisfactory. Some units, following the recommendation of the American Academy of Pediatrics,⁹⁶ use penicillin or ampicillin as single agents.

Prophylaxis

Acquisition of these organisms by neonates is highly correlated with maternal carriage, although nosocomial transmission acts as an additional source. Attempts to reduce the risk of neonatal group B streptococcal disease are discussed elsewhere (see Ch. 55).

BRAIN ABSCESS

The mortality from brain abscess is high and has changed little in the antimicrobial era. The reasons for this are complex, but particularly important among them is the dangerously rapid rise of intracranial pressure which so often accompanies the development of brain abscess during the early stage of cerebritis. Discussion here is confined to antimicrobial aspects of treatment, but other aspects of management are of crucial importance, notably the control of raised intracranial pressure, and drainage (using stereotactic CT scanning) or excision of the abscess. As in other forms of abscess, bacteria may be found in the abscess contents after many days of systemic chemotherapy. Surgical intervention may not be possible with multiple abscesses, and the advent of modern scanning has increased the frequency of non-surgical treatment if the condition can be recognized early and treatment closely monitored.

The causal organisms differ to some extent in their order of frequency with the origins of the abscess, but several studies

have confirmed the importance of anaerobic Gram-negative bacteria, especially *Bacteroides* and *Fusobacterium* spp., and of aerobic and anaerobic streptococci. Enterobacteria of various genera are also commonly found, and staphylococci are important in infection associated with trauma and in spinal epidural abscess. Several species are often isolated from a single specimen when suitable selective techniques are used, especially in abscesses of middle ear origin. De Louvois et al stressed the strong association of *Bacteroides* spp. with temporal lobe abscess and the general importance of streptococci,⁹⁷ especially streptococci of the *anginosus* group (formerly *Str. milleri*). Streptococci were the most prominent single pathogen in non-temporal lobe abscesses but, as Grace and Drake-Lee point out,⁹⁸ *Bacteroides* spp. may also be found in abscesses of sinus origin. A similar distribution of causal organisms is found in cerebral abscess in childhood, common associations of which are cyanotic congenital heart disease, otitis, sinusitis, head injuries and cystic fibrosis. It has to be remembered that, although the dominant organisms in cerebral abscesses are well documented, other less common agents are sometimes encountered, including species of *Actinomyces*, *Nocardia* and fungi. A recent study utilized 16S ribosomal DNA sequencing to identify the bacteria in pus from patients with brain abscesses in France.⁹⁹ This technique identified a much larger number of bacterial species than culture and confirms that the vast majority of brain abscesses are polymicrobial infections.

An appropriate antimicrobial regimen must take into account not only this diverse flora, but also the characteristics of potentially effective drugs in penetrating brain tissue, CSF and abscess cavities. Data on these aspects may be found in the work of Black et al,¹⁰⁰ Picardi et al,¹⁰¹ De Louvois et al^{97,102} and a report by the British Society for Antimicrobial Chemotherapy.¹⁰³ Microbiological data are occasionally available at the time chemotherapy is started (e.g. when brain abscess is diagnosed during the course of sepsis of known etiology). Generally, however, no such information is available and initial antimicrobial policy must be based on the organisms known to be dominant in the etiology of cerebral abscess (Table 50.5), as described above, bearing in mind that the common forms of brain abscess are polymicrobial. Some

authors recommend variations of regimens based on the different frequency of various species found in cerebral abscess associated with different parameningeal or pulmonary sources. These differences are not big enough to allow this sort of fine tuning; a single-unit policy for brain abscess associated with parameningeal or pulmonary sepsis is preferable.

High-dose ampicillin and penicillin retain an important role as they are effective against streptococci, including the microaerophilic species not susceptible to metronidazole, and against most of the relevant anaerobes. The recognition of anaerobes as an important component of the flora of many brain abscesses led to the use of metronidazole, especially relevant as *Bacteroides fragilis* and perhaps some strains of *Prevotella melaninogenica*¹⁰⁴ are penicillin resistant but susceptible to metronidazole. This has led to the widespread use of metronidazole, together with ampicillin or penicillin (or ceftriaxone or cefotaxime), as agents of first choice. Good results in otogenic abscess were reported by Ingham et al,¹⁰⁵ who found that metronidazole, given orally or intravenously, achieved high concentrations in pus or ventricular fluid. In addition to high-dose ampicillin or penicillin and metronidazole, it is now customary to include a cephalosporin such as cefotaxime, ceftriaxone or ceftazidime in the treatment of patients with intracranial infections. Sjölin et al successfully treated 15 patients with a combination of cefotaxime (3 g every 8 h) and metronidazole (500 mg every 8 h) for a minimum of 3 weeks.¹⁰⁶ There are also a number of other reports of the successful use of cefotaxime to treat patients with brain abscess. Both ceftriaxone and ceftazidime achieve therapeutic concentrations in intracranial pus. However, to date, the numbers of patients treated with these cephalosporins are small.¹⁰⁷ Cerebral abscesses in neonates caused by *Proteus mirabilis*, *Esch. coli* or *Serratia marcescens* have been successfully treated with combinations of cefotaxime and gentamicin or, with an even higher success rate, ceftriaxone and amikacin.¹⁰⁸ Chloramphenicol was formerly widely used but now remains a reserve agent because of toxicity concerns. There is very little information on the efficacy of more recently introduced antimicrobials, such as the carbapenems, in the treatment of brain abscess.

Table 50.5 Initial empirical antimicrobial therapy for patients with brain abscess

Infective source	Intracerebral location	Antimicrobial regimen ^a
Paranasal sinuses	Frontal lobe	Cefotaxime 2 g every 6 h or ceftriaxone 2 g every 12 h and metronidazole 7.5 mg/kg every 6 h
Teeth	Frontal lobe	Penicillin G 2.4 g every 4–6 h and metronidazole 7.5 mg/kg every 6 h
Middle ear (less often, sphenoidal sinuses)	Temporal lobe, cerebellum	Ceftazidime (or cefepime) 2 g every 8 h plus metronidazole 7.5 mg/kg every 6 h
Penetrating trauma	Depends on site of wound	Vancomycin 30–45 mg/kg every 8–12 h plus ceftazidime (or cefepime) 2 g every 8 h plus metronidazole 7.5 mg/kg every 6 h
Metastatic and cryptogenic	Multiple lesions (usually in area supplied by middle cerebral artery)	Depends on source: penicillin G 2.4 g every 6 h plus metronidazole 7.5 mg/kg every 6 h if endocarditis or cyanotic congenital heart disease; ceftriaxone 2 g every 12 h or cefotaxime 2 g every 6 h plus metronidazole 7.5 mg/kg every 6 h

^aAdult daily dosages.

Causal organisms in subdural empyema are generally similar to those in brain abscess and a similar antimicrobial policy may be used. For methicillin-sensitive staphylococcal brain abscess a combination of nafcillin or flucloxacillin (or a similar isoxazolyl penicillin) and fusidic acid is suggested. MRSA is a growing problem globally and has been isolated from brain abscesses in both community and nosocomial settings. The optimal management of MRSA brain abscess is unclear at this time. Vancomycin continues to be the mainstay of antimicrobial therapy for infections caused by MRSA; the role of newer MRSA-active agents such as daptomycin and linezolid remains undefined. Other abscesses of hematogenous origin may require specific chemotherapy different from those recommended for the common types associated with parameningeal sources in the ear or sinuses; these must be tailored to the particular organism.

EPIDURAL ABSCESS

SPINAL EPIDURAL ABSCESS

Spinal epidural abscess is a rare but potentially devastating condition. Many abscesses begin as a focal pyogenic infection involving the vertebral disk or the junction between the disk and the vertebral body (pyogenic infectious diskitis); in such cases the abscesses are often located in the anterior aspect of the spinal canal. However, hematogenous spread was identified in 26% of cases, primarily located in the posterior aspect of the spinal canal. Reihnsaus et al performed a meta-analysis of 915 patients with spinal epidural abscesses, 753 of which were bacterial in nature.¹⁰⁹ Of these bacterial abscesses, *Staph. aureus* accounted for 73%, with the remainder caused by other staphylococcal species, streptococci, Gram-negative pathogens and anaerobes. In children, Auletta and John reviewed the literature over 15 years and confirmed that *Staph. aureus* is the predominant pathogen in spinal epidural abscess and community-acquired MRSA has been recognized in pediatric populations.¹¹⁰ For this reason, empirical therapy should be broad spectrum, including a combination of drugs with bactericidal activity against staphylococci, anaerobes and Gram-negative organisms. The vast majority of spinal epidural abscesses should be drained, either surgically or via image-guided methods, and intraoperative cultures obtained for identification of the causative organism(s). If methicillin-sensitive *Staph. aureus* is isolated, successful treatment is possible with a penicillinase-resistant penicillin, first-generation cephalosporin or vancomycin (in the case of a penicillin-allergic patient). Vancomycin should be used for the treatment of abscesses caused by MRSA as experience is limited with other agents active against this pathogen. Parenteral treatment should be continued for at least 4 weeks and may be prolonged for 8 weeks or longer if vertebral osteomyelitis is suspected. When no pathogen is isolated, broad ‘best-guess’ bactericidal cover is safest and best.

INTRACRANIAL EPIDURAL ABSCESS

Intracranial epidural abscesses are less common than spinal epidural abscesses, and less acute in their evolution. They are usually associated with frontal sinusitis, prior craniotomy or mastoiditis. The morbidity and mortality of intracranial epidural abscesses in isolation are low. However, the great majority of patients have an associated brain abscess (up to 17%), subdural empyema (up to 81%) or meningitis (up to 38%). Treatment usually consists of surgical drainage of the abscess and associated infected sinus in addition to intravenous antimicrobial therapy. Empirical antimicrobial therapy should be chosen based upon the probable infection. The regimens listed above for the treatment of spinal epidural abscesses when the etiology is unknown are also appropriate here.

Viral infections of the central nervous system

Kevin A. Cassady

Viral infections of the central nervous system (CNS) occur infrequently and most often result in relatively benign, self-limited disease. Nevertheless, these infections have tremendous importance because of the potential for death and neurological damage. Neural tissues are exquisitely sensitive to metabolic derangements and injured brain tissue recovers slowly and often incompletely. The diseases discussed in this chapter include viral meningitis, encephalitis and transmissible spongiform encephalopathies (TSEs). The definitions of viral CNS disease are often based on both virus tropism and disease duration. Inflammation occurs at multiple sites within the CNS and accounts for the myriad of clinical descriptors of viral neurological disease. *Aseptic meningitis* is a misnomer frequently used to refer to a benign, self-limited, viral infection causing inflammation of the leptomeninges. *Encephalitis* refers to inflammation of parenchymal brain tissue and is usually accompanied by a depressed level of consciousness, altered cognition and frequently focal neurological signs. Slow progressive neurological deterioration, gliosis, abnormal accumulation of prion proteins in the brain and the lack of CNS inflammation characterize the TSEs. Meningitis and encephalitis represent separate clinical entities; however, a continuum exists between these distinct forms of disease. A change in a patient's clinical condition can reflect disease progression with involvement of different regions in the CNS. Therefore, in many cases, it is difficult to accurately and prospectively predict the etiology and extent of CNS infection. To provide organization for this chapter, viral meningitis and encephalitis will be discussed as discrete entities.

EPIDEMIOLOGY

Acute viral meningitis and meningoencephalitis represent the majority of viral CNS infections and frequently occur in epidemics or in seasonal distribution.^{1,2} The etiology and frequency differ based on geography and immunization practices. Enteroviruses cause an estimated 90% of cases (in countries that immunize against mumps), while arboviruses constitute the majority of the remaining reported cases in the USA.^{1,3-5} Mumps virus is also an important cause of viral CNS disease in countries that do not immunize against this virus. Mumps

infection was the second leading cause of aseptic meningitis, accounting for ~30% of the cases in regions that do not routinely vaccinate against the virus.⁶ A retrospective survey performed in the 1980s found that the annual incidence of 'aseptic meningitis' was approximately 10.9/100 000 persons or at least four times the incidence passively reported to the Centers for Disease Control and Prevention (CDC) during the period.² Virus was identified in only 11% of patients in this study. This low viral isolation rate likely reflects the technological limits of the period, the infrequency with which viral cultures were performed, and the decreased incidence of viral CNS disease resulting from widespread vaccination against mumps and polio viruses. With the advent of improved nucleic acid-based diagnostic methods, these data have changed. Isolation rates now approach 50–86%.^{1,7,8}

Similar to viral meningitis, passive reporting systems underestimate the incidence of viral encephalitis.^{1,2} For example, an estimated 20 000 cases of encephalitis occur each year in the USA; however, the CDC received only 740 (0.3/100 000) to 1340 (0.54/100 000) annual reports of persons with encephalitis from 1990 to 1994.^{1,9} A prospective multicenter study in Finland, a region with a low incidence of arboviral encephalitis, found the incidence of encephalitis to be 10.5/100 000.¹⁰ Although nucleic acid-based diagnostic tests have enhanced the detection of viral pathogens, the tests fail to identify a pathogen in the majority (83%) of cases.^{7,11} While the etiology of encephalitis has changed with alterations in the viral reservoirs in North America, the overall death rates from encephalitis have not changed since the late 1970s and 1980s.¹² Herpes simplex virus (HSV) CNS infections occur without seasonal variation, affect all ages, and constitute the majority of fatal cases of endemic encephalitis in the USA.¹ Arboviruses, a group of over 500 arthropod-transmitted RNA viruses, are the leading cause of encephalitis worldwide.^{1,13,14} Arboviral infections occur in epidemics and show a seasonal predilection, reflecting the prevalence of the transmitting vector. Encephalitis occurs in a minority of persons with arboviral infections, but the case fatality rate varies widely, from 5% to 70%, depending upon viral etiology and age of the patient. Based on passive

reporting to the CDC, neuroinvasive West Nile virus infections now far outnumber other arboviral causes of encephalitis in the USA.¹⁵ It is unknown if this is a function of improved testing and more active surveillance for this disease. Historically, La Crosse encephalitis was the most commonly reported arboviral disease in the USA.^{16,17}

Japanese B encephalitis and rabies constitute the majority of cases of encephalitis outside of North America. Japanese encephalitis virus, a member of the flavivirus genus, occurs throughout Asia and causes epidemics in China despite routine immunization.^{1,18} In warmer locations, the virus occurs endemically.^{1,19} The disease typically affects children, although adults with no history of exposure to the virus are also susceptible.²⁰ The disease has a high case fatality rate and leaves half of the survivors with a significant degree of neurological morbidity.¹ Rabies virus remains endemic around much of the world. Human infections in the USA decreased over the past few decades to 1–3 cases per year due to the immunization of domesticated animals. Bat exposure is increasingly recognized as the source of infection. Fifteen percent (685 of 4470) of bats tested carried the rabies virus in one study analyzing the risk of bat exposure and rabies.²¹ Since 1990, bat-associated variants of the virus have accounted for 24 of the 32 cases recorded. In most cases (22 of 24) there was no evidence of bite; however, in half of the cases direct contact (handling of the bats) was documented.²² In areas outside the USA, human cases of rabies encephalitis number in the thousands and are caused by unvaccinated domestic animals following contact with infected wild animals.

Postinfectious encephalitis, an acute demyelinating process, has also been referred to as acute disseminated encephalomyelitis (ADEM) or autoimmune encephalitis. ADEM accounts for approximately 100–200 additional cases of encephalitis annually in the USA and is associated with antecedent upper respiratory virus (notably influenza virus) and varicella infections.^{1,23} In locations that do not immunize against measles and mumps, ADEM produces approximately one-third of the encephalitis cases and remains associated with the exanthematous viruses.^{1,24} Measles continues to be the leading cause of postinfectious encephalitis worldwide and is estimated to occur in 1 of every 1000 measles infections.²⁰

The slow viral brain infections (TSEs) occur sporadically. Creutzfeldt–Jakob disease (CJD), a prototypical TSE, occurs worldwide with an estimated incidence of 0.5–1.5 cases per million population, with high rates of familial occurrence.²⁵ In 1986, cases of a TSE in cattle, bovine spongiform encephalopathy (BSE), were reported in the UK. In addition to affecting other livestock throughout Europe that were fed supplements containing meat and bone meal, cross-species transmission of BSE has been documented, leading to a ban on the use of bovine offal in fertilizers, pet food or other animal feed.²⁵ A decrease in the recognized cases of BSE has occurred since the institution of these restrictions. Concomitant with increased cases of BSE in Europe, an increase in cases of atypical CJD also occurred, suggesting animal-to-human transmission. The report of atypical CJD (unique clinical and histopathological

findings) affecting young adults (an age at which CJD has rarely been diagnosed) and a characteristic methionine at the polymorphic codon 129 led to the designation of a new disease, new variant Creutzfeldt–Jacob disease (nvCJD). As of 2006, a total of 160 cases of nvCJD were diagnosed in the UK and 28 cases outside of the UK.²⁶

PATHOGENESIS

Viruses use two basic pathways to gain access to the CNS: hematogenous and neuronal spread. Most cases of viral meningitis occur following a high titer secondary viremia. A combination of host and viral factors, combined with seasonal, geographical and epidemiological probabilities, influence the proclivity to develop viral CNS infection. Enteroviral meningitis occurs with greater frequency during the summer and early autumn months, reflecting the seasonal increase in enteroviral infections. Enteroviral infections also exemplify the difference that host physiology plays in determining the extent of viral disease. In children less than 2 weeks of age, enterovirus infections can produce a severe systemic infection, including meningitis or meningoencephalitis.⁵ Ten percent of neonates with systemic enteroviral infections die, while as many as 76% are left with permanent sequelae. In children over 2 weeks of age, however, enteroviral infections are rarely associated with severe disease or significant morbidity.⁵

Viral hematogenous dissemination to the CNS involves initial inoculation, local spread and replication, often in regional lymph nodes (e.g. measles, influenza). The virus then enters the circulatory system (primary viremia), enabling virus to seed distant locations of the body. In rare circumstances, such as disseminated neonatal HSV infection, viruses can infect the CNS during primary viremia; however, most viruses infect an intermediate tissue such as the liver and spleen, replicate and then infect the CNS during a prolonged high titer secondary viremia.^{27,28} The pathophysiology of viral transport from blood to brain and viral endothelial cell tropism is poorly understood. Virus infects endothelial cells, leaks across damaged endothelia, passively channels through endothelium (pinocytosis or colloidal transport) or bridges the endothelium within migrating leukocytes.^{1,29,30}

Historically, the peripheral neural pathway was considered the only pathway of viral neurological infection. Contemporary data, however, demonstrate that the circulatory system provides the principal pathway for most CNS infections in humans.¹⁶ Herpes simplex virus and rabies provide examples of viruses that infect the CNS by neuronal spread. Rabies classically infects by the myoneural route and provides a prototype for peripheral neuronal spread.^{1,31} Rabies virus replicates locally in the soft tissue following a rabid animal bite. After primary replication, the virus enters the peripheral nerve by acetylcholine receptor binding. Once in the muscle the virus buds from the plasma membrane, crosses myoneural spindles or enters across the motor end plate.³¹ The virus travels by anterograde and retrograde

axonal transport to infect neurons in the brainstem and limbic system. Eventually the virus spreads from the diencephalic and hippocampal structure to the remainder of the brain, killing the animal.³¹

Viruses exhibit differences in neurotropism and neurovirulence. For example, reovirus types 1 and 3 produce different CNS diseases in mice based on differences in receptor affinities. Viral hemagglutinin receptors on reovirus type 3 bind to neuronal receptors, enabling fatal encephalitis. Reovirus type 1 has a distinct hemagglutinin antigen and binds to ependymal cells, producing hydrocephalus and ependymitis.¹⁶ Receptor difference is only one determinant of viral neurotropism. For example, enteroviruses with similar receptors produce very different diseases. Five Coxsackie B viruses (B1–B5) readily produce CNS infections, whereas type B6 rarely produces neurological infection.^{32,33} Viral genes have been discovered that influence the neurovirulence of HSV-1.³⁴ Mutant HSV-1 viruses with either γ 134.5 gene deletions or stop codons inserted into the gene have a decreased ability to cause encephalitis and death following intracerebral inoculation in mice as compared to wild-type virus.^{34,35}

In patients with acute encephalitis, the parenchyma exhibits neuronophagia and cells containing viral nucleic acids or antigens.^{20,36} The pathological findings are unique for different viruses and reflect differences in pathogenesis and virulence. For example, in cases of typical HSE, a hemorrhagic necrosis occurs in the inferomedial temporal lobe with evidence of perivascular cuffing, lymphocytic infiltration and neuronophagia.^{1,37} Pathological specimens in animals with rabies encephalitis demonstrate microglial proliferation, perivascular infiltrates and neuronal destruction.

Some viruses do not directly infect the CNS but produce immune system changes that result in parenchymal damage. Patients with postinfectious encephalitis (ADEM) exhibit focal neurological deficits and altered consciousness associated temporally with a recent (1–2 week) viral infection or immunization.²⁴ Pathological specimens, while they show evidence of demyelination by histological or radiographic analysis, do not demonstrate evidence of viral infection in the CNS by culture or antigen tests. Patients with postinfectious encephalitis have subtle differences in their immune system and some authors have proposed an autoimmune reaction as the pathogenic mechanism of disease.^{20,24} Postinfectious encephalitis occurs most commonly following measles, varicella zoster virus (VZV), mumps, influenza and parainfluenza infections. With immunization the incidence of postinfectious encephalitis has decreased in the USA; however, measles continues to be the leading cause of postinfectious encephalitis worldwide.¹⁶

The TSEs are non-inflammatory CNS diseases involving the accumulation of an abnormal form of a normal glycoprotein, the prion protein (PrP).³⁸ These encephalopathies differ in mode of transmission. While most of the TSEs are experimentally transmissible by direct inoculation in the CNS, this mode rarely occurs except for iatrogenic transmission.²⁵ The scrapie agent spreads by contact and lateral transmission.

There is no evidence for lateral transmission in the case of BSE or nvCJD and all cases appear to have occurred following parenteral inoculation or ingestion of affected materials. The transmissible agents remain infectious after treatments that would normally inactivate viruses or nucleic acids (detergent formalin, ionizing radiation, nucleases).³⁸ Most of the experimental work on TSEs has involved analysis of the scrapie agent. The current working model is that post-translational alteration of the normally α -helical form of the prion protein results in a protease resistant β -pleated sheet structure that accumulates in neurons, leading to progressive dysfunction, cell death and subsequent astrogliosis. In studies on the scrapie agent and recently with nvCJD, gastrointestinal tract involvement with infection of abdominal lymph nodes occurs first, followed by hematogenous spread throughout the reticuloendothelial system and brain involvement a year or more later.³⁹ Experimental subcutaneous inoculation in mice and goats also leads to local lymph node involvement, followed by splenic spread and then CNS involvement. Cases of nvCJD by blood transfusion have also occurred.⁴⁰ Based on animal studies, there is an equal distribution of the agent associated with leukocytes and free in the plasma with negligible levels associated with the red blood cells and platelets.⁴¹

DIAGNOSIS

Establishing a diagnosis requires a meticulous history, knowledge of epidemiological factors and a systematic evaluation of possible treatable diseases. In the past, investigators failed 50–75% of the time to identify an etiology for encephalitis depending on the study and diagnostic tests used.^{16,42,43} The techniques for identifying viral CNS infection were invasive and often insensitive as they relied on viral culture.⁴² A CSF pleocytosis usually occurs in encephalitis but is not necessary for the diagnosis. White blood cell counts typically number in the tens to hundreds in viral encephalitis, although higher counts also occur.¹ Cerebrospinal glucose levels are usually normal, although some viral etiologies (Eastern equine encephalitis) produce CSF studies consistent with acute bacterial meningitis.¹ With the advent of PCR, reliable diagnosis has improved the timely management of patients with viral CNS infections. The demonstration of viral nucleic acid in the CSF of patients with symptoms of meningitis or encephalitis has replaced viral culture and serological diagnosis for many CNS infections.^{23,44}

For many viruses – HSV, enterovirus, Epstein–Barr virus (EBV), VZV, JC virus, human herpesvirus-6 (HHV-6) – detection of viral nucleic acids by PCR or reverse transcription PCR (RT-PCR) from the CSF has replaced culture and brain biopsy as the standard for diagnosing encephalitis.^{1,45,46} In the case of herpes simplex encephalitis, CSF PCR has a sensitivity of >95% and a specificity approaching 100%.^{47,48} Investigators are increasingly using these sensitive PCR-based diagnostic techniques to correlate treatment response and predict clinical outcomes.⁴⁸

As with any PCR-based technique, nucleic acid contamination of the laboratory area is a concern and results must always be interpreted within a clinical context. While PCR-based assays exist for many viruses, there are still some for which (notably the arthropod-borne viral infections) universal primers are still being developed.⁴⁹ In other cases (cytomegalovirus, HHV-6) the presence of latent virus or a virus associated with inflammatory cells can produce positive results of unknown significance. Molecular diagnostic techniques have greatly improved the speed, sensitivity and specificity of the diagnosis of enterovirus infections.^{3,7} PCR and other molecular biological assays provide rapid and reliable tests for verifying the etiology of certain types of meningitis and can detect low copy numbers of viral RNA in patients with agammaglobulinemia or hyper IgM syndrome. Enterovirus is the cause of ~90% of aseptic meningitis cases for which a pathogen is detected.⁵ These techniques provide results within 24–36 h and therefore may limit the duration of hospitalization, antibiotic use and excessive diagnostic procedures.^{3,44}

Magnetic resonance imaging (MRI) can provide supportive evidence for encephalitis but is rarely diagnostic alone. The increased sensitivity of MRI to alterations in brain water content and the lack of bone artifacts make this the neuroradiological modality of choice for CNS infections.^{50,51} MRI, and especially diffusion-weighted imaging, detects parenchymal changes earlier than CT scan and better defines the extent of a lesion.⁵² Furthermore, MRI is more sensitive for detecting evidence of demyelinating lesions in the periventricular and deep white matter, thus allowing the differentiation of para-infectious from acute viral encephalitis.

TSEs are currently only diagnosed by histological examination, characteristic electroencephalographic (EEG) changes and the clinical context. The clinical diagnosis of a TSE is supported by detection of characteristic EEG changes (periodic sharp and slow wave complexes), the presence of 14-3-3 protein in the CSF, and characteristic MRI findings (increased signal in the basal ganglia in sporadic CJD [sCJD] or evidence of increased signal in the posterior pulvinar in nvCJD).⁵³ Most laboratory tests are of little value in the diagnosis in humans. CSF examination shows normal values or slightly elevated protein levels. The EEG in classic CJD reveals generalized slowing early in the disease, punctuated by biphasic or triphasic peaks late in the disease with the onset of myoclonus. MRI changes late in the illness reveal global atrophy with a hyperintense signal from the basal ganglia.²⁵ Diffusion-weighted imaging and fluid attenuation inversion recovery (FLAIR) remain the most reliable and sensitive imaging techniques for CJD.^{53,54} Histopathological examination of the brain using a specific antibody to the protease-resistant prion protein (PrP-res) confirms the disease. In addition, evidence of gliosis, neuronal loss and spongiform changes support the diagnosis. In cases of nvCJD, characteristic amyloid plaques (so-called florid plaques) microscopically define the disease. The florid plaques are not seen in other TSEs and consist of flower-like amyloid deposits surrounded by

vacuolar halos. The detection of PrP-res in the tonsillar tissue by immunohistochemical staining is also strongly supportive of nvCJD diagnosis.²⁵

GENERAL THERAPY

The approach to a patient with a presumed CNS viral infection must be tailored to the severity and distribution of neurological involvement. After establishing the degree of CNS disease by history and physical examination, and stabilizing the patient (airway, breathing, circulation), the clinician must next ascertain a diagnosis. With the advent of highly sensitive and less invasive diagnostic techniques (CSF PCR), identification of treatable forms of viral CNS disease (notably HSE) is essential in preventing further CNS damage. Potentially treatable diseases (fungal CNS infections, partially treated bacterial meningitis, tuberculous meningitis, parameningeal infection, mycoplasma, fastidious bacterial infections) can mimic viral CNS disease and should be vigorously investigated before attributing the illness to an untreatable viral etiology. The same logic applies to treatable viral infections and non-infectious etiologies. In the normal host, viral meningitis is a relatively benign self-limited disease and does not usually warrant specific antiviral treatment.⁵⁵ In certain cases (e.g. neonate or agammaglobulinemic patient), therapy may be required. After establishing a presumptive diagnosis and instituting therapy, the clinician must anticipate and treat complications (seizures, syndrome of inappropriate antidiuretic hormone secretion, cerebral edema, cardiac arrhythmias or respiratory arrest from brainstem inflammation). Patients in a coma from encephalitis can recover after long periods of unconsciousness. The physician should limit the amount of iatrogenic damage and vigorously support the patient during the acute phase of the illness.

A limited number of antiviral medications are available to treat CNS infections. Prevention remains the mainstay of therapy. Historically the most frequent cause of viral CNS disease, mumps, has largely been eliminated through vaccination. Live attenuated vaccines against measles, mumps and rubella have resulted in a dramatic decrease in the incidence of encephalitis and postinfectious encephalitis in industrialized countries. Vaccination has also changed the character of previously common viral CNS disease. In 1952, poliomyelitis affected 57 879 Americans. Widespread vaccination has eliminated disease in the Western hemisphere and reduced the incidence worldwide.⁵⁶ Vaccines exist for some arboviral infections. Vaccination against Japanese encephalitis virus has reduced the incidence of encephalitis in Asia; however, in China where 70 million children are immunized for this virus, cases still occur annually.^{57,58}

In order to reduce the potential exposure to TSE agents in the blood supply, the US Food and Drug Administration (FDA) has implemented guidelines eliminating whole blood or blood components prepared from individuals who later

developed CJD or nvCJD. Changes in agricultural practices in Europe and bans on infected cattle have been associated with a decline in cases of nvCJD. In North America no cases of nvCJD have been reported and the Department of Agriculture has programs in place to monitor for TSEs in livestock. Further discussion will be limited to those infections for which therapies exist (HSV-1, HSV-2, VZV, cytomegalovirus, HIV, B-virus and enterovirus infection).

CHEMOTHERAPEUTICS

HSV INFECTION – ENCEPHALITIS

The introduction of aciclovir has resulted in a sharp decline in mortality and morbidity from herpes infections. For example, neonatal mortality from disseminated HSV disease and HSE has declined from 70% to 40% since the development of aciclovir and vidarabine.¹ Aciclovir (9-[2-hydroxyethoxymethyl] guanine) is a nucleoside analog that is selectively phosphorylated by the HSV-1 and HSV-2 thymidine kinase gene product and then incorporated into the viral genome during DNA synthesis, resulting in premature DNA chain termination. The Collaborative Antiviral Study Group randomized controlled trials in the 1980s established that 81% of adults with biopsy-proven HSE who received aciclovir at 10 mg/kg every 8 h for 10–14 days survived and 38% of the aciclovir recipients regained normal neurological function.⁵⁹ Early initiation of antiviral therapy is essential for optimal recovery. Patients with encephalitis lasting longer than 4 days had a worse outcome. For HSE, intravenous administration of aciclovir is the treatment of choice and oral antivirals should not be used.

In cases of neonatal HSV infection, aciclovir dosage, treatment duration and toxicities differ from adult HSE therapy. Encephalitis occurs in 33% of neonates perinatally infected with HSV. Neonates with evidence of CNS dysfunction or cutaneous manifestations of HSV infection should be empirically started on high-dose aciclovir until HSV neurological infection can be excluded. In neonates with localized cutaneous or mucocutaneous disease, intravenous aciclovir 15 mg/kg every 8 h (45 mg/kg per day) for a minimum of 14–21 days is the treatment of choice. Neonates demonstrate a much lower rate of viral clearance than do immunocompromised adults, thus justifying the longer duration of treatment.¹ Higher dose therapy, 20 mg/kg intravenously every 8 h (60 mg/kg per day), is used for neonates with disseminated disease or evidence of neurological involvement. A minimum of 14–21 days of therapy is indicated for the treatment of neonatal HSE. In patients who have evidence of viral DNA in the CSF after a standard course of aciclovir, therapy should be extended until virus is no longer detectable. Studies are currently ongoing evaluating the utility of aciclovir therapy for reactivations and suppressive therapy during the first 6 months of life.^{50,60}

Aciclovir is associated with few adverse effects. In patients receiving large doses of aciclovir by rapid infusion, a dose-related nephrotoxicity from crystal deposition has been reported but is readily reversible with slower infusion times and improved hydration.⁶¹ CNS disturbances (hallucinations, disorientation, tremors) have also been reported with aciclovir therapy.^{62,63} Neutropenia is well documented in children receiving prolonged aciclovir therapy.

HSV INFECTION – MENINGITIS

Although no definitive clinical trials have been conducted, most authors recommend the use of intravenous aciclovir (10 mg/kg every 8 h) for HSV meningitis associated with primary HSV-2 infection, as it decreases the duration of primary herpes disease and may limit meningeal involvement.⁶⁴ Recurrent HSV-2 meningitis occurs rarely and recently a single case of meningitis associated with HSV-1 reactivation was reported. At this time there are no data on the benefit of antiviral treatment or on suppressive therapy for recurrent HSV CNS disease.⁶⁵

VARICELLA ZOSTER VIRUS

Varicella immunoglobulin (VZIG) and aciclovir have reduced the complications from primary VZV infection and herpes zoster in the neonate and immunocompromised patient. VariZIG is no longer produced by the Red Cross but is available under an investigational new drug (IND) protocol through FFF Enterprises. Although controlled trials have not evaluated the efficacy of aciclovir in VZV CNS infections, the medication is routinely used to treat this complication.^{66,67} Varicella can produce cerebral vasculitis, postinfectious encephalitis, ventriculitis, meningitis, and, historically, encephalopathy (Reye's syndrome). Other than postinfectious encephalitis, most of the VZV CNS manifestations are rare and occur most frequently in immunocompromised patients. Empirical therapy using intravenous aciclovir 10–15 mg/kg every 8 h for 10 days, combined with prednisone 60–80 mg for 3–5 days, is recommended for patients with large vessel cerebral vasculitis. Small vessel encephalitis should also be treated with aciclovir 5–10 mg/kg every 8 h for a minimum of 10 days.⁶⁷ Myelitis can complicate acute VZV or zosteriform reactivation, especially in immunocompromised patients, and presents as paraparesis 1–2 weeks after the development of a rash. MRI studies demonstrate significant spinal cord involvement, while the CSF from patients frequently demonstrates an inflammatory infiltrate or increased protein levels. The demonstration of VZV in the CSF by PCR or the demonstration of specific antibodies in the CSF confirms the diagnosis. Aggressive treatment with intravenous aciclovir as described above for small vessel encephalitis can produce clinical improvements.⁶⁸

CONGENITAL CYTOEGALOVIRUS INFECTION

Ganciclovir and foscarnet have been used for the treatment of cytomegalovirus encephalitis, although controlled clinical trials have not confirmed the efficacy of treatment. In the case of congenital cytomegalovirus infection, a multicenter study demonstrated slight protection against hearing loss for a subset of congenitally infected neonates receiving intravenous ganciclovir during the first 6 months of life. The children enrolled in this study were severely affected (CNS calcifications, microcephalic) and were closely monitored for development of hepatitis or neutropenia.⁶⁹ A follow-up randomized controlled trial is evaluating the oral prodrug (valganciclovir) and the effect of duration of therapy (6 months vs 6 weeks) upon neurodevelopmental outcome and hearing in symptomatic congenitally infected infants (D Kimberlin, personal communication).

CERCOPITHECINE HERPES INFECTION (B VIRUS)

B virus is indigenous in old world monkeys (rhesus, cynological and Asian species of the *Macaca* genus) and causes a frequently fatal disease in humans if not treated. Infection has been documented in most cases following direct inoculation (bites), although cases exist following exposure to infected materials (animal bedding) as well as human-to-human spread. In humans bitten by an infected animal, the risk of transmission is low, as the frequency of virus excretion is only 2–3% in infected animals at any given time.⁷⁰ Nonetheless, because of the severity of infection, therapy should be instituted immediately. B virus infection in humans produces a rapid infection with evidence of a vesicular rash and an ascending myelitis in most cases within days and progression within a month.^{71,72} Ultimately, 90% of the documented infected persons progressed to develop encephalomyelitis and 70% died.

Management of potential B virus exposure is controversial but guidelines set up by the 2002 B Virus Working Group provide a framework for post-exposure management. Similar to post-exposure rabies treatment, rapid wound decontamination minutes after the injury is the most important component and the only way of preventing infection. Thorough irrigation for 15 min with water or sterile saline (mucosal surfaces), along with washing with detergent or a povidone-iodine-containing solution (non-mucosal surfaces), is critical in preventing infection.^{71,73} In persons bitten by a known infected or seropositive animal, cultures should be obtained from the animal (buccal mucosa of the biting monkey, urogenital area for urine exposure, swab from the cage for infected bedding). Some authors recommend culturing the patient after thorough cleansing and irrigation have been completed. Even more controversial are the recommendations for instituting prophylactic antiviral therapy. In order to be most effective, antiviral therapy must be initiated before the onset of neurological symptoms;

however, few exposed cases progress to disease. The 2002 B Virus Working Group recommended antiviral prophylaxis based upon the likely risk of virus exposure or infection. The likelihood of infection is influenced by: (1) the type of primate exposure (macaque highest risk); (2) timeliness and adequacy of irrigation and first aid; (3) the type, depth and location of the wound; and (4) the type of infectious materials in cases of indirect exposure. Based on the guidelines from the 2002 B Virus Working Group, prophylaxis should be considered or is recommended except for contact with skin where there is no break in the skin or after exposure to a non-macaque species. For high-risk exposures (infected shedding monkeys, monkeys of unknown B-virus serology, ill macaques or a high titer fluid source) prophylaxis is indicated, especially if the wound was not immediately cleansed/irrigated for 15 min, or if the wound is a deep laceration or puncture. Because the inhibitory concentration of aciclovir for B-virus is ~10-fold higher than that for HSV-1, high-dose prophylaxis should be administered. Because valaciclovir and famciclovir achieve higher antiviral bloodstream concentrations, they are considered superior to aciclovir or penciclovir. While recent in-vitro data suggest that the B virus TK gene has lower affinity for the acyclonucleosides (aciclovir, ganciclovir, 5-bromovinyldeoxyuridine) when compared with penciclovir, in-vitro susceptibility studies showed that inhibition of replication of B virus in cell culture did not consistently correlate with substrate affinity.⁷⁴

The 2002 B Virus Working Group recommended the use of the highly bioavailable prodrug valaciclovir (1 g orally every 8 h) because the prodrug provides higher serum levels of aciclovir and, unlike famciclovir, has been evaluated in in-vivo studies.⁷³ If valaciclovir is unavailable, high-dose aciclovir (varicella dose regimen five times per day) was recommended by the 2002 B Virus Working Group. In-vitro data suggest that famciclovir (500 mg orally every 8 h) could be used for B-virus prophylaxis and has higher affinity for the TK gene; however, in-vivo studies are not currently available.^{71,73,74} If B virus is cultured from the wound culture, from the monkey, or if the bitten worker develops cutaneous or peripheral nervous system signs or symptoms of B-virus infection, immediate hospitalization (with body fluid precautions) is required and intravenous aciclovir or ganciclovir instituted until symptoms resolve and three consecutive culture sets are negative.⁷³ Patients with central neurological signs or symptoms of B-virus infection should receive intravenous ganciclovir 5 mg/kg every 12 h according to the 2002 B Virus Working Group recommendations.⁷³

It is equally important in the management of these patients to obtain acute and convalescent serological studies. In patients with B-virus infection (seroconversion or clinical disease), long-term management is essential. Be aware that antiviral prophylaxis, however, can interfere with humoral response and diagnostic studies. Experts at the CDC should be consulted for more detailed information on this subject. In general, long-term management requires monitoring the patient for evidence of virus shedding and in most instances long-term oral antiviral prophylaxis (minimum of 6 months, although some authors recommend lifelong suppression).

ENTEROVIRUS INFECTION

Currently antibody preparations and an antiviral agent, pleconaril, showed activity against enterovirus in case reports and animal studies. Randomized controlled trials, however, have not supported their use in routine enterovirus meningitis.^{75,76}

RABIES VIRUS INFECTION

Pre- and immediate post-exposure prophylaxis are the only ways known to prevent death in rabies-exposed individuals.³¹ Case reports exist of patients surviving symptomatic rabies without prior vaccination.^{77–82} Other case reports, however, indicate that therapeutic pharmacological coma is not universally effective.^{77,79} Most patients who survive rabies have prior immunity or received post-exposure prophylaxis prior to developing symptoms. Both of the surviving patients in the literature developed neutralizing antibodies in the CSF at or shortly after presentation.⁸³ An investigation is currently underway to evaluate the role of pharmacological coma in rabies after one patient without prior immunity survived after receiving this therapy.

Individuals exposed to rabies require vigorous cleansing of the wound, passive immunization with direct administration of rabies hyperimmunoglobulin at the site of the animal bite, and post-exposure intramuscular vaccination with human diploid cell vaccine or rhesus diploid cell vaccine on the first day of treatment and repeat doses on days 3, 7, 14 and 28 after the initial dose. Individuals with frequent contact with potentially rabid animals (veterinarians, animal control staff, workers in rabies laboratories and travelers to rabies-endemic areas) should receive pre-exposure vaccination.

ADEM/POSTINFECTIOUS ENCEPHALITIS

In cases of postinfectious encephalitis or ADEM, no randomized controlled trial has confirmed the benefit of immunomodulatory drugs. In practice, clinicians often treat ADEM with different immunomodulators (corticosteroids, intravenous immunoglobulin preparations, plasmapheresis) in an attempt to limit immune-mediated destruction of the CNS.^{24,84–86} It must be emphasized, however, that no placebo-controlled studies have been performed and immunomodulatory therapy is based simply on isolated case reports. As with most case reports, clinical failures and iatrogenic morbidity from a therapeutic modality are rarely ever reported.

CONCLUSION

Central nervous system infections must be examined in a geographic, cultural and environmental context as well as at the cellular, molecular and genetic levels. The development of

improved diagnostic and molecular biological studies should improve our understanding of viral pathogenesis and the development of targeted therapeutics for viral CNS infection.

CHAPTER**52**

Bone and joint infections

Werner Zimmerli

The different bone and joint infections vary in regard to pathogenesis, diagnostic investigation and treatment. Whereas acute hematogenous osteomyelitis can generally be treated with antibiotics alone, implant-associated osteomyelitis needs careful surgical debridement combined with long-term antibiotics.¹ The presence of infected implant material requires different treatment principles since bacteria adhere to the foreign surface by forming a biofilm.^{2,3} As most antibiotics have no effect on biofilm bacteria, treatment needs to be for as long as a stable internal fixation is required, or an antibiotic should be used with efficacy on stationary phase and adherent bacteria.^{1,2,4}

In the case of diabetic foot ulcers, it is important to know whether the patient has superficial infection or osteomyelitis. Microbiological diagnosis usually requires the culture of invasive biopsies, due to the poor correlation between superficial cultures and bone cultures.⁵ Septic native arthritis and periprosthetic joint infection are different diseases. Whereas the former generally responds to antibiotics and non-invasive joint lavage, periprosthetic arthritis always needs long-term antibiotics combined with careful debridement, surgery and sometimes even joint replacement.⁶

In studies of antimicrobial therapy of bone and joint infection, results are often presented at the end of treatment without adequate follow-up. In a meta-analysis of 167 studies of antibiotic treatment of different types of bone and joint infection, only 37 were randomized and 22 remained eligible.⁷ In 771 out of 927 patients, a 1-year follow-up was reported. In the eligible patients, an eradication rate of 78.6% (95% CI, 66–94%) was found. There were no differences between comparative antibiotic treatment groups, except for rifampicin (rifampin) in device-associated infection.⁴ Interestingly, standard intravenous therapy and oral fluoroquinolones were equivalent in seven studies published between 1987 and 1999.⁷ These data may be outdated because of increasing resistance; *Staphylococcus aureus* is the most frequent micro-organism in bone and joint infection and treatment with fluoroquinolones alone is compromised by the rapid emergence of resistance during therapy.^{4,8} In summary, the following apply to the analysis of antimicrobial therapy of bone and joint infection: (1) end of treatment analysis is useless; 1-year follow-up is adequate; (2) 2-year follow-up is required in device-associated infection; (3) concomitant adequate surgical management is needed in chronic osteomyelitis and periprosthetic joint infection; and (4) when

analyzing older studies, the current resistance pattern of bone and joint pathogens should be considered.

CLASSIFICATION OF OSTEOMYELITIS

There are several classifications of osteomyelitis that consider pathogenesis, duration of infection, localization, presence or absence of an implant, or anatomic type and local host factors. Cierny and Mader developed a classification system which is especially useful for orthopedic surgeons treating patients with chronic osteomyelitis.⁹ For infection specialists, a more useful approach considers the pathogenesis of bone infection.¹⁰ Hematogenous osteomyelitis bacterial seeding in bone mainly occurs in the metaphysis of long bones of prepubertal children and in the vertebral column of adults.¹¹ Exogenous osteomyelitis spreading from a contiguous source mainly follows thorax surgery (sternum osteomyelitis), bite wounds, deep perforating lesions (mainly on feet), chronic ear, nose and throat infections (sinusitis, otitis media), open bone fractures, joint replacement or internal fixation.¹² Another type of exogenous osteomyelitis results from deep soft-tissue infections mainly in diabetic patients with vascular insufficiency and/or neuropathy.¹³

HEMATOGENOUS OSTEOMYELITIS

Hematogenous infection of the metaphysis of long bones is seen in young children. It is mainly caused by *Staphylococcus aureus*, group-B streptococci and various other streptococci. *Haemophilus influenzae* group b has almost disappeared due to widely used vaccination. The main symptoms are fever, local pain, signs of inflammation and sinus tracts in untreated chronic cases. In cases of unclear bone pain after a bacterial infection, osteomyelitis should be sought.

In adults, hematogenous osteomyelitis mainly involves vertebral bodies. The risk of infection rises with increasing age.¹⁴ In almost 60% of cases, spondylodiskitis is in the lumbar or

lumbosacral region. It is mainly caused by *Staph. aureus* (~50%), Gram-negative bacilli (~25%) and streptococci (~10%).^{14,15} Tuberculous or brucellar spondylitis is still prevalent in endemic regions (e.g. Southern Europe), whereas it has almost disappeared in Central and Northern Europe. The predominant symptoms are fever, backache and local pain in the involved vertebrae. Local signs of infection are generally not present. Severe local pain is a classic sign of spinal epidural abscess; neurological signs have to be looked for and emergency MRI evaluation is required.¹⁶ Diagnosis comprises blood cultures, C-reactive protein and white cell differential counts. Imaging procedures include ^{99m}Tc-methylene diphosphonate (MDP) bone scan, antigranulocyte antibody scan, CT scan and MRI.^{14,17} MRI has the highest sensitivity and specificity. However, it should not be used for monitoring progress because of the low correlation between image improvement and healing.¹⁸

Acute hematogenous osteomyelitis can usually be successfully treated with antibiotics alone. Surgery is mainly

required for diagnostic purposes (open biopsy) if blood cultures remain negative which occurs in 22–70% of cases.^{14,19} In addition, surgery is also needed in patients with spinal epidural abscesses or paravertebral extension (e.g. psoas abscess).

Table 52.1 summarizes the antibiotic treatment according to the micro-organism isolated. The duration of therapy is not standardized; controlled studies are missing. A 6-week course of high-dose antibiotics is generally recommended for acute hematogenous osteomyelitis.^{14,20} Treatment is generally started by the intravenous route. However, oral bactericidal drugs with excellent bioavailability are equally effective and allow early switch to the oral route. β-Lactams should not be commenced by the oral route because of their low bioavailability.

Staphylococcal osteomyelitis can be treated with a combination of quinolones (e.g. levofloxacin 750 mg orally per day) plus rifampicin (300 mg orally every 12 h). In a prospective randomized study in patients with deep-seated or bacteremic staphylococcal infection, the quinolone–rifampicin

Table 52.1 Antibiotic therapy for adults with hematogenous osteomyelitis (excludes patients with implant devices)

Micro-organism	Antimicrobial agent ^a	Dose ^b	Route
<i>Staphylococcus aureus</i> or coagulase-negative staphylococci			
Methicillin-susceptible	(Flu)cloxacillin ^c followed by rifampicin, plus levofloxacin	2 g every 6 h 300 mg every 12 h 750 mg every 24 h	i.v. p.o. p.o.
Methicillin-resistant	Vancomycin* or teicoplanin ^d followed by rifampicin plus levofloxacin or fusidic acid or co-trimoxazole	1 g every 12 h 400 mg (6 mg/kg) every 24 h 300 mg every 12 h 750 mg every 24 h 500 mg every 8 h 960 mg every 8 h	i.v. i.v., i.m. p.o. p.o. p.o. p.o.
<i>Streptococcus</i> spp.	Penicillin G ^e or ceftriaxone for 4 weeks, followed by amoxicillin	5 million U (3g) every 6 h 2 g every 24 h 750–1000 mg every 8 h	i.v. i.v. p.o.
<i>Enterococcus</i> spp. (penicillin-susceptible)	Penicillin G or ampicillin or amoxicillin plus aminoglycoside ^f	5 million U (3g) every 6 h 2 g every 4–6 h	i.v. i.v. i.v.
Enterobacteriaceae (quinolone-susceptible)	Ciprofloxacin	750 mg every 12 h	p.o.
Non-fermenters (e.g. <i>Pseudomonas aeruginosa</i>)	Cefepime or ceftazidime plus aminoglycoside ^f for 2–4 weeks, followed by ciprofloxacin	2 g every 8 h 750 mg every 12 h	i.v. i.v. p.o.
Anaerobes ^g	Clindamycin for 2–4 weeks, followed by clindamycin	600 mg every 6–8 h 300 mg every 6 h	i.v. p.o.
Mixed infections (without methicillin-resistant staphylococci)	piperacillin–tazobactam or imipenem or meropenem for 2–4 weeks, followed by individual regimens according to antimicrobial susceptibility	4.5 g every 8 h 500 mg every 6 h 1 g every 8 h	i.v. i.v. i.v.

*Vancomycin trough level should exceed 15 mg/litre.

^aIn the absence of an implant the total duration of antimicrobial treatment is generally 6 weeks.

^bAll dosages are for adults assuming normal renal function.

^cIn patients with delayed hypersensitivity to penicillins, cefuroxime (1.5 g i.v. every 6–8 h) can be administered. In patients with immediate hypersensitivity to penicillins, vancomycin (1 g i.v. every 12 h) is recommended.

^dTrough blood levels should be monitored regularly during treatment.

^eA loading dose of 800 mg i.v. in one or two doses should be given on day 1. Trough level should exceed 20 mg/litre.

^fAminoglycosides can be administered in a single daily dose.

^gAlternatively, penicillin G (5 million U (3g) i.v. every 6 h) or ceftriaxone (2 g i.v. every 24 h) can be used for Gram-positive anaerobes (e.g. *Propionibacterium acnes*), and metronidazole (500 mg i.v. or p.o. every 8 h) for Gram-negative anaerobes (e.g. *Bacteroides* spp.). i.m., intramuscular, i.v., intravenous, p.o. orally.

^hNote: Formulations of amoxicillin-clavulanic acid differ internationally, therefore dose should be checked.

combination was equivalent to standard intravenous therapy.²¹ Clindamycin has good bioavailability, but is only bacteriostatic against staphylococci. Therefore, it is adequate for long-term therapy of chronic osteomyelitis, and should not be given in acute spondylodiskitis caused by *Staph. aureus*. Nowadays, it is no longer adequate to treat staphylococcal osteomyelitis with a quinolone alone, even with newer fluoroquinolones; because of the risk of emergence of resistance, quinolones should always be combined with rifampicin in the treatment of susceptible staphylococci.²¹

OSTEOSYNTHESIS-ASSOCIATED OSTEOMYELITIS

Infections associated with internal fracture fixation generally occur exogenously as a result of the penetrating trauma (pre-operatively), during insertion of the fixation device (intraoperatively) or during disturbed wound healing (postoperatively).²² The most common micro-organisms causing implant-associated infections are *Staph. aureus* (30%), coagulase-negative staphylococci (22%) and Gram-negative bacilli (10%).²³

Infections after internal fixation are classified as early (<2 weeks), delayed (2–10 weeks) and late onset (>10 weeks).^{22,24} Leading clinical signs of early infection are persistent local pain, erythema, edema, wound healing disturbance, large hematoma and fever. Highly virulent organisms (e.g. *Staph. aureus*, Gram-negative bacilli) are frequent agents of early infections. In cases of wound healing disturbance, necrosis of the wound edges or postoperative hematoma and infection must be actively sought.^{25,26}

Persistent or increasing pain, pseudarthrosis, implant loosening and occasionally development of a sinus tract are hallmarks of delayed infection. However, clinical signs and symptoms of infection may be entirely lacking. Delayed and late infections are mainly caused by micro-organisms of low virulence (e.g. coagulase-negative staphylococci). Alternatively, manifestation of infection due to any micro-organism may be delayed because initial antimicrobial treatment was insufficient for complete microbial eradication. Late infections may be caused by a low inoculum or low virulence micro-organisms introduced during penetrating trauma or perioperatively with an insidious onset of systemic or local symptoms.

A combination of clinical, laboratory, histopathological, microbiological and imaging studies is required to diagnose infection. Blood leukocyte count and differential are neither sufficiently sensitive nor specific to confirm osteomyelitis. Repeated postoperative measurements of C-reactive protein, or a secondary increase after an initial postoperative fall, are highly suggestive of infection. Preoperative aspiration of accumulated fluid and intraoperative tissue cultures provide the most accurate microbiological specimens. At least three intraoperative tissue areas should be sampled. Swabs should be avoided because of low sensitivity. It is important to discontinue any antimicrobial therapy at least 2 weeks before collecting tissue cultures.²⁷ If the implanted material is removed,

the use of sonication to dislodge micro-organisms from the surface of explanted devices has the best sensitivity.²⁸ Imaging lacks sensitivity in early infection, but is useful in delayed and late infections to assess the extent of infection.²⁹

Treatment includes both surgery and antibiotic therapy. The goals of treating infection associated with internal fixation devices are to consolidate the fracture and prevent chronic osteomyelitis. Complete eradication of infection is not the primary goal, since the device can be removed once consolidated. If the implant is stable, debridement with retention of the fracture-fixation device combined with long-term antibiotic treatment is reasonable.⁴ In cases of chronic osteomyelitis associated with a fixation device, surgical therapy should always include both orthopedic and plastic reconstructive surgery.

Antimicrobial therapy should ideally be based on clear microbiological evidence. Suggested antimicrobial treatment according to pathogen and its antimicrobial susceptibility has recently been published^{1,6} and is similar to the recommendations for infection without an implant (Table 52.1). A controlled study in patients with device-associated staphylococcal infection supports initial intravenous treatment for 2 weeks, followed by rifampicin (450 mg orally every 12 h) once there is no more wound secretion. The dose of rifampicin in these patients is higher than in the absence of an implant.^{4,21} The suggested treatment duration is 3 months in cases of device retention, but only 6 weeks if the infected device is removed. Except for quinolone-susceptible Gram-negative bacilli, intravenous treatment should be given initially and followed by oral therapy to complete the treatment course.

FOOT OSTEOMYELITIS

Diabetic foot infection is frequent due to the increasing prevalence of diabetes mellitus. Risk factors are: (1) peripheral motor, sensory and autonomic neuropathy; (2) neuro-osteoarthropathic deformities (Charcot foot); (3) arterial insufficiency; (4) uncontrolled hyperglycemia; (5) patient disabilities, such as reduced vision; and (6) maladaptive patient behaviors.³⁰ Diabetics have a 25% lifetime risk of foot complications. Fifteen percent have a risk of infected foot wounds, of which 20–66% involve bone.

Due to the importance of correct therapy, foot osteomyelitis must be diagnosed as early as possible. Most clinicians now rely on the ‘probe-to-bone’ test which has a positive predictive value of 89% which is comparable to MRI.³¹ With this test, touching bone with a metallic instrument is indicative of osteomyelitis. Lavery et al³² reported a lower positive predictive value of only 62%, because of a lower prevalence of osteomyelitis (20% vs 66%). Thus, probe to bone is an excellent test in patients with high pretest probability. Otherwise, MRI should be performed due to its high sensitivity (80–100%) and specificity (80–90%).³¹

The correlation between cultures from bone biopsy and wound biopsy is poor.³³ Identical pathogens were found in

less than 20%.^{34,35} Therefore, treatment of diabetic foot osteomyelitis should be based either on bone culture or empirically on the most frequent micro-organisms. Treatment according to wound biopsy culture results may be inadequate, since coagulase-negative staphylococci, *Corynebacterium* spp. and Gram-negative bacilli are heavily overestimated.³³

According to newer treatment concepts, wound debridement with a 4- to 6-week antibiotic course should replace early amputation. In a review of 11 studies with 546 patients undergoing debridement and 1–6 months of antibiotics, the median remission rate was 65% (29–88%).³⁶ Thus, in about two-thirds of patients, early amputation can be avoided. If the patient can be treated with antimicrobial agents with excellent bioavailability, there is no need for intravenous therapy. However, there are a few exceptions. Patients with *Staph. aureus* infection should be treated initially with a bactericidal agent such as flucloxacillin (2 g intravenously every 6 h) or ampicillin-sulbactam (3 g intravenously every 8 h – see footnote^h in Table 52.1) in case of mixed infection with anaerobes. After about 2 weeks, this regimen can be switched to oral clindamycin (300 mg every 6 h). Similarly, *Pseudomonas aeruginosa* should be treated with an initial 2-week intravenous course (e.g. ceftazidime 2 g every 8 h or piperacillin-tazobactam 4.5 g every 6–8 h) in order to diminish the bacterial density before starting the only possible oral therapy (ciprofloxacin 750 mg every 12 h). This may avoid the emergence of resistance to ciprofloxacin. Other micro-organisms should be treated according to susceptibility testing of bone cultures (Table 52.1). Oral therapy with linezolid (600 mg every 12 h) can be considered.³⁷ However, this option should be restricted to experienced clinicians alert to the myelotoxicity and neurotoxicity of this agent³⁸.

If no bone biopsy is available, empirical treatment should be given. In treatment of naive patients, clindamycin is a good option (300 mg orally every 6 h) since *Staph. aureus*, streptococci and anaerobes are the most frequent micro-organisms in diabetic osteomyelitis.³³ In pretreated patients, Gram-negative bacilli may be selected. Here a combination of clindamycin plus ciprofloxacin (750 mg orally every 12 h) is preferred.

The Infectious Diseases Society of America (IDSA) guidelines³⁰ recommend the following duration of treatment:

- If the patient requires amputation, a postoperative course of 2–5 days is sufficient.
- If there is residual infected soft tissue, a 2- to 4-week course is suggested.
- In case of residually infected but viable bone, a treatment course of 4–6 weeks is recommended.
- In chronic bone infections in which debridement is not possible, or residual bone sequestration is present, at least 3 months' treatment is required.

SEPTIC ARTHRITIS

Rapid diagnosis and prompt local and systemic therapy are key to a good prognosis in acute arthritis. With purulent arthritis, empirical antimicrobial therapy should be started

immediately. Since surgical and antimicrobial treatment differ in the presence of an artificial joint, periprosthetic joint infections are discussed separately.

Bacterial arthritis is caused by either hematogenous seeding or direct exogenous inoculation. In an analysis of 2407 cases, the most common micro-organisms were *Staph. aureus* (44%), group A streptococci (8%), *Streptococcus pneumoniae* (6%) and *Escherichia coli* (4%).³⁹ In intravenous drug users, *Ps. aeruginosa* and *Candida* spp. are frequent pathogens, while in infants below 2 years *Kingella kingae* are encountered.⁴⁰ *Pasteuralla multocida* or *Capnocytophaga* spp. are commonly found after cat or dog bites, while after human bites (e.g. fist-to-mouth trauma) bacteria from the HACEK group should be considered. Gonococcal arthritis should be suspected after sexual exposure, especially if the patient has oligoarthritis and a macular exanthem.⁴¹ Patients with meningococcal arthritis share the same clinical picture.

Signs and symptoms of acute bacterial arthritis include pain, signs of inflammation (redness, heat) and impaired function due to pain and joint inflammation. The pain is present in the neutral position and increases with movement. In 90% of cases, a single joint is affected, predominantly the knee (45–55%) or the hip (15–25%). Septic arthritis is rare in other joints, but can occur even in syndesmoses (symphysis, sacroiliac and sternoclavicular joints).⁴² Careful history may reveal rare diagnoses such as *Brucella* spp. (travel to Mediterranean region), *Salmonella* spp. (food history), *Pasteurella multocida*, *Capnocytophaga canimorsus* (animal bite), *Neisseria gonorrhoeae* (sexual exposure), *Mycoplasma hominis* (gynecological intervention) and *Ps. aeruginosa* (intravenous drug use).

The most important diagnostic investigations are blood cultures (positive in only 50%) and joint puncture. Leukocyte counts in synovial fluid can differentiate between inflammatory and culture-positive infectious arthritis where they exceed 20 000/ μ L. This value has a sensitivity of >80%;⁴³ however, patients with rheumatoid arthritis or crystal synovitis may also have leukocyte counts above this threshold. The culture is positive in 80–90% of patients with bacterial arthritis. The sensitivity increases by using pediatric blood cultures.⁴⁴ In most cases, imaging is unnecessary in acute septic arthritis. Ultrasound may be useful to detect synovial fluid, and bone scan (or CT scan) in sacroiliac arthritis. CT scan is preferred when concomitant psoas abscess is suspected.

Treatment of septic arthritis includes joint decompression and antibiotic therapy. The aim of local treatment is the elimination of granulocytes and their products (proteases) which can rapidly destroy the joint cartilage. Initial empirical antimicrobial therapy should be guided according to the history (see above). In general, an intravenous cephalosporin such as cefazolin (2 g every 8 h), or cefuroxime (1.5 g every 6–8 h) is appropriate. In the case of staphylococcal infection, therapy can be rapidly switched to an oral fluoroquinolone plus rifampicin²¹ which is equivalent to classic intravenous therapy. This is not the case with oral β -lactams due to the inadequate joint drug concentrations. With fluoroquinolone-resistant strains, rifampicin can be combined with co-trimoxazole or fusidic

acid. The total duration of therapy is 4 weeks.²¹ Pneumococci and other streptococci should be treated with penicillin G for 3–4 weeks. Ceftriaxone is an alternative for outpatient therapy. Arthritis due to Enterobacteriaceae, gonococci or meningococci can be treated with an oral fluoroquinolone, once susceptibility is confirmed. The former needs 4 weeks, the latter 2–3 weeks of therapy.

PERIPROSTHETIC JOINT INFECTION

Periprosthetic joint infections (PJIs) are classified as early (<3 months), delayed (3–24 months) and late (>2 years after surgery).¹ In early infection, typical signs and symptoms include fever, shivering and tachycardia. In addition, local signs of postoperative wound infection such as erythema, warmth, a wet or gaping wound, as well as prolonged wound secretion are suspicious for surgical site infection. Early infections are mainly caused by *Staph. aureus* or Gram-negative bacilli. Delayed or low-grade infection is characterized by subtle or absent signs and symptoms. Persistent pain after implantation indicates inflammation and/or early loosening. This type of infection is mainly caused by low-virulence micro-organisms, such as coagulase-negative staphylococci and *Propionibacterium acnes*. Late infection is caused by hematogenous seeding. Hallmarks are sudden local joint pain due to inflammation or increasing pain due to loosening. The main sources of bacteremia are skin, respiratory tract, dental and urinary tract infection.⁴⁵ However, hematogenous infection can also occur after primary *Staph. aureus* sepsis without a detectable focus.⁴⁶

PJI is confirmed if at least one of the following criteria is present: (1) growth of an identical micro-organism in two or more cultures of synovial fluid or periprosthetic tissue; (2) purulence of synovial fluid or the implant site; (3) presence of granulocytes on histopathological examination of periprosthetic tissue; or (4) presence of a sinus tract communicating with the device.⁴⁷

For diagnosis of PJI, blood leukocyte count and differential are neither sensitive nor specific. C-reactive protein (CRP) is elevated after surgery and returns to normal within weeks;⁴⁸ as such, repeat measurements are more informative than a single value in the postoperative period. Procalcitonin or interleukin-6 are no better than CRP for diagnosing PJI.⁴⁹ Synovial fluid leukocyte count and differential allow differentiation of PJI from aseptic failure. The cut-off value of synovial leukocytes is much lower for diagnosing PJI than septic arthritis in native joints. In patients without inflammatory joint disease and PJI of a knee, a synovial fluid leukocyte count of $>1.7 \times 10^9/L$ and differential of >65% neutrophils has a sensitivity for diagnosing PJI of 94% and 97%, and specificity of 88% and 98%, respectively.⁵⁰ In total hip arthroplasty, the optimal cut-off is at 4.2×10^9 leukocytes/L.⁵¹

The diagnosis of infection by plain radiography includes rapid prosthetic migration, rapidly progressive periprosthetic osteolysis and/or irregular periprosthetic osteolysis.⁵² CT scan

is more sensitive than plain radiography in the imaging of joint space. It allows detection of joint effusion, sinus tracts, soft-tissue abscesses, bone erosion and periprosthetic lucency. The main drawbacks are metallic artifacts reducing image quality. MRI can be used safely in patients with non-ferromagnetic implants and has a better resolution for soft-tissue abnormalities than CT. The main disadvantages of MRI are imaging interferences in the vicinity of metal implants. Bone scintigraphy with ^{99m}Tc has a good sensitivity, but a low specificity to diagnose prosthetic joint infection. Scintigraphy with ^{99m}Tc -labeled monoclonal antibodies demonstrates an accuracy in the detection of prosthetic joint infection of 81%.⁵³ Fluorine-18-fluorodeoxyglucose (FDG) positron emission tomography (PET) has a sensitivity of 91% and a specificity of 87% for detecting PJI.⁵⁴

Superficial wound or sinus tract cultures often yield skin micro-organisms and should be avoided. The yield from synovial fluid culture varies from 45% to 100%. Sensitivity may be improved by inoculation into a pediatric blood culture bottle.⁴⁴ The most reliable specimens for detecting micro-organism(s) are samples from periprosthetic tissue during surgery. At least three intraoperative tissue specimens should be sampled.¹ Swabs have a low sensitivity and should be avoided. It is important to discontinue antimicrobial therapy at least 2 weeks prior tissue sampling for culture.²⁷ Since implant-associated infection involves microbial biofilms, the yield of implant culture may be higher than the one of tissue specimens. Sonication of implants with the appropriate frequency, power density and time improves the yield of positive cultures in patients pretreated with antibiotics.²⁸

In order to reach the goal of successful therapy, namely a long-term, pain-free, functional joint following complete eradication of infection, a combination of an appropriate surgical procedure and antimicrobial treatment acting on adherent bacteria is needed.^{1,2,4,6,55} The cornerstone of successful treatment is early diagnosis; since treatment is less invasive in patients with a short history of infection (see Fig. 52.1). This requires a high degree of suspicion and strict avoidance of empirical antibiotics where the diagnosis is equivocal.

The choice of antimicrobial agents by pathogen and its susceptibility is summarized in Table 52.1.^{1,6} Based on a controlled trial in patients with orthopedic implant-associated infection, 3 months for hip prostheses and 6 months for knee prostheses is suggested.^{1,4} Intravenous treatment should be administered for the first 2 weeks, followed by oral therapy if a drug with good oral bioavailability is available.

The treatment course can be shortened to 6 weeks after explantation, if all foreign material is removed and no spacer is implanted. In this situation, persistence of a device-associated biofilm can be avoided. After 6 weeks of treatment, reimplantation should be delayed a further 2 weeks in order to obtain tissue specimens for culture and to confirm treatment success. After reimplantation, antimicrobial therapy is reinstated. If cultures of intraoperative specimens remain negative, antibiotic treatment is stopped. Otherwise it is continued for 3 and 6 months, respectively.

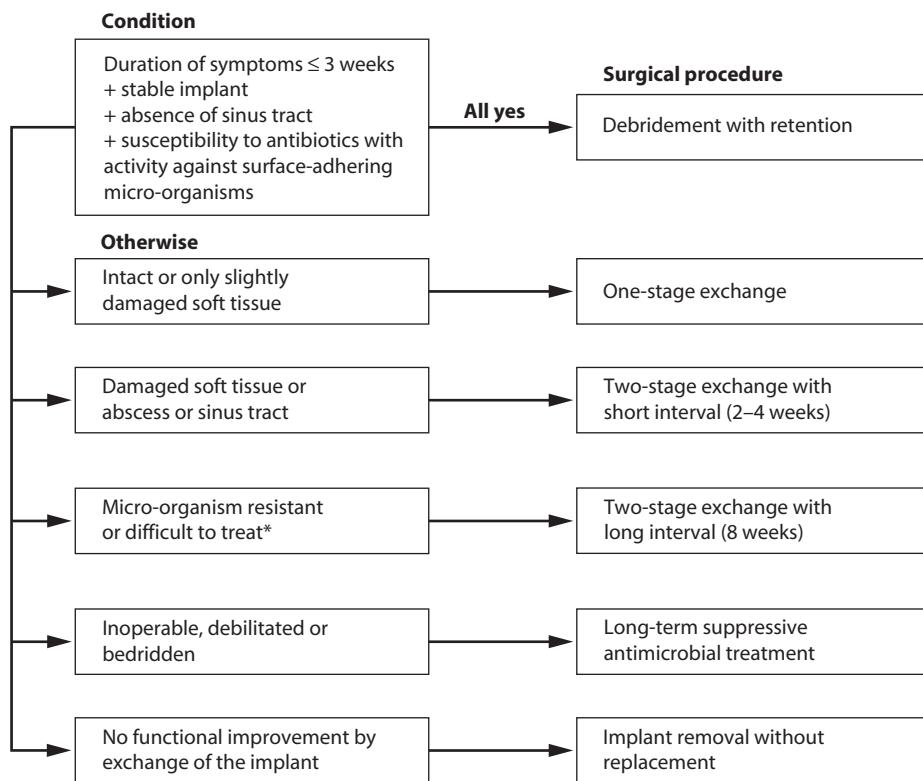

Fig. 52.1 Surgical treatment algorithm for prosthetic joint infections. * Difficult-to-treat micro-organisms include methicillin-resistant *Staph. aureus* (MRSA), small-colony variants of staphylococci,⁶⁸ enterococci, quinolone-resistant *Ps. aeruginosa* and fungi. (Modified from Trampuz A, Zimmerli W. Prosthetic joint infections: update in diagnosis and treatment. *Swiss Med Wkly*. 2005;135:243–251.)

Optimal antimicrobial therapy is best defined in staphylococcal implant infections. Rifampicin combination regimens have excellent activity on susceptible slow-growing and adherent staphylococci.² Rifampicin has proven activity in vitro, in animal models and in several clinical studies.^{1,2,4,56,57} It must always be combined with another drug to prevent emergence of resistance in staphylococci. Quinolones are excellent drugs for combination therapy because of their good bioavailability, activity and safety. Newer quinolones have been studied in experimental bone infections,⁵⁸ but only anecdotal clinical data exist.⁵⁹ Since resistance of staphylococci to quinolones is an increasing problem, other anti-staphylococcal drugs have been combined with rifampicin, such as co-trimoxazole, minocycline, fusidic acid⁶⁰ or linezolid.⁶¹ Linezolid is active against most Gram-positive cocci, including methicillin-resistant staphylococci and vancomycin-resistant enterococci (VRE). However, the success rate in patients with orthopedic infections is modest, with clinical cure rates of 55% and clinical improvement rates of 35%.⁶² Unfortunately, adverse events such as reversible myelosuppression (40%) and irreversible peripheral neuropathy (5%) occur.³⁸ Experimentally, a combination of linezolid with rifampicin is more efficacious.⁶³ Daptomycin is active against several Gram-positive bacteria, including methicillin-resistant *Staph. aureus* (MRSA), vancomycin-resistant *Staph. aureus* and VRE. Its efficacy has been tested in an animal model of implant-associated infections, where it proved better in combination with rifampicin than vancomycin.⁶⁴

In implant-associated infection, antimicrobial treatment without any surgical intervention usually fails. Figure 52.1 provides a treatment algorithm for surgery in PJI.

Debridement with retention has a success rate >80%^{4,65–67} if the patients fulfill the following conditions: (1) stable implant; (2) pathogen with susceptibility to antimicrobial agents active against surface-adhering micro-organisms; (3) absence of a sinus tract or an abscess; and (4) duration of symptoms of infection not more than 3 weeks.

Direct exchange includes the removal and implantation of a new prosthesis during the same surgical procedure. Patients with intact or only slightly compromised soft tissues qualify for this procedure. A success rate of 86–100% can be expected in appropriately selected patients.¹ If resistant or difficult-to-treat micro-organisms are causing the infection, such as MRSA, small-colony variants of staphylococci,⁶⁸ enterococci, quinolone-resistant *Ps. aeruginosa* or fungi, a two-stage revision is preferred. Two-stage exchange includes removal of the prosthesis with implantation of a new prosthesis during a later surgical procedure. In the absence of difficult-to-treat micro-organisms, a short interval until reimplantation (2–4 weeks) and a temporary antimicrobial-impregnated bone cement spacer may be used. If difficult-to-treat micro-organisms are isolated, a longer interval (8 weeks) without a spacer is preferred. The two-stage procedure can be used for every patient and has success rates exceeding 90%.¹ However, the expenditure for the patient and the surgeon is higher than for other surgical options.

Permanent removal of the device is usually reserved for patients with a high risk of reinfection (e.g. severe immunosuppression, active intravenous drug use) or when no functional improvement after reimplantation is expected. Alternatively, long-term antimicrobial suppression may be chosen, if the patient is inoperable, bedridden or debilitated. However, suppressive therapy only controls clinical symptoms rather than curing the infection. Therefore, infection relapses occur in most patients (>80%) when antimicrobials are discontinued.

CONCLUSION

Antimicrobial therapy of bone and joint infection should ideally be based on positive microbiological evidence. As an exception, diabetic foot osteomyelitis may be treated empirically if no debridement surgery is needed. Generally, prolonged treatment courses are required in order to avoid recurrence.

CHAPTER

53 Infections of the eye

David V. Seal, Stephen P. Barrett and Linda Ficker

DEFENSE OF THE OCULAR SURFACE

The commensals of the ocular surface are chiefly Gram-positive bacteria (coagulase-negative staphylococci, diphtheroids and *Propionibacterium acnes*), with occasional Gram-negative bacteria, especially in elderly people. They are found with greater frequency on the lid margin than in the conjunctival sac. *Staphylococcus aureus* colonizes up to 10% of normal lids where it can have both a pathogenic and commensal role; this rate is increased to as much as 70% in atopic individuals.^{1,2}

The cornea and conjunctiva are protected by a tear film with an outer lipid, a middle aqueous and an inner mucin layer. The aqueous layer is of lacrimal origin and contains several antibacterial proteins. Non-specific defense mechanisms in the tears include lysozyme, lactoferrin and the defensins, while specific mechanisms involve IgA antibodies directed against a wide range of organisms. There is cooperation between specific and non-specific mechanisms. At the ocular surface potent antimicrobials (such as lysozyme and IgA) are entrained in the mucus film and maintain an antimicrobial presence in the surface microenvironment. With age, tear secretion and the concentration of protective lacrimal proteins falls. This situation is magnified in the dry eye, including Sjögren's syndrome, where lacrimal secretion is compromised and surface defenses are lowered.

Infection at the ocular surface involves binding of organisms by bacterial ligands or adhesins to specific surface molecules, which initiate the process of invasion. For example, *Pseudomonas aeruginosa* lipopolysaccharide binds to the lectin galectin-3 present on corneal epithelial cells; experimental infection can be inhibited passively by antibodies against either molecule or by active immunization against lipopolysaccharide.

PHARMACOKINETICS

The bulbar conjunctiva and corneal epithelium are relatively impermeable to water-soluble drugs, which penetrate poorly into the anterior chamber. Water-soluble, proprietary

ophthalmic preparations, such as gentamicin sulfate, are available as eye drops or ointments at high concentration (e.g. 0.3%) relative to their effective antimicrobial concentration and are thus active in the treatment of surface ocular infections such as conjunctivitis. In contrast, agents with a relatively high lipid-water solubility (such as the fluoroquinolones, fusidic acid, chloramphenicol and the sulfonamides) readily penetrate the conjunctiva and cornea to enter the tissues of the anterior segment.

If the surface epithelium is breached, as by corneal ulceration, water-soluble drugs can diffuse more readily into the anterior segment in high concentration. This can be enhanced using antibiotic concentrations exceeding those of commercially available preparations (fortified drops). The topical route is unable to produce therapeutic concentrations in the posterior segment of the eye because of diffusion barriers across the lens and zonule and the vitreous. Also, drug is lost from the vitreous and aqueous to the systemic circulation across the iris and retina or by aqueous drainage.

The surface epithelial barrier can be circumvented by delivering a bolus of drug under the conjunctiva (subconjunctival injection) or close to the surface of the globe (sub-Tenon's injection). These periocular routes deliver effective antimicrobial concentrations into the anterior segment of the eye (e.g. cornea and anterior chamber) and, less often, the posterior segment (e.g. the vitreous). Drugs may, however, be injected directly into the vitreous to treat infections of the vitreous and retina and controlled-release devices may be implanted in the scleral wall or suspended in the vitreous to provide long-term drug delivery.

THE BLOOD-OCULAR BARRIERS

In the uninflamed eye, barriers exist to the transfer of antibiotic from the circulation into the eye. A blood-aqueous barrier inhibits the entry of water-soluble drugs across the epithelium of the ciliary body into newly formed aqueous, and a blood-retinal barrier limits the entry of such drugs into the vitreous

humor. Although drugs may reach a high concentration within the choroid via its fenestrated capillaries, diffusion across the outer retina is obstructed by tight junctions between the cells of the retinal pigment epithelium (the outer blood-retinal barrier), and across the retinal capillaries by endothelial tight junctions (the inner blood-retinal barrier).

In addition, anionic drugs (such as penicillins, cephalosporins and quinolones) present in the vitreous are actively transported out of the eye by the iris and ciliary epithelia, the retinal capillary endothelial cells and the retinal pigment epithelium (RPE), giving a half-life of about 8 h for such drugs injected into the vitreous. There is also a passive route for outflow of the drugs, regardless of charge, by forward diffusion into the aqueous.

These barriers affect the potential for drugs to enter the vitreous space after systemic administration, as well as their retention after direct injection into the vitreous. In the uninflamed eye, the highest aqueous concentrations using the systemic route are achieved by lipid-soluble drugs such as chloramphenicol or the fluoroquinolones. Negligible concentrations are achieved using water-soluble drugs, particularly those in anionic form (such as the penicillins and cephalosporins), which are actively transported out of the eye.

In the inflamed eye, breakdown of the blood-ocular barriers allows higher concentrations of antibiotic to be achieved in the ocular compartments following systemic therapy. Effective antimicrobial concentrations may be reached in the aqueous, but concentrations in the vitreous are still too low to provide adequate therapeutic levels, for instance in the treatment of endophthalmitis. Vitreous concentrations after high-dose systemic therapy in such situations will be subtherapeutic (0.5–2 mg/L) and much lower than those achievable by direct injection into the vitreous (up to 1000 mg/L). The latter route is always favored in the treatment of endophthalmitis and reliance should not be made on intravenous therapy alone.

The above barriers (Fig. 53.1) do not exist for other orbital structures. Thus, infections within the orbit or ocular adnexae (the eyelids, lacrimal gland and nasolacrimal system) are readily accessible to systemic antibiotics.

MODES OF DELIVERY OF ANTIBIOTICS TO THE EYE

Some modes of delivery discussed here are outside the specifications of the product license and should be used at the clinician's discretion. Infections of the eye are treated primarily with antimicrobials administered topically, or as local injections, which may be supplemented by the systemic route. This leads to some differences in practice from the treatment of infections in other body sites; for example, resistance to antibacterials has to be assessed in the context of the higher concentrations that can be achieved by local administration, and antimicrobial prophylaxis for procedures such as cataract surgery routinely continues for 7 days postoperatively, in

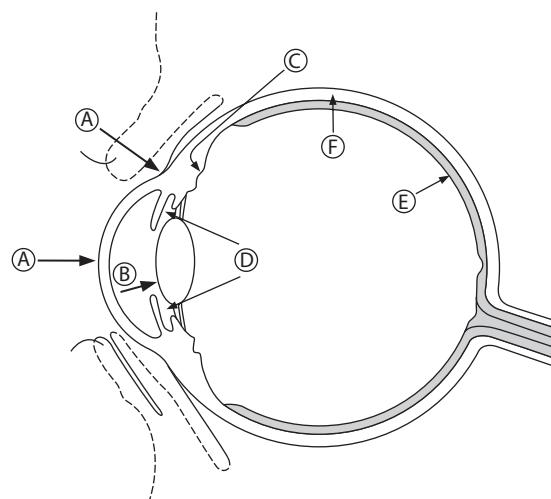

Fig. 53.1 (A) Epithelial barrier (breached by an ulcer; negotiated by topical drops or subconjunctival injection). (B) Aqueous-vitreous barrier. (C) Blood-aqueous barrier limits entry into the aqueous from the blood. (D) Iris pigment epithelial pump removes anions from the aqueous. (E) Blood-retinal barrier; external, pigment-epithelial barrier. (F) Internal, capillary-endothelial barrier. There is an outward pumping of anions across the retina.

contrast to the single preoperative dose that is normal in most branches of surgery.

TOPICAL PREPARATIONS

Drops and ointments are the standard means of administering antibiotics to the surface of the eye, either for prophylaxis or treatment. Ointments (Box 53.1) prolong contact and permit less frequent instillation but should not be mixed with aqueous drops. Prior to the availability of commercial topical quinolone drugs (0.3–0.5%), the preparation of fortified antibiotic eye drops was advocated for the treatment of suppurative keratitis. Their use still has a place. Fortified drops are prepared by combining commercially available parenteral preparations with artificial tear preparations or sterile water to widen the range and concentration of agents used (Table 53.1).^{3–6}

Various studies in the past have tried to increase the concentration of antibiotics in the anterior chamber to levels in excess of minimum inhibitory concentrations (MICs) of common ocular pathogens, either for prophylaxis or for treatment. This can be achieved with systemic dosage of lipophilic antibiotics such as chloramphenicol or Septrin (Bactrim, co-trimoxazole) but both are considered to be too toxic to the bone marrow for routine use in prophylaxis. Azithromycin and clarithromycin given systemically accumulate in the aqueous humor well in excess of MICs of Gram-positive cocci and bacilli but may not have good activity against Gram-negative bacteria. Others have tried to increase diffusion from the corneal surface into the anterior chamber, either by iontophoresis or by removing the corneal epithelium.

Box 53.1 Topical antimicrobial ointments

Antibacterial eye ointments	
Chloramphenicol ^a	1%
Chlortetracycline	1%
Erythromycin	0.5% (not commercially available)
Framycetin	0.5%
Gentamicin	0.3%
Neomycin	0.5%
Rifampicin	2.5% (not commercially available)
Sulfacetamide	2.5–10%
Tetracycline	1%
Antibacterial ointment combinations	
Graneodin:	
Neomycin	0.25%
Gramicidin	0.025%
Polyfax:	
Bacitracin	500 U/g
Polymyxin B	10 000 U/g
Polytrim:	
Trimethoprim	0.5%
Polymyxin B	10 000 U/g
Antiprotozoal eye ointment	
Dibromopropamidine	0.15%

^aThere is no evidence from new studies that topical chloramphenicol use in the eye contributes to bone marrow toxicity.⁴

In studies using aqueous drops of quinolones such as levofloxacin, ofloxacin and ciprofloxacin in humans, these have been given twice to four times preoperatively, sometimes with added oral dosing, but sampling has only taken place at the start of cataract surgery.³ Such studies have produced levels of 0.4–1.6 µg/mL against an expected MIC required to inhibit the growth of 90% of organisms (MIC_{90}) for common ocular pathogens up to 1.0 µg/mL. While the concentration on the ocular surface will be bactericidal, the levels achieved within the anterior chamber will be subinhibitory.

A new technique of pulsed dosing was introduced for the European Society of Cataract and Refractive Surgeons' (ESCRS) prophylaxis study of endophthalmitis following cataract surgery (see p. 682) using levofloxacin 0.5% preserved with benzalkonium chloride. Two drops were given before surgery – 60 and 30 min preoperatively – and three drops postoperatively, once immediately at the end of surgery, then 5 min later and finally 5 min later again. Sampling took place in 30 volunteers at the start of surgery, after the first two doses as for other studies, withdrawing 50 µL of aqueous humor. Volunteers were later sampled at 5, 15, 30, 45, 60 or 90 min, each on one occasion only following the fifth postoperative dose, aspirating separate 50 µL samples with a needle and tuberculin syringe.³ All samples were stored at –20°C and transported on ice to Santen Oy in Finland for high-performance liquid chromatographic analysis of levofloxacin levels.

It was found that pulsed dosing with levofloxacin 0.5%, a quinolone that is water and lipid soluble, increases the concentration in the anterior chamber by 10-fold from 0.4 µg/mL at the

Table 53.1 Selected topical antimicrobial drops: commercially available and fortified extemporaneous preparations

Antibacterial eye drops	Fortified^a preparation	Commercial
Amikacin	25/50 mg/mL	
Bacitracin	50 mg/mL	10 000 U/mL (Not in UK)
Cefuroxime		5 mg/mL
Chloramphenicol ^b		3 mg/mL (0.3%)
Ciprofloxacin		3 mg/mL
Gentamicin	15 mg/mL	10 mg/mL
Fusidic acid gel		10 mg/mL
Levofoxacin ^c		5 mg/mL (0.5%)
Ofloxacin		3 mg/mL (0.3%)
Penicillin G	5000 U/mL (0.3%)	
Piperacillin	50 mg/mL	
Propamidine isethionate		1 mg/mL (1%)

^cUsed for pulse dosing to achieve high levels in the anterior chamber.³

^dAqueous suspension.

^eFor the treatment of *Acanthamoeba* keratitis.^{5,6}

time of surgery (after two doses) to a maximum of 4.4 µg/mL 60 min after the fifth dose (Fig. 53.2).³ This level is four times in excess of the MIC_{90} for common ocular pathogens including *Staph. aureus*, *Streptococcus pneumoniae*, *Ps. aeruginosa* and *Haemophilus influenzae*. At 90 min after the fifth dose, the mean level was still 3.1 µg/mL. The half-life was estimated to be approximately 60 min.³ It can be speculated, but not proven, that repeat dosing at 2-hourly intervals will maintain levels of levofloxacin in the anterior chamber close to 4 µg/mL.

The possible benefits of using this new pulsed dosing regimen are discussed below under refractive surgery and endophthalmitis prophylaxis following cataract surgery (p. 681). The recent introduction of single-dose 0.5 mL containers of unpreserved levofloxacin 0.5% (in the UK, Germany and Nordic countries) is particularly suitable for pulsed dosing at the time of surgery as it removes any possible toxicity of the preservative (benzalkonium chloride).

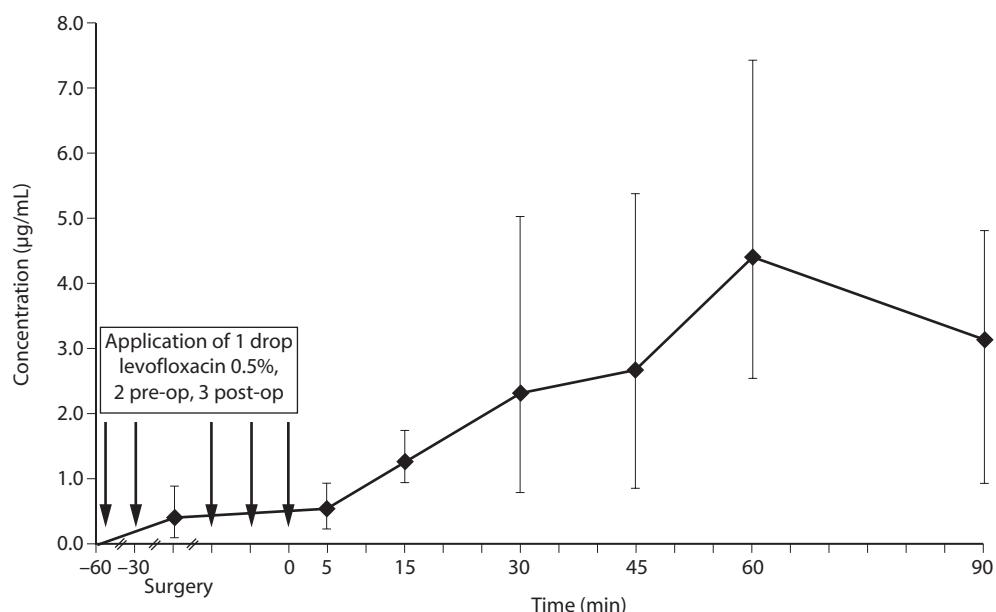

Fig. 53.2 Pulsed dosing of aqueous levofloxacin drops (0.5%) twice preoperatively (60 and 30 min) and three times postoperatively (0, 5 and 10 min) in cataract surgery showing the concentrations achieved in the anterior chamber up to 90 min after the 5th dose.³ From Sundelin K, Seal D, Gardner S, et al. Increased anterior chamber penetration of topical levofloxacin 0.5% after pulsed dosing in cataract patients. *Acta Ophthalmol (Copenh)*. 2009;87:173–178.

Ofloxacin aqueous solution is marketed at a concentration of 0.3% rather than 0.5% and is absorbed similarly to levofloxacin. However, 50% of ofloxacin is virtually inactive. This means that use of 0.5% levofloxacin will achieve a concentration of active antibiotic inside the anterior chamber that is four-fold higher than that of ofloxacin. To inhibit and kill bacteria, a level of antibiotic is needed that is at least four times and preferably 10 times in excess of the MIC₉₀.

Unit doses of moxifloxacin are produced at a concentration of 0.5% and without preservative. Animal data only are available, but peak concentrations similar to levofloxacin can occur, although the half-life of moxifloxacin in the anterior chamber appears much shorter than that of levofloxacin. Moxifloxacin has an advantage of increased activity against streptococci and methicillin-resistant *Staph. aureus* (MRSA). As such, it is better retained for therapy rather than routine prophylaxis unless a surgical unit has a particular problem with a moxifloxacin-sensitive, levofloxacin-resistant bacterium when its possible use for prophylaxis may be justified. However, moxifloxacin-resistant bacteria do occur and are discussed in the section on endophthalmitis (p. 681).

PERIOCULAR INJECTION

Subconjunctival delivery involves the injection of 0.25–1.0 mL of antibiotic solution under the conjunctiva. There is some leakage of antibiotic back into the conjunctival sac, but the bolus chiefly acts as a depot for diffusion which will produce transient high levels of antibiotic in cornea, sclera, choroid and aqueous and, to a lesser and variable extent, the vitreous. Vitreous levels are lower because of the absorption of drug

into the choroidal and retinal circulations, and because of the natural barriers to penetration into the vitreous across the retina (see above). Doses for subconjunctival injection include 125 mg for cefuroxime, 40 mg for gentamicin, 34 mg for clindamycin and 25 mg for vancomycin.

Peak aqueous levels are achieved in the first hour and effective levels are maintained for about 6 h. Inclusion of adrenaline (epinephrine) in the subconjunctival injection prolongs antibiotic activity for 24 h or more, so that injections may be repeated less frequently. This is contraindicated in patients with cardiac disease, and caution must be exercised in the elderly, or when patients are receiving general anesthesia with halothane. Where possible, the injection is delivered close to the site of infection, since tissue levels are highest near the injection site.

A sub-Tenon's injection is delivered in a similar volume but more deeply into the orbit, beneath Tenon's capsule and close to the sclera. Care must be taken to avoid penetration of the globe. It is said to achieve higher levels in the posterior eye than the more anterior, subconjunctival route.

Periorcular injections require local anesthesia, and are not without complications. Conjunctival ischemia and necrosis may occur locally and orbital hemorrhage and penetration of the globe have been reported. Although high aqueous levels can be achieved, they are not sustained.

INTRAVITREAL INJECTION

Intravitreal antibiotic injection is the standard treatment for endophthalmitis. Injected antibiotic persists in the vitreous in effective concentrations for up to 96 h. Only a small volume

Table 53.2 Selected intravitreal and parenteral antibiotics

Intravitreal injection ^a agent	Dose (µg)	Effective duration (h)	Intravenous injection, dose
Amikacin	400	24–28	15 mg/kg every 24 h ^c
Amphotericin	5–10	–	0.25–1.0 mg/kg every 24 h ^c
Cefuroxime	2000	16–24	0.75 g every 8 h
Ceftazidime	2000	–	1–2 g every 8–12 h
Chloramphenicol ^b	–	–	1 g every 6–8 h
Clindamycin	1000	16–24	0.3–0.6 g every 8 h
Gentamicin	100–200	48	5 mg/kg every 24 h ^c
Vancomycin	1000	25	1 g every 12 h

^aMaximum intravitreal injection volume is usually 0.2 mL, i.e. 0.1 mL of each agent used in combination.

^bChloramphenicol given systemically penetrates into the vitreous to treat acute bacterial endophthalmitis satisfactorily providing the organism is sensitive to it; it should be reserved for therapy when intravitreal antibiotics cannot be given, but must be used within 48 h of the start of endophthalmitis if useful vision is to be saved.

^cAdministered in three divided doses.

is injected (up to 0.2 mL), and an equal volume of vitreous withdrawn, to minimize ocular pressure elevation and to provide a specimen for culture. The retina is sensitive to toxic damage; amounts injected are based on animal toxicity studies. Selected doses are indicated in Table 53.2.

The vitreous is entered via the pars plana to avoid retinal injury. Sampling may be combined with a total vitrectomy to reduce the infective load and facilitate drug diffusion. The injection can be repeated at 48–72 h intervals according to clinical response. Subsequent vitreous samples can be used to assay the vitreous level of antibiotic.

Cationic drugs such as gentamicin have longer half-lives in the vitreous than anionic drugs such as penicillin, which are actively transported out of the vitreous space. This effect is less in the inflamed eye. Persistence of drug can be prolonged if the same drug is given systemically, since the outward diffusion gradient is decreased. In the case of certain anionic drugs, such as the penicillins, cephalosporins and ciprofloxacin, levels can be further increased by parenteral probenecid. This raises plasma levels by inhibiting renal tubular excretion and blocks active transport out of the eye.

THE SYSTEMIC ROUTE

Systemic medication may be used to treat preseptal and orbital cellulitis, dacryoadenitis, acute dacryocystitis and the rare condition of ocular 'erysipelas' (necrotizing fasciitis of the eyelids), which may need surgical debridement. In the management of chronic blepharitis, tetracyclines used in low dose (e.g. oxytetracycline 250 mg every 12 h) may act by an effect on meibomian oil composition through inhibition of bacterial lipases. In rosacea-associated blepharitis, oral tetracycline 250 mg every 12 h or doxycycline 100 mg once daily will be effective in 50% of patients.⁷ Minocycline has also been found effective.⁸

Systemic medication may be combined with local therapy in the treatment of ophthalmia neonatorum due to *Neisseria gonorrhoeae*, *Chlamydia* spp. or, rarely, *Pseudomonas* spp. It is also used in the treatment of adult chlamydial or gonococcal eye disease.

Systemic chemotherapy has no place in the management of uncomplicated bacterial keratitis. It is often employed in high dosage as adjunctive treatment of bacterial endophthalmitis but must not be used alone without intravitreal injection. It is essential in the management of metastatic endophthalmitis associated with septicemia. High-dose regimens should be closely monitored.

THE ROLE OF BIOFILMS IN OCULAR INFECTION

Many serious ocular infections are caused by virulent organisms invading a compromised eye. Increasingly, however, indolent infections result from organisms harbored in biofilms, carried by a therapeutic device, including contact lenses, lens cases, sutures and explants, keratoprostheses and intraocular lens implants. Similar infections occur on prosthetic heart valves, joint prostheses and indwelling catheters. The polymer becomes a physical vector, conveying the biofilm to the eye.

THE BIOFILM

MICRO-ORGANISMS RESPONSIBLE

A biofilm is an association of replicating micro-organisms within their polysaccharide glycocalyx. Certain strains of *Staph. epidermidis* or *Pseudomonas* spp. secrete a glycocalyx, which will attach to and encase the biopolymer, dividing slowly and colonizing the device. Attachment may be enhanced for *Staph. epidermidis* and *Staph. aureus* by the presence of fibronectin.

Free-swimming organisms such as *Ps. aeruginosa* are ideally suited to the formation of biofilms. Having formed a glycocalyx they divide at a slower rate than in the planktonic conditions (5–15 times slower). Bacteria within the biofilm are relatively inaccessible to antibiotics, biocides, surfactants, antibodies, bacteriophages and neutrophils, and are consequently better able to survive attack. The levels of antibiotics required to inhibit growth within the biofilm may be 20–1000 times higher than that required to inhibit planktonic growth. Antigens expressed at the biofilm surface can activate complement.

Biofilm-related infections tend to be chronic, resistant to antibiotics, polymicrobial and culture negative, since treatment may effectively free tissue fluids from planktonic forms, and shedding may be intermittent. The sensitivity to antibiotics of shed bacteria is usually higher than those within the biofilm. To obtain positive cultures it may be necessary to sample directly from the device and to release the bacteria with ultrasound. Simple or non-nutrient agar should be used in addition to normal cultural procedures.

Antibiotic resistance within the biofilm results in part from binding of the antibiotic, with a variable effect on sensitivity. Thus ciprofloxacin is inhibited more than tobramycin. In addition, antibacterial enzymes, such as β -lactamases produced by resistant staphylococci, are concentrated within the biofilm and reduce the antibiotic action of some penicillins and cephalosporins.

BIOFILMS ON OPHTHALMIC BIOMATERIALS

Silicone polymers, polymethylmethacrylate, hydrogels, nylon, polypropylene, aluminum oxide ceramics and Teflon may be non-specifically colonized. Biofilms are encountered in the following situations causing ocular infection.⁹

CONTACT LENSES

The incidence of contact lens-associated keratitis increased greatly with the introduction of hydrogel lenses, particularly for extended wear and to a lesser extent with daily wear. Risk is associated with overnight wear and poor lens hygiene. A number of studies have demonstrated the same strains of organism in the lens case and in saline dispensers used for lens care.

The sequence of events leading to infection is as follows:

1. Organisms, such as staphylococci, are transferred to the surface of a contact lens from the commensal population of the eye or by lens handling when there is poor lens hygiene.
2. Overnight wet storage of a soft hydrogel lens provides an environment which encourages the glycocalyx formation.
3. Homemade storage solutions from a saline dispenser increase the bacterial load by adding organisms from the dispenser nozzle.
4. Organisms within an established biofilm are relatively protected from storage preservatives, although the

preservatives may kill organisms shed from the biofilm.

Lens storage cases tend to be washed in tap water, contaminating the case with coliforms, *Ps. aeruginosa* and *Acanthamoeba* spp. The lens and its case become a reservoir for organisms and a physical vector from which organisms or their products can be transferred to the ocular surface on the lens to establish an infection.

The risk of infection is multiplied five times when there is extended, overnight wear of the lens because of the increased exposure time and because conditions at the ocular surface are altered during prolonged eye closure.¹⁰ During sleep, the ocular surface is in a proinflammatory state and the tears are rich in polymorphonuclear neutrophils and their digestive enzymes. Tear flow is almost at a standstill and IgA makes up the major fraction of the tear proteins. The new extended-wear silicone hydrogel lenses provide greater oxygen transmission and reduce the risk of hypoxia and corneal edema, but microbial keratitis still occurs similarly to other extended-wear lenses.¹⁰ In addition, the risk of microbial keratitis with daily disposable lenses has not been found to be reduced but vision loss is less likely to occur.¹⁰

CONTACT LENS-ASSOCIATED KERATITIS

Ps. aeruginosa is the most common cause of contact lens-associated keratitis followed by *Staph. aureus* and coagulase-negative staphylococci. Those coagulase-negative strains with virulence factors for contact lens-associated keratitis adhere more effectively to biomaterials and resist disinfection.

Acanthamebae are of particular interest because their growth is encouraged by the presence of other organisms and they feed on bacterial products. The trophozoite and cyst stages are introduced from tap water, showers and hot tubs. In the USA and the UK about 85% of infections have been contact-lens associated; in South India most of the infections arise from corneal trauma to the eyes of paddy-field workers.

Mycotic keratitis in soft lens wearers occurs most frequently in relation to extended-wear therapeutic lenses, when yeasts predominate, or with aphakic lenses, when filamentous fungi are more frequent.

Prevention of biofilm-related, contact-lens-associated keratitis

Preventive measures include:

1. Good hygiene and removal of proteinaceous contact lens deposits.
2. The use of cleaners and surfactants to remove adherent micro-organisms or 'multipurpose solutions' that clean and disinfect (polyhexamethylene biguanide or polyquat) with little toxic residual activity.
3. Avoidance of home-prepared saline.

Hydrogen peroxide within 10 min is an effective microbicide against bacteria and within 60 min against some filamentous

fungi. Hydrogen peroxide 3% is effective against the trophozoites and cysts of *Acanthamoeba* spp. over a period of 6 h. Catalytic neutralization of hydrogen peroxide allows microbial contamination and is not recommended. The ‘gold standard’ for soft lenses is 3% hydrogen peroxide overnight followed by neutralization with a thiosulfate/catalase solution made up from tablets in the morning.

SUTURES

Biofilms can form around unburied sutures with a sequence of events including attachment to the hydrophobic polymer, colonization and biofilm formation. Once formed, a suture biofilm may give rise to a stitch abscess, corneal abscess or infectious crystalline keratopathy.

Infectious crystalline keratopathy is an indolent corneal infection when bacterial multiplication occurs within a biofilm within the stroma, in which the close packing of microorganisms and disturbance of stromal lamellae give rise to a crystalline appearance on biomicroscopy.¹¹ Most cases occur as a complication of surgery or keratitis. The organism responsible for infectious crystalline keratopathy is usually an α -hemolytic streptococcus, although other bacteria and, rarely, fungi or amebae have been incriminated. For streptococci, intensive treatment with topical vancomycin or bacitracin is recommended, although penetration is poor in the absence of an epithelial defect.

PUNCTAL PLUGS

Punctal plugs are used to provide long-term occlusion of the lacrimal puncta, in order to conserve tears in dry eye states. Biofilms around punctal plugs occasionally give rise to canalicularitis or dacryocystitis.

EXPLANTS FOR RETINAL SURGERY

Both solid and sponge explants cause infection by means of a biofilm, although bacteria adhere more readily to sponge explants, presumably because of their greater surface area. Organisms include *Staph. aureus*, coagulase-negative staphylococci, *Ps. aeruginosa*, *Proteus* spp., *Moraxella* spp. and *Branhamella catarrhalis*; coagulase-negative staphylococci predominate. The frequency of infection has been estimated to be 0.6%.

INTRAOCULAR LENS IMPLANTS

While 15–40% of aqueous samples at the end of cataract surgery contain bacteria, endophthalmitis is not an inevitable consequence. Lens implantation can nonetheless be associated with

a chronic, saccular or capsular-bag-associated endophthalmitis due to coagulase-negative staphylococci, diphtheroids and *P. acnes* from a biofilm around the implant or due to macrophage-associated bacteria within the capsule remnant.¹² The non-purulent inflammatory reaction is thought to be due to anterior-chamber-associated immune deviation. Systemic azithromycin or clarithromycin can provide effective therapy and high intracellular concentrations.^{13,14}

MICROBIAL INFECTIONS OF THE EYE

BLEPHARITIS

Blepharitis is an inflammation of the lid margins involving either the lash line (anterior blepharitis) or the meibomian oil glands (posterior blepharitis). Both forms are often associated with skin diseases such as seborrhoeic and atopic dermatitis and rosacea.

ANTERIOR BLEPHARITIS

‘Staphylococcal’ blepharitis implies an anterior blepharitis with lash collarettes, crusting, lid ulceration and folliculitis, and a positive culture for *Staph. aureus*. This is an indication for antimicrobial treatment. However, a positive culture alone does not warrant treatment since the lid margins are colonized with *Staph. aureus* in 6–15% of normal persons, rising to 50% in atopes.^{1,2} Coagulase-negative staphylococci are isolated from over 80% of normal lid margins as commensals.

Chronic anterior blepharitis is common and requires regular cleansing of the lid margins with dilute bicarbonate or baby lotion to remove adherent scales. Misted lashes must also be removed. Culture of the lid margin requires ‘scrubbing’ with a swab soaked in sterile broth, and plating directly onto blood agar and a selective medium for *Staph. aureus*. Blepharitis due to *Staph. aureus* is treated with topical ophthalmic fusidic acid gel 1%, 2–4 times daily, or with ocular Polytrim or ocular tetracycline. A highly active staphylococcal blepharitis merits a course of systemic antistaphylococcal therapy, such as flucloxacillin (oxacillin) or erythromycin (500 mg every 6 h for 4 days). Patients should be encouraged to wash with antiseptic soaps such as chlorhexidine to suppress the carriage of *Staph. aureus* at other skin sites.

Anterior blepharitis may respond to short courses of 0.5% hydrocortisone lotion or ointment applied sparingly to the lid margin.

POSTERIOR BLEPHARITIS

The most common form is obstructive meibomian gland dysfunction (MGD), which is highly symptomatic. Lid margins are thickened and red, there is plugging of the meibomian gland orifices and lid oil is poorly expressible. MGD

is treated by daily heat to the lids to increase oil fluidity, and firm massage to express retained secretions.

Generally, MGD is not an infective condition but both anterior and posterior blepharitis are accompanied by an increase in commensals, which produce lipases capable of releasing fatty acids from the lipid esters of the tear oils. These contribute to the inflammation. Lipases are inhibited by sub-antimicrobial levels of tetracycline, given intermittently as oxytetracycline (250 mg every 12 h) or doxycycline (50 mg/day), for 3 months which can be repeated after a 3-month interval. Minocycline has been proposed for recalcitrant staphylococcal blepharitis⁸ or erythromycin in children to avoid dental abnormalities.

ATOPIY

Atopic blepharitis should not be confused with staphylococcal blepharitis, although they may coexist. Non-inflamed lids in patients with atopic dermatitis are colonized with *Staph. aureus*,^{1,2} as are the conjunctivae, nasal mucosae and skin. While tear IgE levels are high, they are not directed against *Staph. aureus* antigens.¹ Anterior and posterior blepharitis occurring in association with atopic dermatitis are treated as for non-atopes.

ROSACEA

Rosacea is also associated with blepharitis and the lids are often colonized by *Staph. aureus*. Although cell-mediated immunity to *Staph. aureus* is enhanced, it is not known whether this is cause or effect. In a randomized, placebo-controlled crossover trial, symptomatic improvement of blepharitis in mild rosacea occurred in 90% of patients receiving topical fusidic acid (Fucithalmic) compared with 50% in those on oral oxytetracycline.⁷ This improvement did not occur in non-rosacea blepharitis. The non-infective keratitis of rosacea is treated with topical steroid.

STYES

Styes are painful microabscesses of the lid margin, at the base of a lash follicle. Colonization of the lash base with *Staph. aureus* is well recognized. Styes may respond to the application of heat, combined with a topical antibiotic with good tissue penetration, every 4–6 h (e.g. ofloxacin, ciprofloxacin, chloramphenicol or fusidic acid gel). Resistant cases may require treatment with a systemic antistaphylococcal agent.

CHALAZIA

A chalazion is a granuloma within the meibomian glands, associated with obstruction of the gland orifices. It usually forms a painless swelling, which may resolve without treatment or may require incision and curettage. Secondary infection with pain can occur which responds to systemic antimicrobials.

CONJUNCTIVITIS

Conjunctivitis can be due to bacteria, chlamydia, viruses, fungi, protozoa and helminths (Box 53.2). Non-infective causes include allergy or toxicity. Toxicity may be due to preservatives, such as benzalkonium chloride, associated with tear substitutes or occasionally to circulating bacterial toxins.

CLINICAL PRESENTATION

Bacterial conjunctivitis presents with an acute purulent discharge, which frequently becomes bilateral. Viral conjunctivitis is usually associated with a watery discharge and in both

Box 53.2 Microbial and other causes of conjunctivitis

Bacteria

- *Staphylococcus aureus*, associated with blepharitis
- *Streptococcus pneumoniae*, associated with sinus disease
- *Str. pyogenes*, associated with throat infections
- *Listeria monocytogenes*, associated with rural and farmyard dust (farmer's eye)
- *Corynebacterium diphtheriae*, associated with a pseudomembrane
- *Neisseria meningitidis/gonorrhoeae*, associated with throat/genital infection
- *Pseudomonas aeruginosa*, associated with contact lens wear
- *Klebsiella pneumoniae* and other Enterobacteriaceae, associated with contact lens wear
- *Proteus* spp., associated with old age (more in men than women)
- *Moraxella* spp., associated with damaged ocular surface
- *Haemophilus influenzae*, associated with intrinsic throat flora

Chlamydia

- *Chlamydia trachomatis*, associated with overcrowding, poor hygiene and flies (encouraged by cattle dung) in the Near and Middle East and tropics
- Trachoma/inclusion conjunctivitis, associated with genital infection in Western countries

Viruses

- *Herpes simplex*, associated with corneal disease
- *Herpes zoster*, associated with affection of the fifth nerve
- Adenovirus, associated with epidemics from shipyards, close-living quarters, and eye clinics (via tonometers and staff handling of patients); early diagnosis is required to bring outbreaks to a quick halt
- Acute hemorrhagic conjunctivitis: enterovirus 70, poliovirus and Coxsackie A24v are associated with epidemics and occasional paralysis; it is associated with foreign travel, especially tropical areas of Asia
- Conjunctivitis occurs with systemic infection in measles, mumps and dengue, glandular fever and hepatitis A infection

Fungi

- Fungal conjunctivitis is uncommon, but may complicate fungal keratitis

Helminths

- *Thelazia capillaris* and *Thelazia californensis*, associated with birds in the Middle East and the USA
- *Loa loa*, subconjunctival worm occurring in tropical countries

Protozoa

- Protozoa include *Acanthamoeba* spp., associated with contact lens wear, or rural corneal trauma and keratitis

viral and chlamydial conjunctivitis there is often a follicular conjunctival response. Bacterial conjunctivitis may sometimes be confused with viral or chlamydial disease but an associated urethritis or proctitis points to chlamydial infection.

MICROBIAL DIAGNOSIS AND TREATMENT

The patient's history will often give a clue to the organism responsible.

Presumed bacterial conjunctivitis

Swabs should be collected for smears (for Gram and acridine orange stains) and for culture on blood and chocolate agars (and a selected gonococcal agar if relevant). Culture should take place in carbon dioxide at 37°C for 48 h. Treatment is listed in Table 53.1 and Box 53.1 (p. 669).

Presumed chlamydial conjunctivitis

The diagnosis is confirmed by polymerase chain reaction (PCR) or using a monoclonal antibody (e.g. the 'Syvamicrotrak' test). Conjunctival cells are scraped using a spatula and placed on special slides provided in the kit.

The older and cheapest method involved Giemsa staining for intracytoplasmic (Bedson) bodies (complete chlamydial cells lacking a traditional bacterial cell wall). Under ultraviolet light the stained chlamydiae fluoresce yellow, a non-specific reaction which renders the method more sensitive.

Presumed viral conjunctivitis

Diagnosis is carried out by PCR tests on conjunctival scrapings.

THERAPY

Bacterial conjunctivitis

Therapy requires antibacterial drops or ointment for 5 days. If a primary culture is not collected, treatment with a broad-spectrum antibiotic should be given, such as chloramphenicol,⁴ levofloxacin or another quinolone or Polytrim. If treatment fails, conjunctival specimens should be collected after stopping drop therapy, including specimens for chlamydia where appropriate.

Ophthalmia neonatorum

Ophthalmia neonatorum is defined as any purulent discharge from the eyes during the first 28 days of life. The presentation may be hyperacute and infection may progress rapidly to keratitis and perforation, leading to blindness. It is

an important cause of blindness in low-income countries. Ophthalmia neonatorum in the UK occurs in up to 12% of live births but gonococcal infection is now rare. Elsewhere, the incidence of gonococcal conjunctivitis varies from 0.04% of live births in the West to 1.0% in parts of Africa. The incidence of neonatal chlamydial ophthalmia in London has been estimated at less than 1%.

Neonatal prophylaxis is not used in Western countries. If needed, topical tetracycline protects against both gonococcal and chlamydial ophthalmia, without the toxicity of silver nitrate drops (Créde's solution).

Systemic treatment for gonococcal keratoconjunctivitis is essential, with 30 mg of benzylpenicillin/kg in every 12 h for 7 days. Isolation of penicillin-resistant strains has led to the use of β-lactamase-stable cephalosporins such as ceftriaxone 25–40 mg/kg intravenously every 12 h for 3 days, combined with topical saline lavage and antibiotic ointment (e.g. ocular gentamicin). Single-dose intramuscular therapy may be appropriate when there is no corneal involvement. As is the case with neonatal chlamydial ophthalmia, the infection must be treated systemically as well as topically.

TRACHOMA AND OTHER CHLAMYDIAL DISEASE

Ocular infection by *Chlamydia trachomatis* takes three forms: trachoma, adult chlamydial ophthalmia and neonatal chlamydial ophthalmia.

Trachoma affects 500 million people in developing countries and accounts for 5–10 million blind patients. It is caused by the chlamydial serovars A, B and C, and is transmitted by 'eye-seeking' flies. In hyperendemic areas 30–50% of the population have active disease and 10% exhibit blinding sequelae. Although infection may be encountered as early as the second month of life, active inflammatory disease is most common in preschool children, when the infection leads to conjunctival scarring, entropion and trichiasis, causing recurrent microbial keratitis from repeated corneal infection and trauma. Blinding sequelae occur after the age of 40 years. Public health intervention is required to prevent spread of the infection and reinfection during childhood. The World Health Organization program for the elimination of trachoma (GET 2020) has adopted the SAFE strategy of control measures (**S**urgery for ectropion and entropion, **A**ntibiotics for infectious trachoma, **F**acial cleanliness to reduce transmission by the fly vector and **E**nvironmental improvements, such as control of disease-spreading flies, improved access to clean water and provision of latrines).¹⁵

Adult chlamydial ophthalmia, also known as inclusion conjunctivitis, and neonatal chlamydial ophthalmia result from sexual transmission. They are caused by serotypes D–K. The adult disease has its greatest prevalence between the ages of 15 and 20 years. The neonatal form may rarely occur immediately after birth, but presents most commonly in the first week or up

to 6 weeks later. Treatment of maternal genital *C. trachomatis* infection during pregnancy, usually with erythromycin, is an important preventive measure.

TREATMENT

C. trachomatis is unresponsive to aminoglycosides and only partially susceptible to chloramphenicol and penicillin, which adversely affect growth in culture media. For this reason, transport media for chlamydial culture do not contain penicillin. The organism is fully sensitive to the tetracyclines, erythromycin and other macrolides including azithromycin, rifampicin (rifampin) and the quinolones. Some authorities regard quinolones as second-line treatment. It is also sensitive to chlorhexidine.

Topical treatment of trachoma with tetracycline or erythromycin ointment or quinolone drops can be effective given every 8–12 h for 6 weeks. In trachoma, treatment of other family members or whole villages is necessary to prevent reinfection. Treatment of the early active inflammatory stages is effective with a single oral dose of azithromycin, which is now the preferred therapy, but the cost is higher.¹⁶

Mass treatment of villagers with single-dose azithromycin has been shown to reduce the prevalence and intensity of infection in a Tanzanian community when infective levels remained low for 2 years after treatment.¹⁶ However, more recent work has found that trachoma and ocular *C. trachomatis* were not eliminated 3 years after two rounds of mass treatment with azithromycin in a trachoma hyperendemic village, again in Tanzania, which is disappointing.¹⁷ Continued implementation of the SAFE strategy is needed in this environment to eradicate the infection.

Systemic therapy is necessary for the treatment or prophylaxis of systemic manifestations such as cervicitis, uveitis, upper respiratory or ear disorders and Reiter's disease in adult chlamydial ophthalmia, and for pharyngitis, vaginitis and a potentially fatal pneumonitis in the neonatal disease.

Adult chlamydial ophthalmia treatment with oral tetracycline, erythromycin or rifampicin for 2 weeks has been recommended but long-acting tetracyclines, such as doxycycline and minocycline, offer convenience and improved compliance, as fewer doses are required and dietary constraints are not necessary. Oral azithromycin therapy is effective with a single dose. The patient and partner(s) should be checked for genital carriage and treated with erythromycin or azithromycin if positive.

A suitable treatment for neonatal chlamydial ophthalmia is oral erythromycin 50 mg/kg per day in four divided doses for 2–3 weeks. Topical therapy may be used adjunctively, but is inadequate on its own (see also Ch. 56).

VIRAL CONJUNCTIVITIS

Primary herpes simplex causes a watery blepharoconjunctivitis, which responds well to aciclovir ointment 3% five times daily.

Adenovirus conjunctivitis may begin unilaterally, but commonly becomes bilateral and may cause a disabling punctate keratitis. In its acute form it lasts up to 21 days, but full recovery from visual sequelae may take several months. No commercial agent is currently available for treatment. Current management is palliative; samples should be collected to confirm the diagnosis by PCR and to highlight the risk of potential epidemics.

Acute hemorrhagic conjunctivitis may occur in epidemics and is due to enterovirus 70; mild paralysis occasionally ensues. Diagnosis is usually clinical. Viral culture should be performed if possible for epidemiological reasons. No specific antiviral therapy is available and treatment is symptomatic.

OTHER FORMS OF CONJUNCTIVITIS

Treatment of *Acanthamoeba* conjunctivitis and episcleritis is dealt with in section on keratitis (p. 677).

CANALICULITIS

Recurrent unilateral conjunctivitis due to an antibiotic-sensitive bacterium such as *H. influenzae* can be the presenting symptom of a canalicularis due to *Actinomyces* spp. (formerly *Streptothrix* or *Leptothrix* spp.) or *Arachnia propionica*. The organism does not usually invade the canaliculus wall but forms a 'fungal' ball that obstructs the lumen. The canaliculus provides a microaerophilic environment, which supports the growth of non-fastidious anaerobic bacteria, and becomes infected with endogenous flora.

Pus, massaged along the canaliculus to the punctum, can be Gram stained to show typical, branching Gram-positive bacilli. Prolonged anaerobic culture on blood agar plates is necessary to demonstrate actinomycetes. Thioglycolate broth should also be inoculated. Sensitivity tests should be performed.

Actinomyces and *Arachnia* spp. are usually sensitive to penicillin, tetracycline and erythromycin but resistant to aminoglycosides. Initial treatment involves irrigating the canaliculus with penicillin. If this fails, the canaliculus is opened and debrided and material removed is Gram stained and cultured. The canaliculus should be treated with 5% povidone–iodine for 5 min as an effective antiseptic and syringed daily for 7 days with penicillin.

DACRYOCYSTITIS

Acute dacryocystitis is caused by nasolacrimal stasis, with *Staph. aureus* or streptococci as the usual causes. Infection may respond to systemic chemotherapy or require drainage of a lacrimal sac abscess and ultimately dacryocystorhinostomy.

Chronic dacryocystitis, commonly involving Gram-negative organisms, can only be treated effectively by relieving the nasolacrimal duct obstruction.

The postoperative infection rate in patients undergoing dacryocystorhinostomy is greatly reduced by a single dose of intraoperative cefuroxime intravenously (750 mg).

MICROBIAL KERATITIS

Suppurative bacterial keratitis presents clinically with acute pain, globe redness, lid swelling, watering and visual loss, accompanying a corneal stromal infiltrate or abscess with an overlying ulcer. Common causes are given in Box 53.3. It is usually central, but can be peripheral, particularly if traumatic. Because the cornea is only about 0.5 mm thick, such an ulcer may rapidly progress to perforation within 24 h of onset. In this case, in the aphakic or in the pseudophakic eye with a capsulotomy, there is access to the vitreous space and a secondary endophthalmitis may supervene. There is an urgent need to treat bacterial keratitis with high doses of effective antibiotic. Corneal transplantation may be required later to deal with corneal scarring or perforation.

In northern climates bacteria account for over 80% of cases, with 60% in the south, where fungal keratitis is more common. In tropical regions the risk of fungal infection is even higher,¹⁸ and mixed bacterial and fungal infections are common.

Box 53.3 Bacteria causing bacterial keratitis

Gram-positive cocci

- Staphylococcus aureus*
- Coagulase-negative staphylococci (in the compromised eye)
- Streptococcus pneumoniae*
- Streptococcus pyogenes*
- Viridans streptococci (in the compromised eye)
- Anaerobic streptococci (rare)

Gram-negative coccobacilli

- Moraxella* spp.
- Neisseria gonorrhoeae*
- Neisseria meningitidis*

Gram-positive rods

- Corynebacterium diphtheriae* (rare)
- Diphtheroids (rare)

Gram-negative rods

- Pseudomonas aeruginosa* (associated with contact lens wear)
- Proteus* spp.
- Klebsiella pneumoniae*
- Escherichia coli*
- Serratia marcescens*
- Acinetobacter* spp.
- Morganella morganii*
- Other enteric bacteria

Acid-fast bacteria

- Mycobacterium chelonei*
- Nocardia asteroides*

In the past, suppurative keratitis was due chiefly to trauma, or occurred in compromised eyes with existing corneal disease. In recent years, however, there has been a rapid increase in contact-lens-associated keratitis, most of which is bacterial. In general, the risk is much lower for wearers of hard lenses than soft-lens wearers and is greater with extended wear than daily wear. The risk has not been removed by the introduction of 'daily disposable' contact lenses or oxygen-permeable silicone hydrogels.¹⁰

In previous and current multicenter case-controlled studies, the overall risk for ulcerative keratitis with extended-wear lenses was four times greater than that for daily wear.¹⁰ In addition, overnight wear of contact lenses increased the risk of keratitis to five times that occurring with daily wear alone.^{10,19} Wearing soft contact lenses in corneal graft patients also increases the risk of microbial keratitis.

The incidence of contact-lens-associated microbial keratitis has been estimated to be 1 in 500 for extended-wear patients and 1 in 2500 in daily-wear patients.^{10,19} The bacteria responsible for contact lens-associated keratitis include those usually associated with suppurative keratitis, but Gram-negative bacteria are more common than Gram-positive, with *Ps. aeruginosa* the most frequent. Contamination of contact lens care solutions is an important potential source of keratitis, with homemade solutions a major risk factor. The number of contact lens wearing patients infected with *Acanthamoeba* spp. has reduced considerably since the introduction of multipurpose solutions based on polyhexamethylene biguanide (PHMB).

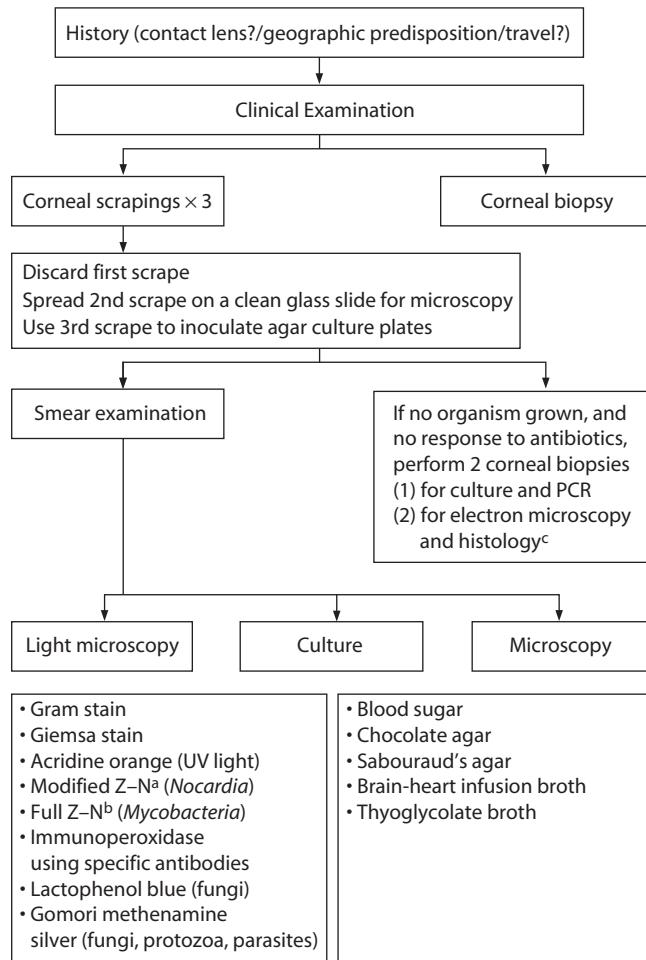

DIAGNOSIS

Diagnosis depends on smears and cultures from direct scrapes of the corneal ulcer (Fig. 53.3). The base and edge of the ulcer are most likely to yield organisms.

One drop of unpreserved amethocaine or benoxinate is instilled. The first scrape should be discarded. The second scrape should be taken for microscopy, using a platinum spatula, large-gauge needle or surgical blade. A fresh sterile instrument is used for each sample and the material gathered is spread onto a clean glass slide and air dried. A third scrape should be cultured by plating out directly onto blood, chocolate and Sabouraud agars; then a fluid medium, preferably brain-heart infusion, should be inoculated with the same instrument. In addition, a mycobacterial culture medium should be inoculated if the keratitis is chronic, although the atypical *Mycobacterium chelonae* will grow on blood agar if incubated for 1 week at 37°C. With chronic ulcers, blood agar should be incubated for 1 week in 4% CO₂ in order to culture *Nocardia* spp.

When keratitis due to *Acanthamoeba* spp. is suspected, an appropriate specimen should be taken (see p. 667–679).

Media should be inoculated directly at the slit lamp or operating microscope. If possible, duplicate specimens should be taken, to culture at different temperatures. Transport media

^aModified Ziehl-Neelsen stain: use hot carbol fuchsin, rinse with weak (acetic) acid (5%) and no alcohol for *Nocardia* spp., *M.leprae*.

^bFull Ziehl-Neelsen stain: use hot carbol fuchsin, rinse with concentrated acid and 95% alcohol for 15 seconds for mycobacteria

^cCollect sample in gluteraldehyde

Fig. 53.3 Flow chart for investigating microbial keratitis. PCR, pulsed chain reaction.

should not be necessary. Culture of agar plates should always take place at 37°C for 1 week. The fluid media should be incubated at 30°C in 4% CO₂ for at least 3 weeks. Anaerobic cultures should be considered when there is an unsatisfactory response to therapy.

Stains include Gram stain and acridine orange for common bacteria, modified Ziehl-Neelsen stain (decolorizing with 5% acetic acid only) for *Nocardia* and mycobacteria, full Ziehl-Neelsen stain for mycobacteria and periodic-acid Schiff (PAS) or methenamine silver (Grocott) stains for fungi and protozoal cysts. Selective stains include the use of labeled polyclonal or monoclonal antibodies. Acridine orange and Gram stains together will identify organisms in about 80% of cases. It is also possible to maximize the available material by decolorizing and restaining the same slide with a further intermediate stain and finally an end stain.

TREATMENT OF SUPPURATIVE KERATITIS

Treatment is initiated with a commercial preparation of levofloxacin 0.5%, ofloxacin 0.3% or ciprofloxacin 0.3%, or, alternatively, with combination drop therapy using fortified preparations prepared in the hospital pharmacy. A common empirical combination is gentamicin or tobramycin 1.5% (15 mg/mL) with cefazolin or 5% cefturoxime (50 mg/mL).

Trials have demonstrated that monotherapy with fluoroquinolones is as effective as combination therapy in the treatment of bacterial keratitis,^{20–23} with greater toxicity in the combined group. Fortified preparations may have an advantage in the management of advanced disease. The growing recognition of bacterial resistance to the fluoroquinolones^{24,25} suggests that there should be caution in adopting monotherapy as a universal approach.

Drops are given every 15–30 min, day and night, and then hourly for the first 3 days, then 2-hourly by day and night, weaning according to response and cultural findings. It is unusual to modify therapy on the basis of the smear report alone, unless fungi are identified. An exception is the identification of *Str. pneumoniae*, when penicillin drops should be substituted. Successful eradication of bacterial infection is reported in about 90% of patients treated in this way.

Unpreserved levofloxacin 0.5% is now available in the UK, Germany and Nordic countries; other countries and the above have levofloxacin 0.5% preserved with benzalkonium chloride. Levofloxacin has the advantage of twice the activity of ofloxacin, half of which is inert, and is marketed at the higher concentration. Ofloxacin treatment causes less irritation than ciprofloxacin, which can leave microcrystalline corneal deposits.

Moxifloxacin (0.5% unpreserved)²⁶ and gatifloxacin (0.3% preserved) are available in some countries; moxifloxacin has the advantage of increased activity against streptococci but should be reserved for this purpose and not used for prophylaxis. Fortified gentamicin drops cause an inferior, perlimbal conjunctival necrosis which resolves on withdrawing therapy.

If monotherapy is used, a loading dose of one drop every minute for five doses can be initiated, and repeated hourly, to achieve high initial levels in the cornea. In the USA, a regimen of fortified drops every 15–30 min day and night is recommended on an outpatient basis for 3 days in the first instance. In the UK it is usual to admit patients to hospital. Systemic antibiotics have no place in the management of bacterial keratitis in the absence of limbal involvement or perforation.

Where frequent application is not possible, as in a child or a disturbed individual, subconjunctival injections of gentamicin 40 mg and cefazolin 100 mg can be delivered under general anesthetic. In the absence of cardiac disease, inclusion of adrenaline (epinephrine) 0.3 mL (of 1:1000) in 1 mL of solution prolongs the tissue concentration of antibiotic from 6 to 24 h. Other regimens are given in Box 53.4.

Box 53.4 Suppurative bacterial keratitis: specific antibiotic regimens for topical or periocular therapy

Initial therapy

To treat unknown organism(s) (new case or no growth on presentation):

- levofloxacin 0.5% or, if unavailable, ofloxacin 0.3%

These therapies will treat the following organisms:

- *Staphylococcus aureus*
- Coagulase-negative staphylococci
- *Streptococcus* spp.
- *Pseudomonas aeruginosa*
- *Klebsiella* spp.
- *Proteus* spp. and other Enterobacteriaceae
- *Haemophilus influenzae*

MRSA keratitis

Moxifloxacin 0.5% or, if non-responsive, vancomycin* 5%

***Pseudomonas aeruginosa* infection (culture-proven)**

Levofloxacin 0.5% or a combination of piperacillin* (5%) + gentamicin* (1.5%) and/or ceftazidime* (5%)

Mycobacterial keratitis

Amikacin* 5% and/or levofloxacin or other quinolone

Nocardial keratitis

Amikacin* 5% and/or vancomycin* 5% and trimethoprim* 0.1% ± azithromycin*

See text.

Fungal keratitis (hyphae or yeasts seen on smear or fungus cultured)

Hyphal infection (*Aspergillus* spp., *Fusarium* spp.): natamycin* (5%) or amphotericin* B (0.15–0.3%).

Yeast infection (*Candida* spp.): clotrimazole* (or other imidazole*) at 1% in arachis oil eye drops or flucytosine* 1% drops.

*Needs to be prepared by local hospital pharmacy.

Antibiotics should be modified according to the results of cultures and clinical response. If there is a clear clinical response, the same regimen should be continued. Susceptibility tests may be misleading because they assume lower tissue antibiotic levels than achievable in the cornea during topical therapy. Therapy is reduced by increasing the time interval between drops every 3–4 days and not by reducing their concentration. The decision to terminate therapy is based on the clinical response and the nature of the causative organism.

If there is no response, topical therapy should be stopped and the clinical condition reappraised after 24 or 48 h when the cornea is scraped again. A full search must be made for fastidious organisms.

If no organism is identified, a second-line broad-spectrum empirical antibiotic regimen should be started, to include antimicrobial action against resistant streptococci, *Nocardia* and mycobacteria. This may include drop therapy with topical vancomycin 50 mg/mL (5%) plus amikacin 50 mg/mL (5%) and trimethoprim 0.1% (given as Polytrim), substituting erythromycin (0.5%) or rifampicin (2.5%) ointment at

night. This is less likely to be necessary since the introduction of topical quinolone therapy, since quinolones are effective against *Nocardia* and mycobacteria, although not against resistant streptococci.

Special cases

Treatment of *M. chelonae* infection requires topical amikacin or a quinolone. This mycobacterium, which causes a chronic keratitis and may follow radial keratotomy, is resistant to the common antituberculosis drugs.

Nocardia spp. cause a refractory keratitis. Therapy usually demands surgery to debulk the infectious load plus antibiotics. Antibiotics alone often fail despite apparent full *in-vitro* sensitivity. A combination of topical amikacin (always) plus erythromycin and/or vancomycin and/or trimethoprim has been used successfully. Isolates are resistant to penicillin but may be sensitive to sulfonamides. The new generation of macrolides (azithromycin and clarithromycin) may prove useful.

ACANTHAMOEBA INFECTION

Acanthamebae are free-living protozoa, found in fresh-water ponds, lakes, domestic water supplies, swimming pools and soil. Subclinical exposure occurs frequently and antibodies against *Acanthamoeba* are common. *Acanthamoeba* keratitis was first recognized between 1973 and 1975 and this was followed in the 1980s by a virtual epidemic of cases, related to the expansion of contact lens use: in various series, 71–85% of patients have been contact lens wearers.²⁷ In the UK, this infection has occurred in 1 in 6750 contact lens wearers but the figure has reduced since multipurpose solutions were introduced for lens storage and disinfection. In Asia it is associated with rural, traumatic eye disease and presentation is often late.

Persons who present with an unusual keratitis after exposure to hot tubs or natural springs may have *Acanthamoeba* keratitis. A high index of suspicion must be maintained for all contact-lens-related keratopathies presenting with epithelial infiltrations, especially with a ‘snowstorm’ appearance, multiple superficial abscesses or dendritiform ulcers. Keratoneuritis (corneal nerve infiltration) is diagnostic and *Acanthamoeba* cysts may be visible *in vivo* by confocal microscopy. Suppurative keratitis that is ‘culture-negative’ and resistant to standard therapy may be due to infection with *Acanthamoeba* spp.

Diagnosis

Early diagnosis, when the infection is confined to epithelium or anterior stroma, is important for successful outcome. Sheets of cells should be removed for both culture and microscopy. Identification of cysts in wet mounts may establish the diagnosis within 10 min of collection. The epithelial material is

placed in a conical tube containing 2 mL saline, agitated on a vibrator, centrifuged and the deposit inspected by wet-field microscopy at $\times 100$.

If the disease has progressed to a stromal ring abscess, epithelial scrapes may not yield viable organisms. Cysts from the midst of the abscess may fail to excyst, and results may be delayed. Corneal biopsy allows sampling of the deep infiltrate for viable trophozoites. Both culture and electron microscopy are useful to demonstrate stromal amebae.

For culture, scrapes are inoculated onto non-nutrient agar, ideally made up in Page's amebal saline. If non-nutrient agar without Page's saline is used, then the plate should be pre-inoculated with a suspension of heat-killed *Klebsiella pneumoniae* or other Enterobacteriaceae as a nutrient source for the amebae. The plate is incubated at 32°C for 4 weeks. Amebae are usually visible by light microscopy after 1 week; after 2 weeks the whole plate is covered by the typical double-walled, star-shaped cysts. Isolates should be sent to a reference laboratory for in-vitro drug sensitivity testing and genotyping.

Treatment

Acanthamoeba spp. exist in two forms: the free-living trophozoite is relatively responsive to therapy, whereas cysts may be highly resistant. Cysts form in response to adverse conditions and may remain viable for years. Acanthamebae do not invade the epithelial cells themselves but are found between them, where host defense depends on phagocytosis by macrophages. Drugs are therefore targeted to the stroma, to amebae internalized within cysts, rather than to the epithelial cells. Thus the cationic antiseptics chlorhexidine⁵ and PHMB,⁶ which do not penetrate the epithelial cell, are highly effective in the treatment of *Acanthamoeba* keratitis and other forms of amebic keratitis.

Treatment should begin with either 0.02% (200 mg/L) chlorhexidine in physiological saline^{5,6} or with PHMB (0.02%);⁶ however, the latter is less available and not licensed for use as a drug. Both agents are highly effective against the trophozoite and cystic forms of the organism. The diamidines – propamidine isethionate (Brolene) 0.1% or hexamidine isethionate (Desmodine) 0.1% – are usually used in combination with the above biguanide drugs.⁵ Propamidine has been used effectively in combination with neomycin but most cysts are resistant to neomycin, and propamidine is moderately toxic with intensive use.

Drops are given hourly day and night for the first 3 days, reducing to 2-hourly by day only. This requires admission to hospital. Adjunctive therapy includes oral flurbiprofen, for both non-steroidal anti-inflammatory and analgesic effects, and a topical mydriatic. Thereafter, combination therapy (chlorhexidine or PHMB and a diamidine) should be given 3-hourly by day for 1 month and then 4-hourly by day for up to one further month. Chlorhexidine and PHMB should not be used together because of the increased toxic effect and lack of synergy. Eradication of the *Acanthamoeba* trophozoites and cysts should then be complete but considerable inflammation can persist.

However, Lim et al⁶ have found that live cysts can persist with either chlorhexidine or PHMB therapy in approximately 7% of patients; outcomes were similar when treating with monotherapy of either guanide when the majority of patients were satisfactorily treated. Prolonged treatment for more than 2 months should not be used with either chlorhexidine or PHMB. PHMB is a much larger molecule than chlorhexidine and is less likely to be absorbed into the anterior chamber. If treatment fails, combination therapy with either chlorhexidine or PHMB and a diamidine should be given.

If infection is diagnosed early, cure is possible with complete recovery of vision. Therapy can be limited to 1 month. One week after starting therapy, however, there may be a corneal reaction to the lysis of dead amebae, with localized stromal edema and anterior chamber activity, which lasts up to 3 weeks.⁵ Although this may be suppressed with steroids, their use is not encouraged. Steroid treatment, necessary in cases presenting late with considerable pain, ring abscess and episcleritis, prolongs treatment but can relieve intolerable pain. Steroids appear to have a role in controlling the late immunoinflammatory responses, when the amebae have been killed and antigens remain bound to the corneal stroma or sclera. Adjunctive immunosuppression has been advocated for *Acanthamoeba* scleritis. Steroids suppress the host macrophage response needed for successful treatment so should be restricted as far as possible.

Rapid progressive (mature) cataract and iris atrophy were not seen in the original series of 12 patients treated with chlorhexidine and propamidine in 1996.⁵ They have since been reported anecdotally with chlorhexidine treatment, with two cases published in 2004²⁸ and 6 cases out of 81 patients with laboratory-confirmed diagnosis published in 2008.²⁹ All cases had been treated with prolonged therapy with chlorhexidine, the latter six for 6 months. Cataract may occur and progress during the management of *Acanthamoeba* keratitis in association with anterior segment inflammation, iris atrophy and secondary glaucoma. This is likely due to the toxic effect of chlorhexidine, in particular its absorption into the anterior chamber to damage the lens epithelium. This was an original concern when introducing chlorhexidine therapy for *Acanthamoeba* keratitis.⁵ Chlorhexidine is approximately 50 000 times more active against the membrane of the *Acanthamoeba* cell than the human cell but all epithelial cells are sensitive to it at high concentration. It is well known to delay wound healing at a concentration of 0.5% as exemplified in a pig model.³⁰ Chlorhexidine accumulates in tissues with an ever-increasing concentration, when absorption into the anterior chamber may occur with resulting damage to the epithelia of the lens and iris.

Prevention

Contact-lens storage cases become contaminated with *Acanthamoeba* spp. from the domestic water supply and airborne dust.³¹ Prevention involves use of acanthamebicidal disinfectants in storage and cleaning solutions, of which the best is hydrogen peroxide 3%; if PHMB is included as the

disinfectant, the minimum concentration for an acanthamebicidal effect is 1 mg/L (0.0001%) but needs 5 mg/L for a full cysticidal effect. Chlorine is ineffective against cysts. Storage cases should never be washed in tap water, but with boiled water only, and should be stored dry. This is important because Enterobacteriaceae die quickly in dry conditions, and amebae cannot then multiply.

REFRACTIVE SURGERY-ASSOCIATED INFECTIOUS KERATITIS

A steadily increasing number of infections following laser in situ keratomileusis (LASIK) and photorefractive keratectomy (PRK) have been reported recently, leading to moderate to severe reductions in visual acuity in some eyes.³² The incidence is best provided by a study of 12 668 USA navy and army personnel with a total of 25 337 PRK procedures;³³ infectious keratitis developed in 5 eyes (1 in 5067 procedures) within 2–7 days due to Gram-positive bacteria (GPB). GPB (*Staph. aureus*, coagulase-negative staphylococci, *Str. pneumoniae* and viridans streptococci,^{33–35} MRSA,^{36,37} *Actinomyces* spp.³⁸), mycobacteria (*M. chelonae*^{39–43}) and *Nocardia*⁴⁴ are the common causative organisms. Gram-positive infections are more likely to present within 7 days of LASIK and to be associated with pain, discharge, epithelial defects and anterior chamber reactions. Mycobacterial infections are more likely to present 10 or more days after LASIK surgery. Fungal infections are associated with redness and tearing on presentation and can cause severe reduction in visual acuity; isolates include *Candida parapsilosis*,^{45,46} *Aspergillus fumigatus*,⁴⁷ *Alternaria* spp.,⁴⁸ *Aureobasidium pullulans*,⁴⁹ *Exophiala dermatitidis*⁵⁰ and *Exophiala jeanselmei*.⁵¹ *Acanthamoeba* spp. have been reported recently following refractive surgery for the first time.⁵² An early flap lift and repositioning within 3 days of symptoms has been recommended for better visual outcome.³²

DIAGNOSIS AND TREATMENT

Early diagnosis, appropriate laboratory testing and aggressive antimicrobial therapy can result in good outcomes. Antibiotics are given as for suppurative keratitis above. Topical quinolones are suitable for most GPB except MRSA, when topical vancomycin should be used, and will treat some but not all mycobacteria, when amikacin should be used. Therapy for *Nocardia* spp. and *Acanthamoeba* spp. are given above.

PROPHYLAXIS

Topical quinolones are well suited for this purpose, in particular levofloxacin 0.5%, which should be given at least twice in the 1 hour preoperatively and every 6 h postoperatively for 1 week to suppress contaminating conjunctival bacteria.

The newer ‘fourth-generation’ quinolones – moxifloxacin and gatifloxacin – should be reserved for therapy only.

ENDOPHTHALMITIS

Endophthalmitis implies infection of the vitreous, retina and uveal coats of the eye. It is commonly exogenous and encountered as a complication of intraocular surgery or refractive surgery, or following suture removal after cataract or corneal graft surgery. Alternatively, it may be caused by penetrating eye injury. Organisms introduced into the anterior chamber at the time of cataract surgery may give rise to an acute endophthalmitis. Less pathogenic organisms may induce chronic infection. Some cases of endophthalmitis result from contaminated irrigation fluids, which may lead to an epidemic of infections. The formation of thin-walled drainage blebs after glaucoma operations using mitomycin C may predispose to late infections. The risk of infection is reduced by application of 5% povidone-iodine to the cornea and conjunctiva immediately before surgery.⁵³

Less commonly, endogenous or metastatic endophthalmitis may arise in association with septicemia. This may result from bacterial endocarditis, infusion of contaminated fluids, the presence of infected intravenous lines or in intravenous drug users using contaminated needles or syringes commonly associated with *Candida albicans* infection. In children, pneumonia due to *Ps. aeruginosa* may be the cause of a bilateral endophthalmitis which rapidly leads to blindness.

Patients can present with a fulminant endophthalmitis within 5 days of cataract surgery, often leading to permanent loss of vision. Alternatively, a subacute or chronic endophthalmitis may occur within 12 weeks of surgery, often presenting as a hypopyon uveitis. Risk factors include duration of surgery, iris manipulation, torn posterior capsule with vitreous loss, lens fragments in the vitreous and type of intraocular lens, with silicone intraocular lenses being more commonly associated with infection.⁵³

Causes of acute endophthalmitis include *Str. pyogenes*, *Staph. aureus* and Enterobacteriaceae and, with penetrating injury, *Bacillus* spp. and clostridia. Acute endophthalmitis occasionally follows squint surgery, when infection is usually due to *Staph. aureus*. Surgeons should use appropriate prophylaxis against *Staph. aureus* in atopic or allergic patients. Causes of chronic endophthalmitis include coagulase-negative staphylococci, *P. acnes* and, occasionally, viridans streptococci. Polymicrobial endophthalmitis is also reported, particularly after injury.

DIAGNOSIS AND TREATMENT

Acute endophthalmitis

Endophthalmitis is potentially blinding from irreversible retinal damage occurring within 24–48 h of onset. Early diagnosis and prompt treatment are essential. Bacterial endophthalmitis

is treated with a combination of intravitreal and systemic antibiotic therapy. Subconjunctival therapy currently has no place in treatment and reliance should not be placed on intravenous therapy alone.

The clinical diagnosis of endophthalmitis is based on the presence of pain, vision loss, lid swelling and redness of the eye, including chemosis. A hypopyon uveitis may be present and, most importantly, loss of the red reflex. The vitreous is often opaque.

Microbiological diagnosis requires a vitreous biopsy for smears and cultures. PCR is useful for diagnosis and may yield a higher positive rate than direct culture, especially for Gram-negative organisms.^{53–56} A simultaneous intravitreal injection of an antibiotic combination is given at the time of sampling and repeated at intervals (e.g. 48–72 h) depending on the expected intravitreal persistence of the selected drug and the clinical response (see Table 53.2, p. 671, for dosages); empirical combinations include vancomycin and ceftazidime or vancomycin and amikacin, with restricted use of intravitreal gentamicin due to the macular infarction that it can cause. Unpreserved dexamethasone (400 µg) is given by intravitreal injection to reduce the vitreous inflammatory response and subsequent vitreous organization.⁵⁷

Additional systemic therapy with the same antibiotic as used for intravitreal therapy will maintain effective intravitreal levels for longer by reducing outward diffusion through the retina. High doses are required and there is a need to be aware of the risks of systemic toxicity.

Antibiotic therapy is modified after 24–48 h according to the clinical response and to the antibiotic sensitivity profile of the cultured organism.

Chronic endophthalmitis

A diagnosis of chronic endophthalmitis should be considered in patients presenting late, several days or weeks after surgery, with a ‘hypopyon uveitis’ that has failed to respond to routine topical antibiotic and steroid therapy. Symptoms are less marked than in acute endophthalmitis. Vision loss may be more evident than pain. Chronic endophthalmitis is usually caused by indolent organisms such as coagulase-negative staphylococci or *P. acnes*, capable of forming a biofilm on the lens implant and causing a granular or saccular endophthalmitis.^{12,57}

Diagnosis may be established as late as 1 year after surgery, by an aqueous or vitreous tap, followed by Gram stain and culture or PCR. Microbiological diagnosis may await explantation of the implant and histological examination of the implant and capsular bag.¹²

Initial treatment should commence with oral clarithromycin 500 mg every 12 h for 1 week, followed by 250 mg every 12 h for 3 weeks, as a ‘trial of therapy’.^{13,14} A good response, when it occurs, may be due to concentration of the drug within macrophages containing bacteria.^{12,13} If this treatment fails, then further intravitreal therapy should be given, with emphasis on drugs against Gram-positive organisms, such as vancomycin. Capsulectomy, vitrectomy and removal of the

intraocular lens, with or without lens exchange, may be necessary to eradicate the organism.

PROPHYLAXIS AGAINST POSTOPERATIVE INFECTION

Several approaches can reduce the risk of endophthalmitis following intraocular surgery:

- Meticulous preoperative preparation with occlusive drapes
- Irrigation of the operative field with povidone-iodine (5%)
- Avoidance of contamination of the intraocular lens during insertion
- Use of antimicrobials

Postoperative infection is the most common form of exogenous bacterial endophthalmitis. Sources of organisms include the patients themselves (conjunctiva, cornea and nasolacrimal duct), surgeon (hands, gloves, nose, technique), contaminated instruments, implants, drugs, irrigations and infusions, and environmental sources. Phaco machines, vitrectomy machines and viscoelastic materials may all be sources of infection. Metastatic endophthalmitis occurs after contaminated intravenous infusions and blood transfusions.

Eyelid and conjunctival sac commensals are responsible for 80% of postcataract surgery endophthalmitis. Since eyelid cultures vary from day to day, preoperative cultures are no longer performed, and reliance is placed on preoperative antiseptic preparation with povidone-iodine and an aseptic technique.⁵³

CATARACT SURGERY

The rate of endophthalmitis following modern cataract surgery is 0.1–0.7%. While this rate is low, the risk of blindness presents a challenge to reduce infection.

Some bacteria (predominantly coagulase-negative staphylococci or *P. acnes*) enter the chamber during cataract surgery. Re-entry of the anterior chamber increases this risk. DNA typing of postoperative staphylococcal cultures from lids and those causing endophthalmitis has shown similarity in 85% of cases, suggesting that most patients become infected by their own bacterial flora. To combat this, some surgeons add an antibiotic, such as gentamicin 5 mg/L or vancomycin 10 mg/L, to the irrigant fluid. While this is controversial, there is anecdotal evidence that this approach may reduce the incidence of postoperative endophthalmitis.

Intracameral injection with 1 mg cefuroxime (0.1 mL of 10 mg/mL) around the intraocular lens at the end of surgery has been associated with an incidence of endophthalmitis as low as 0.06%.⁵⁸ This technique was evaluated in the ESCRS Endophthalmitis Study which compared prophylaxis of phacoemulsification cataract surgery prospectively in 16 000 patients with intracameral cefuroxime 1 mg versus topical

levofloxacin 0.5% in a $\times 5$ pulsed dose, as described in the pharmacokinetic section, with the combination and with neither.⁵³ The overall rate of postcataract surgery endophthalmitis was reduced by five times, from 0.3% to 0.06%, in the groups given intracameral cefuroxime. In addition, seven patients developed severe streptococcal infection, with loss of vision in three, in the group of 8000 patients not receiving cefuroxime. However, there was a trend, but not statistically significant, for use of topical levofloxacin drops as well as intracameral cefuroxime. Unfortunately, in the trial design, dosing with the levofloxacin drops was not continued from the pulsed dose regime given at the time of surgery (see Fig. 53.2) until the following morning. This allowed drug levels to fall in the important first 12 h after contamination of the anterior chamber had taken place at the time of the intraocular lens insertion. It is now recommended that dosing with topical levofloxacin should be continued on a 2-hourly basis from the time of surgery until the patient sleeps at night, recommencing 6-hourly on waking for 1 week.

Newer generation fluoroquinolones (moxifloxacin, gatifloxacin) have been promoted as a potential substitute for intracameral cefuroxime. Recent reports, however, describe steadily increasing resistance among endophthalmitis isolates to these fluoroquinolones. Over the period 1990–2004, in 111 ocular endophthalmitis isolates of coagulase-negative staphylococci (CNS), 67.6% being *Staph. epidermidis*, the percentage of strains sensitive to moxifloxacin declined significantly from 96.6% (1990–1994) to 65.4% (2000–2004) ($p = 0.03$), a 32.2% decline over a relatively short period of time.⁵⁹

A significant increase in the prevalence of resistant isolates was also documented for moxifloxacin over this time period ($p = 0.007$), with the MIC₉₀ for moxifloxacin increasing by a factor of 266. The concentrations required to inhibit or kill 90% (the MIC₉₀) rose from 0.12 µg/mL (for 93.2% of isolates) during 1990–1994, to 4 µg/mL (for 100% of isolates) during 1995–1999, and to 32 µg/mL (for 100% of isolates) during 2000–2004.⁵⁹ Overall, only 72.1% of 111 CNS isolates recovered from patients with clinical endophthalmitis were sensitive to moxifloxacin (sensitivity defined as susceptible to 0.5 µg/mL or less).

In the ESCRS study, two of the five *Staph. epidermidis* isolates tested showed reduced susceptibility to moxifloxacin.⁵⁶ This trend – together with reports describing postoperative endophthalmitis after peri- and postoperative use of moxifloxacin and gatifloxacin,⁶⁰ the potentially unresolved question of safe dosage (especially for intracameral use of moxifloxacin)⁶¹ and cautionary statements that moxifloxacin should not be injected directly into the eye⁶² – suggests that large scale randomized trials are needed to validate either prophylaxis with topical moxifloxacin or gatifloxacin, or for intracameral injection of moxifloxacin.

Subconjunctival antibiotics (cefuroxime 125 mg or gentamicin 20 mg) have been given at the end of surgery for many years. Cefuroxime provides good antibiotic prophylaxis against *Staph. aureus*, *Str. pyogenes*, coagulase-negative staphylococci and *P. acnes*. Gentamicin gives poor coverage

against streptococci and *P. acnes*. The subconjunctival route of prophylaxis is not proven to be effective and has been given to many patients who suffer from postoperative infectious endophthalmitis.

Contact between the intraocular lens implant and conjunctiva during insertion can be avoided using injectable foldable lenses. Careful wound closure is also important. It has been suggested that if just one suture was used to close the clear corneal incision made at the time of surgery, then there would be no need for prophylactic antibiotics but surgeons prefer to try to close the wound with an injection of saline into the open edges of the corneal wound to avoid astigmatism from scarring around the suture. However, this wound is known to leak for several days postoperatively, during which time bacteria can egress back through the wound from the conjunctiva into the anterior chamber to cause infection.

Management of surgery in atopy

In the atopic *Staph. aureus* colonizes the skin, including the lids and nasal mucosa, to a high degree.^{1,2} Care is needed when planning intraocular surgery, particularly in the presence of blepharitis. The following additional regimen is suggested:

- Whole-body bathing, including shampooing with 4% chlorhexidine soap, for 72 h before surgery
- Topical antistaphylococcal prophylaxis with fusidic acid (Fucithalmic) for 24 h before surgery
- Intracameral cefuroxime 1 mg around the intraocular lens if having cataract surgery
- Fusidic acid 750 mg every 8 h postoperatively (enteric-coated capsules) or trimethoprim for 5 days.

PREVENTION OF ENDOPHTHALMITIS DUE TO AN INTRAOCULAR FOREIGN BODY

An intraocular foreign body represents a medical emergency, especially metal fragments arising from hammering farmyard equipment, soil-contaminated items and machinery. Seal and Kirkness⁶³ found that 8% of patients with an intraocular foreign body developed endophthalmitis, and half became blind.

Bacillus spp. are the most common virulent pathogens carried by an intraocular foreign body, while *Staph. aureus*, Enterobacteriaceae, streptococci and, occasionally, *Clostridium perfringens* are equally likely to cause sight-threatening endophthalmitis. All patients undergoing removal of a foreign body require intravitreal antibiotic prophylaxis. Any delay, or dependence on intravenous antibiotics alone, will risk blindness.⁶⁴ Intravitreal dexamethasone may reduce early inflammatory signs but may not influence visual outcome.⁶⁵

The regimen shown in Box 53.5 is suggested; cephalosporins are excluded because *Bacillus* spp. produce β -lactamases that inactivate them.

Box 53.5 Prophylaxis against endophthalmitis following intraocular foreign body

Essential prophylaxis

Intravitreal gentamicin 200 µg (or amikacin 400 µg) + vancomycin 1 mg (or clindamycin 1 mg)

Adjunctive prophylaxis

Subconjunctival gentamicin 40 mg + clindamycin 34 mg

Levofloxacin 0.5% (or other quinolone) + clindamycin 20 mg/mL

Intravenous therapy (with same drugs as given intravitreally) – give adequate dosage for weight but assay to avoid systemic toxicity, especially to the kidney and eighth nerve

ORBITAL CELLULITIS

Orbital cellulitis is an extraocular infection presenting with pain, proptosis and diplopia. A few cases follow penetrating injury or panophthalmitis, but most are secondary to sinusitis. The condition commonly affects children, spreading to the orbit across the thin orbital plate of the ethmoid bone. Delayed or inadequate treatment may lead to blindness or death. Retroseptal infection requires multidisciplinary management because of the risk of extension to the eye or cranial cavity. Loculated pus must be drained.

The lid swelling of preseptal cellulitis may resemble orbital cellulitis, but ocular movements are normal and globe inflammation absent in preseptal disease. Diagnosis can be resolved by MRI. It is associated with sinusitis, ocular infection and infected wounds.

Parenteral therapy is directed against common causative organisms: *H. influenzae*, *Staph. aureus*, *Str. pneumoniae* and *Str. pyogenes*. *H. influenzae* is the prominent cause of orbital cellulitis in young children and in this age group amoxicillin-clavulanic acid or cefuroxime are the drugs of choice. Due to the emergence of multiresistant strains of *H. influenzae*, cefotaxime should be given particularly when the clinical response is poor or resistant organisms are isolated from nasal swabs. In adults, therapy is directed against streptococci and *Staph. aureus*, with high-dose intravenous benzylpenicillin and flucloxacillin, clindamycin or vancomycin.

INFECTIONS DUE TO METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS

Methicillin-resistant *Staph. aureus* (MRSA) has become a prominent cause of antimicrobial-resistant infections, and this includes those involving the eye. MRSA causes the same spectrum of ophthalmic infections as methicillin-sensitive *Staph. aureus* (MSSA), and it is not clear that they are of greater virulence;⁶⁶ however, they are frequently resistant to multiple antibiotics and so may be more difficult to treat.

MRSA conjunctivitis is particularly common in elderly patients in residential care and has been found increasingly in some community settings.⁶⁷ Although originally primarily

healthcare associated, recent years have witnessed an upsurge in community-acquired MRSA (CA-MRSA), which has been reflected in their isolation from infections such as keratitis³⁷ and endophthalmitis⁶⁸ following photorefractive and cataract surgery. Although CA-MRSA frequently remains susceptible to the antibiotics favored in ophthalmological practice, such as chloramphenicol and quinolones, healthcare-associated strains are often resistant to the earlier quinolones. Experimental work has suggested that the newer quinolones with enhanced activity against Gram-positive bacteria, such as moxifloxacin, may have superior activity in MRSA endophthalmitis.⁶⁹ However, serious endophthalmitis due to MRSA should be treated with vancomycin by the intravitreal route and keratitis due to MRSA with vancomycin by the topical route. For less serious MRSA eye infections, such as conjunctivitis, other antimicrobials that can be administered include tetracyclines, linezolid and mupirocin which are active against most MRSA infections.

LYME DISEASE

Although ocular manifestations are rare in this tick-borne disease, the spirochete *Borrelia burgdorferi* invades the eye early and remains dormant, accounting for both early and late ocular manifestations. A follicular conjunctivitis occurs in approximately 10% of patients with early Lyme disease, and an interstitial keratitis within a few months of onset. Inflammatory events include orbital myositis, episcleritis, vitritis, uveitis and retinal vasculitis. When serology is negative, a vitreous tap may be required for diagnosis. Neuro-ophthalmic manifestations include bilateral mydriasis, neuroretinitis, pigmentary retinopathy, involvement of multiple cranial nerves, optic atrophy and disc edema. Seventh nerve paresis can lead to neuromotoric keratitis. In endemic areas, Lyme disease may be responsible for approximately 25% of presenting Bell's palsy.

Diagnosis is based on a history of exposure in an endemic area, positive serology and response to treatment. Antibodies may be measured by ELISA and Western blot. PCR has been used successfully for vitreous and cerebrospinal fluid. Serum reagent tests are non-reactive in Lyme borreliosis, but false-positive specific tests for syphilis (e.g. fluorescent treponemal antibody) can occur. The spirochetes have been identified in the vitreous of a seronegative patient with vitritis and choroiditis and cultured from an iris biopsy in a treated patient.

Therapy with doxycycline or amoxicillin is effective in the early stages but serious late complications require high doses of intravenous penicillin or ceftriaxone.

WHIPPLE'S DISEASE

Whipple's disease is a rare systemic disorder with malaise, fever, migrating arthralgias, fatigue, abdominal discomfort, diarrhea and weight loss. Ocular signs include uveitis, vitritis and

retinal vasculitis. Small bowel biopsy shows diastase-resistant PAS-positive macrophages in the mucosal lamina propria. The cause is a Gram-positive actinomycete called *Tropheryma whipplei*. There may be a predisposing immunodeficiency.

Antibiotics that penetrate the blood–brain barrier minimize central nervous system (CNS) complications. Relapse is common. Combination therapy is recommended – e.g. parenteral streptomycin and benzylpenicillin for 2 weeks followed by sulfamethoxazole (800 mg) and trimethoprim (160 mg) (co-trimoxazole) orally twice daily for 1 year.

TOXOPLASMA RETINOCHOROIDITIS

The intracellular protozoan *Toxoplasma gondii* can enter the fetal retina during intrauterine life to cause retinochoroiditis in the second and third decades, when it is the most common cause of posterior uveitis. However, primary toxoplasmosis, which may be subclinical or cause a glandular fever-like syndrome with lymph node enlargement, can produce an acute primary retinochoroiditis. Evidence from Brazil, where the prevalence of ocular toxoplasmosis is high, suggests that the condition is most commonly acquired postnatally.⁷⁰

Therapy is directed against the dividing organism and the inflammatory host response. Small peripheral retinal lesions may be allowed to run their course but lesions near the macula, optic disc or maculopapular nerve fiber bundle, or those associated with severe vitritis, should be treated. Treatment is complicated because tissue cysts, multiplying within retinal cells, are impervious to drug penetration, so that recurrence can be expected. *Toxoplasma* infection is encountered in immunocompromised patients.

TREATMENT

Pyrimethamine and sulfadiazine act synergistically to interfere with folic acid synthesis. They should be commenced early in the course of the disease and continued for 4–6 weeks (Box 53.6). Pyrimethamine therapy should be avoided in early pregnancy and monitored to exclude bone marrow depression. Folinic acid supplements reduce this risk, but platelet and white cell counts should be performed weekly.

Clindamycin has also been shown effective in the treatment of ocular toxoplasmosis but does carry the risk of pseudomembranous colitis.

OCULAR TOXOCARA (LARVA MIGRANS) INFECTION

Toxocara canis is a worm whose natural hosts are the cat and the dog. Humans are accidental hosts, infected by ingesting the ova from contaminated soil. The larval stage causes visceral and ocular larva migrans, but adult worms are not found. These larvae migrate and are deposited in the CNS, including

Box 53.6 Treatment of *Toxoplasma* retinochoroiditis

Regimen

Pyrimethamine^a 100 mg immediately then 25 mg orally per day for 4–6 weeks
and
Sulfadiazine 2 g immediately then 1 g orally every 6 h for 4–6 weeks
and
Folinic acid 3 mg orally or i.m. twice weekly.

Alternative regimen

Clindamycin^b 300 mg orally every 6 h for 4–6 weeks
and
Sulfadiazine 2 g immediately then 1 g orally every 6 h for 4–6 weeks.

^aPyrimethamine may cause bone marrow depression; leukocyte and platelet counts should be monitored weekly.

^bClindamycin may cause pseudomembranous colitis.

the retina. Here they can present as a possible tumor, usually unilateral, for which eyes have been enucleated in the past.

Serological tests only confirm previous exposure and may be negative when a choroidal lesion is present. Fine-needle biopsy in a reference center with cytology for tumor cells and PCR for *Toxocara* antigen is the best approach.

If the retinal lesion is close to the macula, treatment is warranted, with oral diethylcarbamazine 3 mg/kg for 3 weeks. There may be symptoms of allergic reaction to the dying larvae, for which prednisolone is given. Alternative therapies include albendazole or a single dose of ivermectin.

OCULAR ONCHOCERCIASIS

Ocular onchocerciasis, or ‘river blindness’, results from infection with the filarial parasite *Onchocerca volvulus*. The disease is endemic in areas of Africa and Central and South America, where it is a major cause of blindness. The ocular manifestations include keratitis, anterior uveitis, glaucoma, chorioretinitis and optic neuritis.

For several decades diethylcarbamazine and sumarain have been used systemically and have a positive effect on keratitis and uveitis; they are, however, less beneficial in posterior segment disease. The use of diethylcarbamazine may be followed by a severe systemic reaction, which is largely prevented by the use of systemic corticosteroids.

Ivermectin (single 12 mg dose) represents an important advance in the mass therapy of onchocerciasis in endemic areas. It inhibits reproduction by adult female worms so that no new microfilariae are produced for several months. It also kills microfilariae in tissues, including skin and the eye, slowly eliminating them from the anterior chamber with minimal ocular inflammation and little systemic reaction. It has to be given yearly so that the eradication program is a continuous one. Ivermectin should not be given to children under 5 years, to pregnant women or to patients with other severe infections such as trypanosomiasis.

Recently it has been recognized that onchocercal oocytes contain endosymbiotic organisms (*Wolbachia* spp.), which are passed on to the microfilaria and are essential to embryogenesis in the female worm. *Wolbachia* spp. are sensitive to tetracyclines, rifampicin, chloramphenicol and azithromycin. In a trial where doxycycline 200 mg/day for 4–6 weeks was combined with ivermectin, embryogenesis was disrupted for 24 months (1 year longer than ivermectin alone), and microfilaria were absent from the skin after 18 months.^{71,72}

Oral corticosteroid therapy is indicated in vision-threatening disease, but should not be used without concurrent, specific antiprotozoal therapy or in immunocompromised patients.

OCULOMYCOSIS

Fungal infections of the eye are invariably sight-threatening and include keratomycosis, exogenous or endogenous endophthalmitis and orbital mycosis. Although oculomycosis is rare in the UK, it may account for one-third or more of infective corneal ulcers in some rural settings and in developing countries.¹⁸ The management of keratomycosis is summarized in Figure 53.4.

The fungi responsible for keratomycosis, with the exception of *Candida* spp. (common in the UK and northern climates), are mainly filamentous. The species most frequently

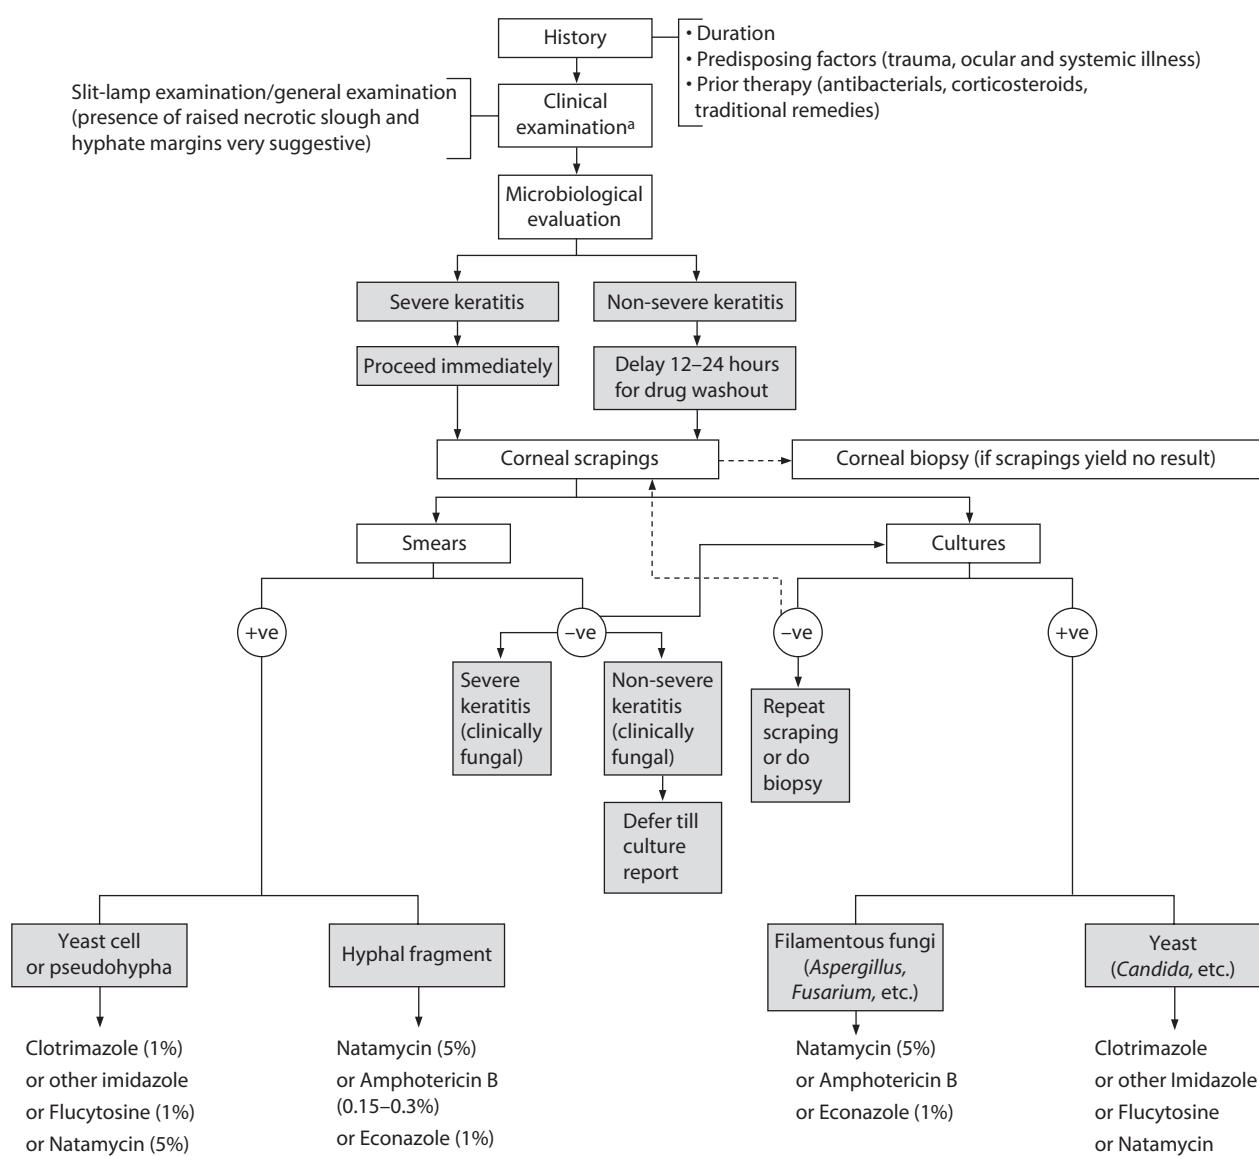

Fig. 53.4 Flow chart for investigating keratomycosis.

encountered are *Aspergillus*, *Fusarium* and *Curvularia*, but prevalence varies geographically. *Candida* spp. are an important cause of endogenous endophthalmitis in intravenous drug users and immunocompromised individuals.⁵⁷ Penetration of drugs such as natamycin and amphotericin B in the treatment of a fungal ulcer is greatly enhanced by the absence of an epithelial barrier.

Because of the toxicity of the most effective antifungal agents, the relatively narrow activity spectrum of some and the difficulties of clinical diagnosis, treatment is rarely instituted in the absence of direct evidence of fungal etiology, based at least on the results of smears. Filamentous fungi such as *Fusarium* spp. can be detected in the cornea in vivo by confocal microscopy, observing hyphal density and morphology, inflammatory and corneal cells,⁶⁹ or by histology of corneal biopsies (Fig. 53.4).

Effective therapy requires mycological identification and, preferably, information about drug sensitivity. The number of drugs available for local ocular use is limited, not only by problems of local and systemic toxicity, but also by poor solubility and ocular penetration. No commercial antifungal preparations are available in the UK for local ocular use; eye drops are formulated from parenteral preparations.

Amphotericin B is active against a wide range of fungal organisms causing oculomycosis including *Aspergillus* spp., *Fusarium* spp. (most but not all isolates) and *Candida* spp. It may be given topically as drops, subconjunctivally or intravitreally. Although it is toxic when used topically at high concentration, in part due to the presence of deoxycholate in the parenteral preparation, the 0.15% formulation is virtually non-toxic. Amphotericin B is given parenterally by slow intravenous infusion in the management of endophthalmitis, often in a background of more widespread systemic infection, in addition to intravitreal therapy. Renal and hematological status must be kept under surveillance and drug levels monitored.

Natamycin (pimaricin) is a tetraene antifungal agent which has been used in the topical treatment of a wide range of filamentous fungi that cause keratitis such as *Fusarium* spp. (particularly *F. solani*) and, to a lesser extent, *Aspergillus* spp. A 5% suspension is available commercially in the USA. It has some topical toxicity.

Imidazoles have also been used effectively in the topical treatment of keratomycosis: clotrimazole, miconazole and econazole are effective against *Candida* spp. and *Aspergillus* spp. but not against the majority of *Fusarium* spp. Generally they have been considered less effective than amphotericin B in clinical use. They can be locally toxic. Ketoconazole is well absorbed after oral administration and is generally well tolerated, although there is a risk of hepatotoxicity. It has been used effectively in oculomycosis caused by *Fusarium* spp., combined with another antifungal agent to prevent the emergence of resistance.

Topical fluconazole is effective in animal models and patients in the treatment of *Candida* keratitis and shows less protein binding than the imidazoles. Itraconazole also has

an enhanced therapeutic index compared to the imidazoles. *Candida* endophthalmitis can be effectively treated with oral fluconazole combined with intravitreal amphotericin B, but vitrectomy and fluconazole alone have also been reported to be successful. Aqueous levels of fluconazole 2 h after oral treatment with 20 mg were 2.7–5.4 mg/L and vitreous levels were up to 1.7 mg/L. Corneal levels were low (0.031 mg/L).

5-Fluorocytosine is active only against *Candida* spp. It is well absorbed by the oral route and achieves high blood and tissue levels. It has been used effectively in the treatment of *Candida* endophthalmitis, in combination with systemic or intravitreal amphotericin to prevent the otherwise rapid emergence of resistant strains. 5-Fluorocytosine has also been used topically (1% suspension) in the treatment of *Candida albicans* keratomycosis.

Thomas, reviewing the results of treating 318 patients with culture-proven keratitis,⁷³ found oral and/or topical ketoconazole and itraconazole useful in treating severe keratitis, especially that due to *Aspergillus* spp.

Fungal keratitis usually responds slowly to antifungal therapy over a period of weeks. Signs of toxicity (conjunctival chemosis and injection, recurrent corneal erosions) should also be observed. Negative scrapings during treatment do not always indicate that the fungus has been eradicated, since it may become deep seated; hence therapy should be maintained for 6 weeks or more. Confocal microscopy has proven valuable for managing treatment, observing morphological changes versus drug application.⁷⁴

Patients who respond most poorly to topical antifungal therapy are those with deep corneal infections and those who have received corticosteroids prior to diagnosis. Fungal growth is aided by corticosteroids and argues against their use alone, or in combination with antifungal agents. Voriconazole, one of the more recent triazoles, has been found effective for treatment of refractory *Aspergillus fumigatus* keratitis⁷⁵ as well as for a broad range of fungal pathogens.⁷⁶ Like voriconazole, caspofungin, which similarly covers a wide range of yeasts and molds, has been used with success in the treatment of endophthalmitis due to *Candida* spp.⁷⁷

Therapeutic surgery may be required for cases which respond poorly to medical therapy. However, therapy should be prolonged, to render the infecting fungus non-viable prior to surgery.

VIRAL INFECTIONS OF THE EYE

HERPES SIMPLEX EYE DISEASE

Herpes simplex keratitis (HSK) affects some 500 000 patients in the USA alone with about 50 000 episodes per annum and is the commonest cause of corneal opacification in the developed world. It is thus a major indication for corneal transplantation⁷⁸ with reported survival rates varying between 14% and 61%.

Primary ocular herpes simplex viral (HSV) infection is a self-limiting disease, expressed as blepharitis, conjunctivitis or punctate keratitis. Zosteriform spread along the fifth cranial nerve axons can then establish latency in the trigeminal ganglion; reactivation, with peripheral viral shedding, causes 'recurrent' disease expressed as epithelial keratitis (dendritic and geographic), stromal keratitis (disciform and necrotizing), limbitis, keratouveitis (and secondary glaucoma) or, rarely, acute retinal necrosis.

Ocular disease may be caused by two types of HSV: type 1 causes non-genital disease and has direct or indirect non-sexual transmission whereas type 2 is primarily sexually transmitted. Thus neonatal disease is usually acquired during birth and is caused by HSV-2 which has shown drug resistance.

An epidemic increase in genital herpes has been observed, hence it is expected that increased neonatal ocular herpes is likely, including delayed acute retinal necrosis syndrome.⁷⁹ Oral-genital transmission has become more common, hence HSV-1 is more frequently caused by sexual transmission. In childhood, herpetic keratitis is more frequently bilateral than when disease develops in adulthood. Children are more likely to suffer recurrent disease and significant visual loss including amblyopia.⁸⁰ Patients with severe atopic disease appear to be at greater risk of herpetic disease⁸¹ and atopy is also increasingly common in children.

HERPES ANTIVIRAL THERAPY

Epithelial keratitis

Early clinical trials established that trifluorothymidine (F3T) was more effective than idoxuridine (IDU) or debridement of the infected corneal epithelium, and that debridement added no adjunctive benefit to F3T alone. These early drugs were incorporated into host DNA and caused toxicity. They have been superseded by more effective non-toxic agents such as aciclovir and the prodrug valaciclovir. Systematic review has confirmed these are equivalent to F3T and IDU but do not cause toxicity.^{82,83} Oral aciclovir (200 mg five times daily) and topical 3% aciclovir (five times daily) are equally effective;⁸⁴ however, oral therapy is more expensive and two randomized controlled trials have demonstrated that 3% aciclovir is equivalent to either 0.05% or 0.15% ganciclovir.⁸⁵ Topical interferon may have additional benefit but as yet there is no evidence base for this.⁸⁶ It is expected that therapy will achieve healing within a week of commencement.⁸⁷

Aciclovir resistance has been documented with cross-resistance to ganciclovir and foscarnet.⁸⁸

Disciform keratitis

This describes a circular focus of corneal edema and is considered to be an immunological response to a viral antigen, hence it requires topical steroid therapy (G Predsol 0.5% five times daily). Antivirals are required to prevent viral shedding

and aciclovir combined with topical steroids has been shown to accelerate disease resolution. The HEDS project (Herpetic Eye Disease Study) addressed the need for steroids by double-blind, placebo-controlled, randomized controlled trial and demonstrated that steroids resulted in resolution of disciform disease at a median 27 days compared with 72 days for the placebo group; topical and oral aciclovir were equivalent both for disease control and recurrence rates.⁸⁹ Intraocular inflammation may be caused by stromal keratitis and is manifest by iritis with aqueous cells, flare and keratic precipitates.

Stromal keratitis

Stromal inflammation may cause progressive stromal lysis and corneal perforation and may be associated with dendritic ulceration. There is randomized controlled trial evidence that antiviral prophylaxis is effective during steroid management of stromal keratitis but no evidence that oral aciclovir influences the development of stromal keratitis in patients treated for epithelial disease.⁹⁰ In patients using long-term topical steroids, those with steroid-dependent stromal keratitis or those with corneal transplants, there is evidence that aciclovir prophylaxis is effective, but the duration of prophylaxis is not established.^{78,91}

Necrotizing retinopathies

These may be caused by either HSV-1 or HSV-2, the latter being a relatively rare but serious infection, usually among neonates. Visual loss occurs due to retinal necrosis or ischemic optic neuropathy and treatment is with high-dose antiviral therapy (Box 53.7) and high-dose oral prednisolone (at least 20 mg/day). Laser therapy or surgery may be indicated for the management of retinal detachment.

PROPHYLACTIC ANTIVIRAL THERAPY

The risk of recurrent HSK is 25% in the year following a first episode and 72% in 10 years,⁹² but this risk is reduced by prophylactic oral aciclovir 400 mg every 12 h.⁹³ It is especially effective for atopic patients.⁹⁴

Box 53.7 Systemic therapy for necrotizing herpetic retinopathy

Intravenous aciclovir 13 mg/kg per day in three divided doses for 14 days, then	
Oral aciclovir 800 mg five times a day	
Oral famciclovir 500 mg every 8 h for 3 months	More effective in immunocompromised patients
Intravitreal ganciclovir 400 mg twice a week, combined with intravenous foscarnet 60 mg/kg three times a week	May delay progress in immunocompromised patients

The risk of corneal transplant failure is determined in part by minimizing the risk of recurrent HSK; prophylactic aciclovir is effective in achieving this⁹⁵ and remains effective beyond 12 months.⁹⁶ Although valaciclovir is equally effective, the dosing may be more acceptable, thereby increasing compliance.⁹⁷

HERPES ZOSTER VIRUS

Involvement of the first division of the fifth cranial nerve by varicella zoster virus (VZV) is associated with ocular features ranging from blepharitis, to persistent conjunctivitis, keratoconjunctivitis, glaucoma, papillitis, ocular nerve palsy and neuralgic ocular pain. This is termed herpes zoster ophthalmicus (HZO).

Oral administration of aciclovir is now standard treatment for HZO at a dose of 600–800 mg five times daily, initiated within 72 h of the onset of skin lesions. It is well tolerated and reduces the incidence and severity of epithelial and stromal keratitis and uveitis. Treatment reduces pain in the acute phase, but not neurotrophic keratitis or postherpetic neuralgia. The higher bioavailability of valaciclovir and famciclovir has allowed their use in more convenient dosing schedules at 1 g every 8 h and 500 mg every 8 h for 7 days, respectively, with faster resolution of acute pain in herpes zoster infection. Placebo-treated patients in a trial of intravenous aciclovir therapy suffered progression until topical aciclovir was started.

Intravenous aciclovir has replaced vidarabine as the treatment of choice in the management of HZO in AIDS and other immunocompromised patients, and intravenous foscarnet has been used effectively for the treatment of those patients with aciclovir-resistant HZO.

Although the use of topical ocular steroids to suppress the inflammation does not have the dire consequences seen with HSV eye disease (e.g. induction of dendritic or geographic ulceration), outcome in those treated with aciclovir alone may be better than in those receiving steroids alone (aciclovir 3% ointment vs betamethasone 0.1% ointment, five times daily). No recurrence occurred in the aciclovir-treated group, whereas the recurrence rate was 63% in the steroid-only group. Such recurrences were more difficult to suppress than the initial disease features. Corneal epithelial disease healed significantly more quickly in the aciclovir patients.

ADENOVIRUS KERATOCONJUNCTIVITIS

Adenovirus (ADV) infection causes epidemic forms of clinical disease, including pharyngeal conjunctival fever (ADV-3, -4 and -7), follicular conjunctivitis (ADV-1–11 and ADV-19) and epidemic keratoconjunctivitis (EKC). EKC is a self-limiting disorder characterized by a follicular conjunctivitis and a multifocal keratitis, with subepithelial features developing at 10–14 days after the onset of the disease. These infiltrates can be confused with *Acanthamoeba* keratitis but with

Acanthamoeba infection they occur within the first 7 days after onset. These infiltrates may persist for weeks or months, giving rise to disabling symptoms of glare and discomfort. Although subepithelial infiltrates may be suppressed by topical steroids, they reappear on steroid withdrawal, with a return of symptoms. Therefore, in practice, steroids are used only for selected, highly symptomatic patients and are weaned slowly, over a period of months. It appears that topical ciclosporin (cyclosporin) can be used in a similar fashion. Nosocomial, hospital outbreaks of EKC may be reduced by establishing appropriate infection control policies.

No antiviral agents are available commercially for the treatment of adenovirus infection.

OTHER VIRAL INFECTIONS

Most cases of measles are associated with conjunctivitis. Measles keratitis is a major cause of blindness in developing nations where secondary infection and vitamin A deficiency are compounding factors. Although there is no specific antiviral agent available, topical antibiotics and systemic vitamin A supplements improve the prognosis.

ACQUIRED IMMUNE DEFICIENCY SYNDROME

Human immunodeficiency virus (HIV) has been identified in tear fluid, conjunctiva, corneal epithelium and retina, and can give rise to a retinal microangiopathy, but the principal ophthalmic manifestations of acquired immune deficiency syndrome (AIDS) relate to florid opportunistic infections and to conjunctival and orbital involvement with Kaposi's sarcoma and other neoplasms. Therapy is directed against the relevant organism and generally is more intense and prolonged than is required in immunocompetent individuals. Highly active antiretroviral therapy (HAART) in AIDS patients leads to a striking fall in HIV load and substantial improvements in immune functions, including increases in total CD4 and CD8 cell counts, in memory and naive T-cell subsets, and in antigen responses to certain opportunistic pathogens. HAART leads to improved survival and reduced progression of HIV disease, with complete or partial resolution of infections or malignancies.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is the most common of the ocular opportunists and produces a hemorrhagic, necrotizing retinitis. Because the onset of retinitis is often asymptomatic, it is recommended that in patients with AIDS with blood CD4⁺ counts below 50 cells/ μ L, ophthalmological examinations are carried out on a monthly basis. The onset or reactivation of CMV retinitis is heralded by elevated or rising blood CMV DNA levels.

During the first 7 years after infection, fewer than 1% of HIV-infected persons present with CMV retinopathy as the initial manifestation of AIDS, but CMV retinitis is found in approximately 18% of terminal AIDS patients, bilateral in about 17%. The delay from presentation with HIV infection is shorter in bilateral cases. HSV, Epstein–Barr virus and *Toxoplasma* occasionally cause a clinically similar retinitis.

In a study of CMV retinitis in AIDS patients, 58% presented with unilateral disease and 15% of these developed contralateral infection, despite treatment with ganciclovir. The risk factors for progression or involvement of the fellow eye have been reviewed.⁹⁸

The incidence of CMV disease and of CMV relapse has fallen significantly since the introduction of HAART,^{99,100} including the frequency of CMV-related retinal detachment. However, subclinical infections may be awakened at the initiation of HAART, and CMV retinitis may be activated when it is necessary to interrupt HAART for reasons of toxicity. At present, with the use of nucleoside and non-nucleoside analogs and protease inhibitors, CMV retinitis does not frequently pose an immediate threat to vision, but it may do so with development of retinal detachment, in association with peripapillary disease or by affecting the central retina. Retinal detachment, an important cause of blindness from CMV retinitis, can be treated successfully by vitrectomy, silicone oil and endolaser.

In patients with AIDS receiving HAART and treated additionally for CMV retinitis, it has been possible to withdraw anti-CMV therapy without major risk of reactivation of the retinitis for at least 48 weeks after ceasing antiviral therapy.¹⁰¹ Reactivation, if it occurs, is more likely in those patients whose CD4⁺ counts fall below 50 cells/ μ L and in whom there are signs of virological failure. At the time when CMV retinitis has become inactive, patients receiving HAART are at risk of developing a visually symptomatic ‘immune recovery’ vitritis or uveitis and macular edema, thought to represent a T-cell-mediated reaction to latent CMV antigens. The vitritis responds to treatment with periocular steroids without reactivation of the retinitis.

CMV retinitis occurring in AIDS patients implies a high risk for the development of CMV encephalitis. Vice versa, in patients with AIDS without CMV retinitis, CNS symptoms are unlikely to be attributable to CMV infection.

SYSTEMIC THERAPY

Progression of CMV retinitis may be delayed in the short term by intravenous ganciclovir or foscarnet.¹⁰² Repeated, local intravitreal therapy is more effective and particularly valuable when there are no signs of disseminated CMV disease. Ganciclovir, a virustatic drug similar in structure to aciclovir and foscarnet, improves or temporarily stabilizes the retinitis in the majority of patients receiving long-term maintenance therapy. Ganciclovir and foscarnet are equally effective in controlling CMV retinitis, but foscarnet is less well tolerated. Repeated therapy is indicated because of the high relapse rate. Ganciclovir is given by intravenous infusion over

1 h in a dose of 5 mg/kg every 12 h. Valganciclovir, the oral prodrug of ganciclovir, has excellent oral bioavailability, giving high ganciclovir blood levels without the need for prolonged intravenous access.

Intravenous administration of ganciclovir results in intravitreal concentrations which are subtherapeutic (0.93 ± 0.39 mg/mL) for many CMV isolates, which explains the difficulty of long-term complete suppression of CMV retinitis by this route.

Combined daily therapy with ganciclovir and foscarnet has been shown to be beneficial, with prolonged intervals between progression without increased toxicity. Such therapy may halt the progress of peripheral outer retinal necrosis in AIDS patients.

Improved results have been achieved with cidofovir treatment with 5 mg/kg once weekly for 2 weeks, then 5 mg/kg every other week, which retarded the progression of retinitis in AIDS patients compared to delayed therapy. Toxicity to cidofovir may occur in the form of proteinuria (23%), neutropenia (15%) and uveitis, and may lead to discontinuation of the drug.

INTRAOCULAR DELIVERY

Intravitreal injection of antiviral agents is effective in the treatment of CMV retinitis, and avoids the risk of systemic toxicity. Intravitreal ganciclovir or foscarnet has been given on a weekly basis with little local ocular complication and no greater risk of retinal detachment. An intravitreal dose of ganciclovir (0.2–0.4 mg) is as effective as intravenous therapy, and a dose of 2 mg in 0.05–0.1 mL probably provides adequate intravitreal levels (0.25–1.22 μ g/L) for up to 7 days. Levels at 24 h have been recorded as 143.4 μ g/L and at 72 h as 23.4 μ g/L. This higher dose (2 mg) has been used effectively to produce prolonged remission, with a low relapse rate (5% at 44 weeks).¹⁰³ The intravitreal dose of foscarnet is 2.4 mg in 0.1 mL. A lower dose of these agents has been given in patients whose eyes contain silicone oil in relation to retinal surgery.

Intravitreal cidofovir, together with oral probenecid, has also been effective in halting progression of CMV retinitis. Fomivirsen is an antisense oligonucleotide newly approved for intravitreal use.

More recently, the development of intraocular controlled-release devices has provided the opportunity to deliver drugs for prolonged periods with minimum local toxicity. Rhegmatogenous detachments can occur in CMV retinitis, with or without systemic treatment or ganciclovir implant therapy, but implants do not appear to increase the risk of detachment.¹⁰⁴

TOXOPLASMA

Ocular toxoplasmosis in patients with AIDS is less common than CNS involvement. It may be the cause of presentation, with blurred vision and floaters, or pronounced visual loss from macular, papillomacular bundle or optic nerve head involvement.

The retinochoroiditis is unassociated with a pre-existing retinochoroidal scar, suggesting that the lesions are a manifestation of acquired rather than congenital disease. Lesions may be single or multifocal, in one or both eyes, or consist of massive areas of retinal necrosis. They may resemble those of CMV retinitis and may occur concurrently in the same eye. In comparison, toxoplasmic lesions tend to be thick and opaque, with smooth borders and a relative lack of hemorrhage.

Treatment of toxoplasmic ocular infection with pyrimethamine, clindamycin and sulfadiazine is effective in over 75% of patients. Once resolution is observed, maintenance therapy is continued, as relapses occur in the absence of treatment. Corticosteroid treatment is unnecessary and its use has been associated with the development of CMV retinitis.

PNEUMOCYSTIS JIROVECII

Pneumocystis jirovecii (formerly *Pneumocystis carinii*) can cause a choroidopathy as a result of systemic spread from primary lung infections. Multiple yellow placoid fundus lesions are seen.

CANDIDA ALBICANS AND CRYPTOCOCCUS NEOFORMANS

These can also produce retinal lesions or endophthalmitis, particularly in AIDS patients who are intravenous drug users. A bilateral epithelial keratopathy caused by *Encephalitozoon* has been described in an HIV-positive patient with cryptococcal meningitis, which responded to itraconazole given for the meningitis.

HERPES ZOSTER OPHTHALMICUS

This occurs in a more severe and chronic form in AIDS and may require prolonged systemic penciclovir therapy.

MICROSPORIDIA

Microsporidial keratoconjunctivitis in a patient with AIDS has responded to treatment with dibromopropamidine isethionate ointment.

OTHER INFECTIONS

VIBRIO SPECIES

In the coastal regions of the Gulf of Mexico, infections with *Vibrio* spp. are responsible for gastroenteritis, wound infections and septicemia. Penland et al¹⁰⁵ reported *Vibrio* spp. as a cause of conjunctivitis, keratitis and endophthalmitis on the Texas Gulf Coast, often following eye trauma with contaminated

water containing shellfish or exposure to brackish sea water. Responsible organisms include *V vulnificus*, *V albensis*, *V fumigatus* and *V parahaemolyticus*. Jung et al reported a case of endogenous endophthalmitis from South Korea caused by *V vulnificus* after ingestion of raw seafood.¹⁰⁶

54 Urinary tract infections

S. Ragnar Norrby

This chapter deals with cystitis, pyelonephritis, prostatitis and urethritis caused by pathogens other than sexually transmitted ones such as *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis* and *Ureaplasma urealyticum*. Cystitis and pyelonephritis are characterized by significant bacteriuria, which was originally defined by Kass as 10^5 colony forming units (cfu) or more per mL in each of two voided urine samples or any bacterial count in urine obtained by catheterization or bladder puncture.¹ This concept has now been redefined (Table 54.1), based on studies showing that by lowering the bacterial counts and including pyuria, the diagnostic sensitivity can be increased without marked loss of specificity.^{2–4}

Both cystitis and pyelonephritis can be classified as symptomatic or asymptomatic, complicated or uncomplicated, and sporadic or recurrent. This classification is meaningful because etiology, choice of antibiotics, treatment times and needs for follow-up differ considerably between the various types of infection. The approximate frequencies of the various types are outlined in Table 54.2.

Asymptomatic bacteriuria is common in girls and occurs in 1–7% of adult women, depending on age. All patients with long-term urinary catheters have significant bacteriuria, which in most cases is asymptomatic. Many patients with cystitis who do not respond bacteriologically to antibiotic treatment but have persistent bacteriuria are also asymptomatic.

Complicated cystitis or pyelonephritis is defined as infections in patients with anatomical or functional defects which facilitate establishment of bacteriuria and/or make elimination of bacteriuria difficult. Examples of such defects are congenital anomalies of the urethra, ureters or kidneys, foreign bodies (stones, catheters), residual bladder urine due to obstruction or neurological disease, tumors and obstructions of the urethra by strictures, prostate hyperplasia, prostate cancer or prostatitis. Diseases that may aggravate the course of pyelonephritis (e.g. diabetes mellitus with nephropathy and malignant hypertension) are sometimes considered complicating factors. However, these conditions do not increase the risk of establishment of bacteriuria. Significant bacteriuria in a man should always be considered a complicated urinary tract infection; the length of the male urethra prevents ascending infections and establishment of bacteriuria in a healthy man.

Cystitis and pyelonephritis are often recurrent infections, both in patients with uncomplicated and complicated infections but more commonly in the latter. Recurrent urinary tract infections can be subclassified into relapse, when the same bacterial strain that caused the previous episode is isolated, or reinfection, when the causative pathogen is a new strain. There is no internationally accepted definition of a recurrent urinary tract infection. In clinical trials it is often defined as more than one episode in 6 months or more than two episodes in 1 year. Consequently, sporadic infections occur less than twice per 6 months or less than three times per year. It should be noted that this classification does not include chronic infections; chronic pyelonephritis and chronic glomerulonephritis are inflammatory diseases, albeit often aggravated by infections.

Urethritis is an inflammation of the urethra without concomitant significant bacteriuria. In patients with sexually transmitted diseases, urethritis is a well-defined concept (see Ch. 56). However, when such organisms are not identified and significant bacteriuria is not present, the 'urethral syndrome' becomes a microbiologically poorly defined disease, usually without identified etiology.

Prostatitis is an inflammation of the prostate gland, which often also involves the seminal vesicles. When prostatitis is caused by bacterial pathogens it is subdivided into acute and chronic bacterial prostatitis, which may or may not be associated with significant bacteriuria.

Table 54.1 Definitions of bacteriuria in midstream urine samples. Note that in all patients with symptomatic infections, pyuria must also be present⁴

Type of infection	Definition
Acute uncomplicated cystitis in women	
Infections caused by Gram-negative bacteria	$\geq 10^3$ cfu/mL
Infections caused by staphylococci	$\geq 10^2$ cfu/mL
Acute uncomplicated pyelonephritis	
Infections caused by Gram-negative bacteria	$\geq 10^4$ cfu/mL
Infections caused by staphylococci	$\geq 10^3$ cfu/mL
Complicated infections and infections in men	$\geq 10^4$ cfu/mL
Patients with asymptomatic bacteriuria	$\geq 10^5$ cfu/mL in two samples

From Rubin EH, Shapiro ED, Andriole VT, Davis RJ, Stamm WE. Evaluation of new anti-infective drugs for the treatment of urinary tract infections. *Clin Infect Dis*. 1992; 15(suppl 1): S216–S227.

Table 54.2 Approximate frequencies of various types of symptomatic urinary tract infections in an unselected material of outpatients with significant bacteriuria

Type of urinary tract infection	Approximate frequency (%)
Cystitis	90
Pyelonephritis	10
Uncomplicated infections	98
Complicated infections	2
Sporadic infections	75
Recurrent infections	25

EPIDEMIOLOGY AND PATHOGENESIS

Urinary tract infections occur in all ages and are most common in sexually active women. Below the age of 3 years, symptomatic cystitis or pyelonephritis is somewhat more common in boys than in girls due to the higher frequency of congenital defects of the male urethra. In very old people bacteriuria is more common in men than in women due to the high frequency of prostate disease.

Cystitis and pyelonephritis are infections resulting from the aerobic fecal flora.⁵ The pathogenesis of these infections should be considered from two aspects: host factors and virulence factors of the infecting organisms.

HOST FACTORS

Host factors of importance for establishment of bacteriuria are the ones mentioned above defining a complicated cystitis or pyelonephritis. In addition, the short length of the female urethra explains the higher frequency of bacteriuria in adult women than in adult men. Also in women without urinary tract defects bacteria can ascend the urethra and reach the bladder. In postmenopausal women atrophy of the vaginal mucosa constitutes an important and usually treatable (with topical or systemic estrogen) complicating factor, which is surprisingly often overlooked.

Establishment of significant bacteriuria in a woman is facilitated by a high number of bacteria in the periurethral area. This is achieved during sexual intercourse, which often leads to bacteriuria if the bladder is not emptied post-coitus.

In men, especially those who are sexually active, the source of a bacteriuria may be prostatitis. Otherwise a prerequisite for bacteria to reach the bladder in sufficient amounts to establish bacteriuria is a turbulent urine flow, which may result from strictures or obstruction of the urethra.

Irrespective of age and gender, pyelonephritis almost invariably results from bacteria ascending the ureters. This is facilitated by defects in the ureteral bladder sphincters causing ureteric reflux during micturition. Such defects may be congenital but are also common in pregnant women during the

latter half of pregnancy due to the pressure of the uterus on the bladder. Pyelonephritis is also common in patients with ureteral stones or stones in the renal pelvis. Pyelonephritis and renal abscesses resulting from hematogenous dissemination of bacteria from other infectious foci is extremely rare but may be seen in patients with endocarditis.

VIRULENCE FACTORS

Virulence factors of the organisms causing cystitis and pyelonephritis have been extensively studied. With the most common etiological agent, *Escherichia coli*, it has been demonstrated that an important virulence factor is the ability of the bacterial cells to adhere to epithelial cells in the urinary tract mucosa.⁶ This is achieved by antigens located on the fimbriae of the bacteria, which adhere to glycosphingolipid receptors on the epithelial cells. As a result of adherence, transportation of bacteria in the urethra and the ureters is facilitated. Another consequence of adherence is that cytokines (e.g. interleukins 1, 6 and 8) are released and that invasive infections are facilitated.⁶⁻⁸ Adherence is important in patients without complicating factors but seems less important when such factors are present.⁹ Other defined bacterial virulence factors are the antigenic structures of Enterobacteriaceae, the O, H and K antigens and the polysaccharide capsules. Virulence factors in Gram-positive organisms of importance in urinary tract infections are less extensively studied. In some situations (e.g. after treatment of bacteriuria caused by Gram-negative bacteria) the pathogenicity of Gram-positives in an asymptomatic patient should be questioned.¹⁰

ETIOLOGY

Bacteriuria is acquired by the fecal-genital route, often via periurethral colonization in women. With the exception of patients who have rectovesical fistulas or other abnormal communications between the bladder and the intestines or vagina, anaerobic bacteria rarely cause bacteriuria. The most common organisms causing bacteriuria are listed in Table 54.3.

In women with sporadic uncomplicated cystitis or pyelonephritis, the etiology is quite predictable; about 85% of these patients will have infections caused by *Esch. coli*. The second most common organism is *Staphylococcus saprophyticus*, which accounts for about 10% of the infections. However, in north Europe *Staph. saprophyticus* has a seasonal pattern:¹¹ it is normally not found between November and March and reaches a peak in July and August, when it causes up to 40% of all uncomplicated infections. The reason for this variation is unknown and it is not seen in the Southern Hemisphere.¹²

Esch. coli is also the most common etiology in recurrent and/or complicated cystitis and pyelonephritis but other Gram-negatives as well as enterococci become increasingly frequent. Of importance in these patients is the antibiotic treatment given for the preceding episode, which is likely to have

Table 54.3 Etiology of cystitis and pyelonephritis

Bacterial species	Dominating type of infection
<i>Escherichia coli</i>	All types
<i>Staphylococcus saprophyticus</i>	Uncomplicated cystitis and pyelonephritis in women during April to September
<i>Klebsiella</i> spp.	Recurrent/complicated infections
<i>Enterobacter</i> spp.	Recurrent/complicated infections
<i>Enterococcus</i> spp.	Recurrent/complicated infections
<i>Proteus</i> spp.	Tumors or stones
<i>Morganella morganii</i>	Recurrent/complicated infections
<i>Pseudomonas</i> spp.	Recurrent/complicated infections, bladder catheters
Other organisms	Recurrent infections

selected resistant organisms. Organisms such as *Enterobacter* spp., *Pseudomonas aeruginosa*, *Pseudomonas* spp., *Acinetobacter* spp., *Burkholderia* spp. and *Citrobacter* spp. typically appear in patients who have received repeated antibiotic courses or who have acquired their bacteriuria in hospital.

Proteus spp., *Morganella morganii* and *Providencia* spp., which all grow in alkaline pH, are common findings in patients with kidney or bladder stones or tumors. Since *Proteus* spp. is also common in the preputial flora, it is often a contaminant in urine samples from young boys.

Fungal growth in the urine is in most cases due to *Candida albicans* or other *Candida* spp. The clinical importance of funguria is uncertain or doubtful in patients with bladder catheters. In patients without catheters growth of *Candida* may reflect a renal infection resulting from hematological dissemination of the organisms. In rare cases candiduria is also seen as a result of the formation of a mycelial ball in the bladder.

DIAGNOSIS

CLINICAL DIAGNOSIS

Patients with cystitis are afebrile and the dominating symptoms are dysuria, frequent micturition and/or suprapubic pain. Sometimes macroscopic hematuria is present, especially in infections caused by *Staph. saprophyticus*.¹¹ With the exception of hematuria these symptoms are difficult or impossible to differentiate from those of urethritis unless the patient has a urethral discharge.

Pyelonephritis is a systemic infection; the patients develop fever and may have signs of septicemia, which occurs in up to 30% of patients with this infection.⁹ Other symptoms are chills and flank pain. Differential diagnoses are urinary stones, cholecystitis, appendicitis and basal pneumonia. The clinical symptoms of pyelonephritis are often masked by patients taking drugs with analgesic and/or antipyretic activity.

In children urinary tract infections often present with few clinical symptoms and fever may be the only symptom of pyelonephritis.

Acute prostatitis is characterized by symptoms similar to those of cystitis but the patient also has a distinct tenderness and enlargement of the prostate at rectal palpation. In chronic prostatitis the symptoms may be more diffuse and the prostate is often normal at rectal examination.

RADIOLOGICAL DIAGNOSIS

Radiological examinations are rarely indicated in the acute phase of a urinary tract infection. An exception is when an obstruction of a ureter is suspected in a patient with signs of pyelonephritis. In children with pyelonephritis or with recurrent cystitis, radiological examinations for identification of congenital anatomical defects and/or ureteral reflux should be performed after treatment of the acute infection. For detection of vesicoureteral reflux in children, contrast-enhanced ultrasound is recommended as a better alternative to micturating cystourethrography.¹³

In adults who have recovered from pyelonephritis it is recommended that ultrasound or a radiological examination is performed to exclude renal scars from childhood episodes of pyelonephritis.^{14,15}

LABORATORY DIAGNOSIS

The keystone in the diagnosis of cystitis and pyelonephritis is the demonstration of significant bacteriuria. The reference technique is the quantitative urine culture. The sample can be obtained as a clean-catch (midstream) urine or by bladder puncture or catheterization. Bladder puncture is the preferred technique in small children, especially boys. After sampling, the urine must be kept chilled (but not frozen) until analyzed. If there is likely to be a delay in transportation to a laboratory, a dip-slide culture can be used. With this technique an agar-covered slide is dipped in urine and incubated overnight at room temperature or a small incubator. It provides results in terms of quantity of bacteria and differentiation of Gram-negative and Gram-positive organisms. The slide can then be sent to a microbiological laboratory for determination of species and antibiotic susceptibility.

In patients with infections caused by Gram-negative bacteria other than *Pseudomonas* spp. bacteriuria can also be demonstrated by the nitrite test, a rapid paper-strip test. Nitrite is formed by bacterial metabolism of nitrate and is not normally present in urine. A positive nitrite test has a very high specificity. The sensitivity, however, is low because the method requires bladder incubation and because Gram-positive bacteria and *Pseudomonas* do not form nitrite.

Urine cultures should always be obtained in patients with complicated infections, recurrent infections or pyelonephritis. In patients with sporadic uncomplicated cystitis, etiological diagnosis should be optional, especially when the local antibiotic susceptibility pattern is known.

A marker for significant bacteriuria is pyuria. Demonstration of pyuria is best achieved by microscopy of unspun urine using a Bürker counting chamber and defining pyuria as $>10 \times 10^6$ leukocytes per liter of urine. The second-best method is to use a leukocyte esterase paper-strip test. Sediment microscopy has a low reliability because it is a technique that cannot be standardized.¹⁰ Marked pyuria in a patient with negative bacteriological cultures should lead to a suspicion of renal tuberculosis (*see Ch. 58*).

There is no specific laboratory test for the differentiation of cystitis from pyelonephritis. Patients with pyelonephritis normally have increased serum concentrations of C-reactive protein and peripheral white blood cell counts may be increased. Erythrocyte sedimentation rate is not always increased when the patient is first seen but is likely to rise during the following days. A regular finding in patients with acute pyelonephritis is that the concentration ability of the kidneys is reduced. This can be measured as urine osmolality after 12 h of no fluid intake or, more easily, by a subcutaneous (not nasal) challenge with antidiuretic hormone. However, this test cannot be used when the patient is febrile and it is therefore a confirmatory test, which can be done once the patient's condition has improved.

Bacteria causing pyelonephritis form complexes with antibodies. Therefore, detection of antibody-coated bacteria by immunofluorescence has been used as a method to differentiate cystitis and pyelonephritis. However, this test has tended to show a high frequency of false-positive results if a reasonable sensitivity is strived for, or too many false-negative results if the specificity of the test is high.

The etiological diagnosis of prostatitis is difficult. The most ambitious technique is to culture four samples:

- The first portion of a voided urine sample
- A midstream urine portion
- Prostate secretion obtained by rectal massage of the prostate
- The first portion of new voided urine sample.^{16,17}

Patients with acute or chronic bacterial prostatitis should be culture positive with the same organism in all four of these samples.

ANTIBIOTIC TREATMENT

Antibiotic treatment of cystitis and pyelonephritis is normally empirical. Women with acute cystitis are rarely willing to wait 24 h for treatment and patients with acute pyelonephritis should be treated as soon as possible to avoid damage to the kidneys and reduce the risk of serious systemic manifestations of the infections.

PHARMACOKINETIC REQUIREMENTS

All antibiotics used for treatment of urinary tract infections with significant bacteriuria should be excreted via the kidneys. This makes drugs such as chloramphenicol and the

tetracyclines less suitable because they are lipid soluble, with elimination mainly via liver metabolism resulting in low urine concentrations. In patients with pyelonephritis it is also important that the antibiotic achieves serum concentrations sufficiently high to eliminate bacteremia. With renally excreted antibiotics therapeutic concentrations are normally achieved in the renal parenchyma.

In patients with prostatitis special pharmacokinetic requirements apply. The prostate tissue is a difficult-to-penetrate compartment. Moreover, the pH of the prostatic and vesicular fluid varies and is often altered by infection. Hence, the drugs used must be active at a wide range of pH values. Finally, in chronic prostatitis calculi may be present, which reduce the efficacy of antibiotic treatment.

SAFETY CONSIDERATIONS

Uncomplicated cystitis is an infection that constitutes no threat to the patient if adequately treated. When such infections are treated it is a prerequisite that the antibiotics used have the highest possible degree of safety; serious or life-threatening adverse effects cannot be accepted even if they appear in very low frequencies. On the other hand, in patients with pyelonephritis the infection *per se* constitutes a considerable risk to the patient, which makes adverse effects to the treatment given more acceptable if a high degree of efficacy can be expected.

CHOICE OF ANTIBIOTICS

Of paramount importance in this respect is the local antibiotic resistance pattern: it is not possible to extrapolate susceptibility data generated in one country to another. In the hospital environment there may be marked differences between hospitals in the same country in the frequency of resistance to commonly used antibiotics. The local microbiological laboratories must provide data from regular resistance surveillance studies performed on clinically relevant collections of bacterial strains. Results obtained in outpatients should be considered separately from hospital-generated data. Preferably, resistance surveillances should be prospective and denominator driven. If they are made (as is often the case) on routine samples sent to a diagnostic laboratory, they are likely to overestimate frequencies of resistance because cultures are more often taken in patients with recurrent infections or treatment failures.

Due to high frequencies of antibiotic use, antibiotic resistance in urinary isolates is becoming an increasing problem, especially since more and more isolates are multiresistant.^{18–21}

DOCUMENTATION OF ANTIBIOTIC EFFICACY

Treatment of urinary tract infections with antibiotics aims at eliminating the symptoms and, most importantly in patients with cystitis or pyelonephritis, the bacteriuria. Systematic

Table 54.4 Requirements of clinical trials of antibiotic treatment of urinary tract infections

Criterion	Requirements
Type of infection	Only one – e.g. uncomplicated cystitis in women or complicated infections in either sex
Sample size	For trials in cystitis at least 200 patients with confirmed bacteriuria per treatment group; smaller samples for complicated infections and pyelonephritis
Entry criteria	Verified pyuria and/or positive nitrite test, typical symptoms, urine for culture
Control	Well-documented regimen
Design	Always prospective, controlled and randomized. Preferably double-blind
Endpoints	Bacteriological efficacy, clinical efficacy and safety. Efficacy to be analyzed 5–9 days and 4–6 weeks after treatment
Analyses	Both intention-to-treat analysis of outcome in all patients randomized and per-protocol analysis of patients fulfilling defined criteria (e.g. minimum treatment time, bacteriuria pretreatment and at least one follow-up visit)

evaluation of antibiotic efficacy is made in clinical trials. Table 54.4 lists minimal requirements on clinical trials of antibiotic treatment of cystitis and pyelonephritis. Most trials initiated by pharmaceutical companies today fulfill these criteria. However, before the mid-1980s many clinical trials often included too few patients to allow any conclusions to be drawn.

TREATMENT OF CYSTITIS

Cystitis accounts for approximately 90% of all infections with significant bacteriuria. Typically, about 75% of women with cystitis have sporadic infections and 25% recurrent infections in an unselected sample. Complicated infections are seen in only about 2% of unselected patients. Most of the patients with cystitis are women aged 15–50 years.

In addition to antibiotic treatment, it is important to provide advice to the patient on how to prevent recurrences. Sexually active women should be told that emptying of the bladder after intercourse will reduce the risk of recurrences.

Although cystitis is a self-limiting benign infection in most patients, antibiotic treatment is recommended,²² the most important reason being to prevent ascending infections and pyelonephritis.

A large number of antibiotics are used for treatment of uncomplicated cystitis. A general rule is that oral β-lactam antibiotics (ampicillin, amoxicillin, carbapenems, cephalosporins, amoxicillin-clavulanic acid and other β-lactam-β-lactamase inhibitor combinations and pivmecillinam) seem to be considerably less efficacious in eradicating bacteriuria than trimethoprim-sulfonamide combinations, trimethoprim or fluoroquinolones (Table 54.5).^{10,23} This is not due to more

Table 54.5 Bacteriological efficacy in a study comparing a β-lactam (ritipenem acoxil) with a fluoroquinolone (norfloxacin) for 5 days' treatment of uncomplicated cystitis in women¹⁰

Follow-up and outcome	Treatment	
	Ritipenem acoxil	Norfloxacin
5–9 days post-treatment		
No bacteriuria	51/122 (42%) ^a	77/114 (68%)
Superinfection	22/122 (18%)	20/114 (18%)
Persistence	41/122 (34%) ^a	12/114 (11%)
Not assessable	8/122 (7%)	5/114 (4%)
3–4 weeks post-treatment		
No bacteriuria	31/59 (53%)	52/82 (63%)
Recurrence	17/59 (29%)	16/82 (20%)
Reinfection	11/59 (19%)	8/82 (10%)
Not assessable	0/59	6/82 (7%)

From The Swedish Urinary Tract Infection Study Group. Interpretation of the bacteriological outcome of antibiotic treatment for uncomplicated cystitis: impact of the definition of significant bacteriuria in a comparison of ritipenem axetil with norfloxacin. *Clin Infect Dis.* 1995;20:1507–1503.

frequent resistance to β-lactams than to other antibiotics in bacteria causing bacteriuria: a possible explanation is that β-lactam antibiotics are rapidly eliminated (i.e. the urine becomes free from antibacterial drug about 12 h after the last treatment dose). On the other hand, with trimethoprim, trimethoprim-sulfamethoxazole and fluoroquinolones, high concentrations of drug are maintained in the urine for 24 h or more after the end of treatment. Another possibility is that the latter drugs reduce the periurethral inoculum more effectively than β-lactams, thereby reducing the risk of recurrences.

There are no major differences in clinical efficacy between antibiotics used for the treatment of uncomplicated cystitis. Irrespective of whether the bacteriuria is eliminated or not, symptoms tend to disappear after 3 days. Thus, there is a poor correlation between clinical efficacy and bacteriological efficacy.

The treatment time in uncomplicated cystitis is a controversial issue. Recommendations range from a large single dose to 7 days or more of treatment. A short treatment time offers better patient compliance, reduces costs and minimizes risks of adverse effects; however, all antibiotics tested in sufficiently

Table 54.6 Comparative efficacy of trimethoprim-sulfonamide combinations and β-lactam antibiotics when used for different treatment times in patients with uncomplicated cystitis¹⁸

Treatment time	Rate of eradication of bacteriuria and treatment	
	Trimethoprim-sulfonamide	β-Lactam
Single-dose	267/300 (89%)	58/60 (66%)
3-day	139/147 (95%)	282/343 (82%)
>5-day	294/308 (96%)	370/423 (88%)

Fluoroquinolone-resistant isolates of *Escherichia coli* from outpatients are frequently multidrug resistant: results from the North American Urinary Tract Infection Collaborative Alliance-Quinolone Resistance Study. *Antimicrob Agents Chemother.* 2006;50:2251–2254.

Table 54.7 Frequencies of adverse events reported after treatment of uncomplicated cystitis¹⁸

Treatment time	No. of patients with adverse events and treatment	
	Trimethoprim-sulfonamide	β-Lactam
Single-dose	30/404 (7%)	23/212 (11%)
3-day	13/195 (7%)	55/630 (9%)
>5-day	101/406 (25%)	126/934 (14%)

From Karlovsky JA, Hoban DJ, DeCorby MR, Laing NM, Zhanell GG. Fluoroquinolone-resistant isolates of *Escherichia coli* from outpatients are frequently multidrug resistant: results from the North American Urinary Tract Infection Collaborative Alliance–Quinolone Resistance Study. *Antimicrob Agents Chemother.* 2006; 50:2251–2254.

large trials have been found to be less effective if used as a single dose than in a longer treatment time (Table 54.6).²³ Differences exist between antibiotics. For trimethoprim–sulfamethoxazole and other combinations of trimethoprim and sulfonamides, high cure rates could be demonstrated after administration of a single dose. Treatment for 3 days improved the efficacy but no further benefits were achieved with longer treatment times. However, with prolonged treatment the frequencies of adverse events increased markedly in patients receiving trimethoprim–sulfonamide combinations whereas the safety of β-lactam antibiotics was far less affected by the treatment time (Table 54.7). Fluoroquinolones also seem to be relatively effective if used for 3 days or less and probably little is gained by increasing the treatment time to 5 days or more.

It is recommended that a short course (3 days or less) of trimethoprim–sulfamethoxazole, another trimethoprim–sulfonamide combination or trimethoprim alone is used as first-line treatment of sporadic uncomplicated cystitis when the local susceptibility pattern so allows. The documentation of efficacy is less comprehensive for trimethoprim because for many years trimethoprim–sulfamethoxazole was the gold standard in clinical trials. In pregnant women nitrofurantoin or a β-lactam antibiotic for 5–7 days should be used. β-Lactam antibiotics should otherwise generally be used restrictively due to their poor bacteriological efficacy.

Older, non-fluorinated quinolones should not be used for treatment of any type of urinary tract infection because they are considerably less active than the fluorinated quinolones and resistance emerges in high frequencies with these antibiotics. Moreover, resistance to older quinolones increases the risk of resistance to fluoroquinolones. Resistance to these antibiotics is chromosomal. With the non-fluorinated derivatives a single mutation of one the bacterial genes coding for the DNA gyrase (topoisomerase I), which is the main target for quinolones, will result in resistance (see Ch. 3). Such mutations occur in a frequency of about 10^{-8} . The new fluoroquinolones are 100–1000 times more active and require two consecutive mutations in species such as *Esch. coli* before the organisms become resistant, which is likely to occur at a frequency of 10^{-16} . If an old quinolone is used, the first mutation

is often initiated, and the risk for mutation to resistance against the fluoroquinolones (if they are used) then increases from 10^{-16} to 10^{-8} .

Patients with recurrent uncomplicated cystitis are more likely to have bacteriuria caused by organisms other than *Esch. coli* or *Staph. saprophyticus*. Pathogens that should be covered are enterococci and *Klebsiella* spp. The choice of antibiotics will depend on the treatment used for the preceding episode. Fluoroquinolones, if they have not been used in the same patient recently, are very likely to be effective. To preserve the usefulness of the fluoroquinolones for treatment of these more serious infections and patients with pyelonephritis, these antibiotics are not recommended as first-line drugs for treatment of uncomplicated sporadic cystitis.

In women with frequently recurring cystitis and in whom underlying complicating factors have been excluded, short-term self-treatment has been proven to be effective.^{24,25}

No follow-up procedures are warranted following treatment of uncomplicated sporadic cystitis. The patient should be told to come back if she again experiences clinical symptoms. However, advice should always be given about ways to avoid recurrences – e.g. double- or triple-voiding, generous fluid intake and (as mentioned above) post-coital bladder emptying.

Antibiotics for treatment of uncomplicated sporadic cystitis can often be chosen without urine cultures, based on knowledge of the local antibiotic susceptibility pattern. In patients with complicated infections (which are typically recurrent), and in patients with uncomplicated infections that recur, urine cultures should be performed routinely.

Antibiotics used for treatment of complicated and recurrent cystitis are the same as those used in sporadic uncomplicated infections. However, β-lactams tend to perform even less well than in sporadic cases and treatment must last 5 days or longer. In these patients the urine should be cultured after treatment to identify and eliminate any complicating factors.

TREATMENT OF PYELONEPHRITIS

Pyelonephritis may be a life-threatening infection. In adults, septicemia may lead to septic shock. In children, there is a marked risk for developing renal scars, which may lead to permanent renal damage if the patient develops recurrent urinary tract infections involving the affected kidney.^{14,15} Correct choice of empirical antibiotic treatment is therefore essential.^{22,23} The first therapeutic decision to be taken is whether or not the patient needs parenteral treatment. If an injectable antibiotic is needed, there are several alternatives for empirical treatment. In patients with community-acquired sporadic infections, a group 3 (second-generation) cephalosporin (e.g. cefuroxime), an aminoglycoside or, in some countries, trimethoprim–sulfamethoxazole is likely to be effective; ampicillin, amoxicillin and groups 1 and 2 (first-generation) cephalosporins (cephalotin, cefazolin, cefadine and others), against which more than 10% of *Esch. coli* strains are resistant, are not recommended.

In patients with hospital-acquired infections a group 4 or group 6 (third-generation) cephalosporin such as ceftazidime, cefotaxime or ceftriaxone, a carbapenem (imipenem or meropenem), an aminoglycoside or a fluoroquinolone (e.g. ciprofloxacin or levofloxacin) are effective in most countries.

In the acute phase of pyelonephritis, renal function is always reduced. This, together with the fact that β -lactams, aminoglycosides and quinolones all achieve high concentrations in urine, blood and renal tissues, allows the use of low doses (e.g. cefuroxime 750 mg every 8 h, 3 mg/kg per day of gentamicin, netilmicin or tobramycin, and 200 mg every 12 h of intravenous ciprofloxacin). Some patients with pyelonephritis may be given oral antibiotics throughout the course of treatment. Preferred antibiotics are the fluoroquinolones, which are more efficacious than oral β -lactam antibiotics.²⁶ Because quinolones are not recommended for pregnant women, and since the therapeutic efficacy of oral (but not parenteral) β -lactams must be questioned, oral treatment is not recommended initially in pregnant women with signs of pyelonephritis.

An insufficiently studied problem is what to use when a patient started on parenteral treatment is to be switched to an oral regimen. Clinical trials of antibiotics have traditionally not been directed towards this problem and few studies have evaluated the normal clinical situation – i.e. that a patient is treated parenterally for 24–48 h and then continued on an oral antibiotic. At present the best choice for oral follow-up to an injectable antibiotic in a patient with pyelonephritis seems to be a fluoroquinolone.

The treatment time is traditionally 2 weeks in pyelonephritis. Longer periods seem not to increase the cure rates but are likely to result in higher frequencies of adverse reactions to the antibiotics used. One study comparing ciprofloxacin for 7 days with trimethoprim-sulfamethoxazole for 14 days showed equally good results in the two groups.²⁷ Further studies are needed in this field. The efficacy of treatment for pyelonephritis should be followed up with urine cultures at least once after treatment.

ASYMPTOMATIC BACTERIURIA

Most patients with asymptomatic bacteriuria should not be treated. This is certainly true for patients with bladder catheters: in such cases treatment will only result in selection of increasingly resistant bacterial strains and, if the patient should develop a systemic infection, it may be difficult to find an active antibiotic. Early studies indicated that asymptomatic bacteriuria in elderly people was correlated to an increased mortality; however, more recent investigations have not shown that bacteriuria per se is an independent risk factor for increased mortality.^{28–30} In one such study antimicrobial treatment of asymptomatic bacteriuria did not affect mortality. Exceptions to this rule are pregnant women and patients who are to undergo urogenital tract surgery: both these categories should be screened for bacteriuria and treated if positive. Antibiotics recommended are those used for treatment of uncomplicated cystitis. In other categories of patients (e.g. elderly people and those with diabetes mellitus), screening for bacteriuria is not recommended because treatment of asymptomatic bacteriuria has not been proven to have beneficial effects.

PROPHYLAXIS AND LONG-TERM TREATMENT

Antibiotic prophylaxis of cystitis and pyelonephritis should be used very restrictively. Patients with frequent recurrences of these infections should be investigated in order to find and eradicate complicating factors leading to the recurrences. In some patients episodes of cystitis or pyelonephritis may require prolonged treatment to prevent recurrence before surgery is performed. An important group in which such prophylaxis is indicated is children with congenital anatomical defects. Several studies have indicated that reflux and pyelonephritis in young children are correlated with renal cortical damage and scarring.

In a small fraction of patients with recurrent cystitis or pyelonephritis, mainly girls and young women, no complicating factor can be identified. Such patients benefit from prophylaxis and should be given nitrofurantoin or trimethoprim once daily at bedtime to ensure high bladder concentrations of drug during sleep. The treatment time is normally 6 months but several years of treatment may be required.

As mentioned above, cystitis in older women is often due to atrophic changes of the vaginal mucosa, increasing the periurethral bacterial inoculum. Elderly women should therefore be examined for vaginal atrophy; if present, atrophy should be treated with estrogen to prevent recurrence. Intravaginal treatment with estriol seems to give the lowest frequencies of adverse reactions.^{31,32} In a randomized trial in older women, trimethoprim prophylaxis was only marginally better than cranberry juice for prevention of recurrences of urinary tract infections.³³

TREATMENT OF PROSTATITIS

Antibiotic treatment of prostatitis differs from that of cystitis and pyelonephritis, both in choice of antibiotic and in treatment time. In patients in whom gonorrhea and chlamydial infection have been excluded, identification of the etiology can be attempted using segmented urine culture (*see above*). However, in most cases this procedure is too cumbersome and treatment is started without etiological verification. Drugs frequently used and well documented are trimethoprim-sulfamethoxazole, tetracyclines (e.g. doxycycline) and fluoroquinolones. Treatment should last 3 weeks or longer.

TREATMENT OF FUNGURIA

When *Candida* sp. is isolated in the urine and considered clinically relevant, treatment should be given. Amphotericin B is generally active against *Candida* and resistance has never been reported. However, the drug is difficult to administer and has considerable nephrotoxicity. One alternative in selected patients is local instillation of amphotericin B.³⁴ The azole derivatives (e.g. fluconazole and itraconazole) are liver metabolized and achieve low urine concentrations. Resistance

to these drugs may occur; *Candida krusei* and *Candida glabrata* are normally fluconazole resistant. An alternative choice for treatment of candiduria, if the isolated organisms are susceptible, is 5-fluorocytosine (flucytosine) which is excreted by the kidneys and achieves high concentrations in renal tissue. However, caution should be taken not to use too high a dose of this drug, which may lead to adverse reactions. Optimally, serum concentrations of flucytosine should be kept between 25 and 75 mg/L during the entire dose period.

CHAPTER**55**

Infections in pregnancy

Phillip Hay and Rüdiger Pittrof

On a global scale, infection during or after pregnancy is an important public health problem and a leading cause of pregnancy-related health loss. The prevention and appropriate treatment of infection in pregnancy must have a high priority in any health service. Healthcare interventions during pregnancy, the puerperium and the lactational period differ from those occurring at other times as they may affect the health of both mother and fetus/baby.

Possible outcomes of pregnancy-related infections are shown in Table 55.1. The US Food and Drug Administration (FDA) categories for prescribing antimicrobials are shown in Table 55.2.

While treating infections in pregnancy can improve the health of mother and fetus/baby, it may result in congenital or neonatal health problems or litigation. In affluent countries approximately 1 in 400 babies is affected by a birth defect with a teratogenic etiology. If nutritional supplements are excluded, medication to treat infection constitutes the largest single group of prescribed drugs. As patients often assume that congenital malformations are secondary to a drug taken in pregnancy¹ and attorneys offer ‘no-cost litigation’, litigation following antimicrobial treatment is a real risk of prescribing in pregnancy.

GENERAL PRINCIPLES OF DRUG USE IN PREGNANCY AND THE PUERPERIUM

As for any medical intervention, antimicrobial treatment in pregnancy aims to maximize expected benefits while minimizing expected harms. The frequency of harmful outcomes of treatment or its omission is uncertain for most conditions and drugs. When estimating the risks of a treatment, teratology studies in non-human primates offer the best predictors of human teratogenicity as they have a sensitivity and specificity of >90%.²

When treating infection in pregnancy and the puerperium the prescriber has to decide:

1. when to initiate treatment; when the diagnosis is suspected, as in possible maternal pyelonephritis.

2. when the diagnosis is confirmed, for example maternal tuberculosis, or when the risk of congenital or neonatal problems is minimized as in maternal HIV infection after the first trimester of pregnancy.
3. which medication to use – whether scientific data is available regarding the safety of various treatments options in pregnancy. Unfortunately, little information is available to assess the frequency of maternal side effects.
4. how the physiological changes in normal and abnormal pregnancy (Table 55.3) affect the pharmacokinetics, dose regimen and side effects of the treatment chosen.

While there is little information as to how these changes affect the pharmacokinetics of antimicrobial medication, it is reasonable to assume that, for a given dose and dose interval, serum levels of antimicrobial agents will be 10–15% lower than in a similar non-pregnant patient.³

SPECIAL CONSIDERATIONS FOR ANTIMICROBIAL TREATMENT IN PREGNANCY OR DURING LACTATION

ANTIBACTERIALS

AMINOGLYCOSIDES

Aminoglycosides readily cross the placenta, and fetal blood concentrations reach 20–60% of maternal blood levels. Following the long-term use of streptomycin for the treatment of maternal tuberculosis, eighth nerve damage has been reported in the neonate, but short-term use of aminoglycosides at therapeutic dose is extremely unlikely to result in fetal ototoxicity.⁴ The physiological changes in pregnancy may make it very difficult to maintain therapeutic levels of aminoglycosides in mother (or fetus) and regular monitoring of serum is indicated.

Table 55.1 Theoretically possible outcomes of pregnancy-related infections

Outcome	Example
Healthy mother and healthy fetus	Common cold (most infections)
Mother without apparent health problems, congenital infection with abortion, stillbirth or long-term morbidity of the child	Untreated latent syphilis infection
Maternal infection causing minimal maternal illness but resulting in congenital infection	Cytomegalovirus infection causing mental retardation Parvovirus infection causing non-immune hydrops fetalis, toxoplasmal congenital eye disease
Maternal infection causing (preterm) delivery of non-infected child	Urinary tract infection with high maternal fever, malaria
Maternal infection causing (preterm) delivery of an infected child	Chorioamnionitis secondary to ascending lower genital tract infection (group B streptococcus, bacterial vaginosis, toxoplasmosis, rubella)
Maternal death or long-term morbidity following inadequate treatment (this may also affect the health of the fetus/baby)	Postabortion or puerperal sepsis leading to maternal death or infertility
Treatment of maternal illness causing fetal problems	Treatment of maternal infection with aminoglycosides resulting in 8th cranial nerve damage of the fetus
Treatment of maternal illness causing neonatal problems	Neonatal gray syndrome following maternal chloramphenicol treatment Neonatal kernicterus following maternal long-acting sulfonamides
Litigation of the prescribing physician (not uncommon)	Treatment of maternal illness and birth of a child with congenital abnormalities not related to the infection or treatment

Table 55.2 US Food and Drug Administration (FDA) categories for prescribing antimicrobials in pregnancy

FDA definition	FDA pregnancy category		
	B	C	D
Animal reproduction studies fail to demonstrate a risk to the fetus and adequate and well-controlled studies of pregnant women have not been conducted	Safety in human pregnancy has not been determined, animal studies are either positive for fetal risk or have not been conducted, and the drug should not be used unless the potential benefit outweighs the potential risk to the fetus	Positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experiences, but the potential benefits from the use of the drug in pregnant women may be acceptable despite its potential risks	
Amoxicillin, ampicillin, azithromycin, carbenicillin, cefazolin, cefotaxime, cefoxitin, ceftriaxone, cefuroxime, cefalexin, cefalotin, clindamycin, cloxacillin, dicloxacillin, erythromycin, metronidazole, naftcilin, nitrofurantoin, sulfonamides, vancomycin	Aciclovir, amikacin, chloramphenicol, ciprofloxacin, clarithromycin, fluconazole, gentamicin, imipenem, trimethoprim	Tetracyclines, tobramycin	

Antiretroviral agents Shown in Table 55.4

Source: Perinatal HIV Guidelines Working Group. Public Health Service Task Force recommendations for use of antiretroviral drugs in pregnant HIV-infected women for maternal health and interventions to reduce perinatal HIV transmission in the United States. April 29, 2009; pp 1–90. Available at <http://aidsinfo.nih.gov/ContentFiles/PerinatalGL.pdf>, table 2, pp 23–25.

Group A

FDA definition: Adequate and well-controlled studies of pregnant women fail to demonstrate a risk to the fetus during the first trimester of pregnancy (and there is no evidence of risk during later trimesters).

Antimicrobials: there are no antimicrobials in this group.

Group X

FDA definition: Studies in animals or reports of adverse reactions have indicated that the risk associated with the use of the drug for pregnant women clearly outweighs any possible benefit.

Antimicrobials: there are no antimicrobials in this group.

**CEPHALOSPORINS**

The cephalosporins are the most commonly prescribed antibiotics in pregnancy. All cephalosporins cross the placenta and no adverse fetal effects have been reported in humans.

However, testicular damage has been observed in male rats following intrauterine exposure to *N*-methylthiotetrazole cephalosporins. Many group 3 and group 4(second- and third-generation) cephalosporins contain this side chain (see Ch. 13) and should be used with caution in pregnancy. Cefoxitin (a group 3 cephalosporin) does not contain the side chain.

Table 55.3 Implications of physiological changes in pregnancy

Physiological effects in pregnancy	Therapeutic implications
Increased blood volume (>40% at term) and total body water	Possibly larger loading dose
Decreased serum albumin concentration	Possible underestimation of free active drug
Increased hepatic metabolism, increased creatinine clearance	Possible increased drug clearance and need for higher doses and/or shorter dose intervals
Decreased gastrointestinal motility	Unpredictable absorption of oral medication. Possibly increased frequency of gastrointestinal side effects
Pathophysiological changes in pre-eclampsia (proteinuric hypertension in pregnancy). Compared with normal pregnancy: reduced intravascular volumes and total body water, serum albumin and creatinine clearance	Use high doses for drugs with a wide safety margin (such as penicillins) and/or monitor therapeutic levels of drugs with narrow safety margin (such as aminoglycosides) frequently

CLINDAMYCIN

Cord blood levels of clindamycin are only 15–50% of those in maternal blood. Clindamycin has not been linked to congenital abnormalities. However, this is based on limited data and in a recent review by Nahum and colleagues⁵ clindamycin, together with gentamicin and vancomycin, was classified as undetermined.

CHLORAMPHENICOL

Chloramphenicol has not been associated with an increased risk of congenital malformation. However, when given in late pregnancy there is a theoretical risk of ‘gray baby syndrome’ (cyanosis, vascular collapse and death in premature neonates).

MACROLIDES

The most commonly used macrolides are erythromycin, azithromycin and clarithromycin. Placental transfer of these antibiotics is low and no fetal problems have been reported.

While there is considerable evidence of the safety of azithromycin in pregnancy it is still labeled as a category B drug by the manufacturer.

Clarithromycin is usually used for the treatment or prophylaxis of *Mycobacterium avium* complex in HIV-positive patients. There are no large studies of this drug in pregnancy and its manufacturer rates it as category C.

Erythromycin has been used extensively in pregnancy but may be associated with an increased risk of cardiovascular malformations and pyloric stenosis.⁶

METRONIDAZOLE

Metronidazole is the treatment of choice for trichomoniasis and anaerobic infections. It crosses the placenta readily and

cord blood levels are similar to maternal blood levels. In mice and bacteria it is tumorigenic and mutagenic, but no such observations have been made in humans, and administration to over 1000 women during the first trimester of pregnancy did not result in an increased rate of malformations.⁷ A possible association between vaginal treatment with metronidazole during the first trimester of pregnancy and congenital hydrocephalus has been described.⁸ Metronidazole should be used during the first trimester only if the benefits outweigh the potential risks. Metronidazole concentrates in breast milk, causing it to taste bitter and may thus cause problems with breastfeeding.

NITROFURANTOIN

Nitrofurantoin is commonly used for the treatment of urinary tract infections in pregnancy. As it crosses the placenta, it could cause hemolysis in a fetus with glucose-6-phosphate dehydrogenase deficiency. With our current knowledge, ‘treatment with nitrofurantoin during pregnancy does not present detectable teratogenic risk to the fetus’.⁹

PENICILLINS

Although all penicillins cross the placenta rapidly and result in cord blood concentrations that may be higher than those observed in maternal blood, there is good evidence of their safety in pregnancy⁵ and no evidence that they are teratogenic.

QUINOLONES

In a study of 549 pregnancies exposed to quinolones during the first trimester, no increased rate of malformations was observed.¹⁰ However, quinolones are not recommended in pregnancy as they can cause lesions of the cartilage leading to lameness and arthropathy in immature dogs.

SULFONAMIDES AND TRIMETHOPRIM

Sulfonamides inhibit folate synthesis and may thus be associated with an increased risk of congenital malformations. Sulfonamides cross the placenta readily and compete for fetal and neonatal bilirubin binding sites. In the neonate this could cause hyperbilirubinemia. An association between folic acid antagonist treatment in early pregnancy and neural tube defects has been reported.¹¹

TETRACYCLINES

Tetracyclines readily cross the placenta and when given in the second half of pregnancy are deposited in the long bones (no adverse effects) and deciduous teeth (causing yellow-brown discoloration) of the fetus. The impact of pregnancy on the frequency or severity of adverse side effects of tetracyclines in the mother is unknown but gastrointestinal problems appear to be more frequent. Except for the treatment of penicillin-allergic patients for whom desensitization is not available, tetracyclines are rarely indicated in pregnancy or during lactation.

GLYCOPEPTIDE ANTIBIOTICS (VANCOMYCIN AND TEICOPLANIN)

There are insufficient data to comment on the safety of vancomycin and teicoplanin in pregnancy. Vancomycin can be ototoxic and nephrotoxic and, as it crosses the placenta, similar effects could also occur in the fetus. Manufacturers advise use only if potential benefit outweighs risk, and monitoring of levels of vancomycin to minimize the risks of fetal toxicity.

OTHER ANTIBIOTICS

There are insufficient data to comment on the safety of aztreonam, imipenem, linezolid or daptomycin in pregnancy. Fusidic acid is not known to be harmful.

ANTITUBERCULOSIS DRUGS

There is good evidence that antituberculosis drugs do not increase the frequency of congenital malformations. Rifampicin (rifampin), ethambutol and isoniazid have no apparent adverse effects and, therefore, are considered safe throughout pregnancy. As pyridoxine requirements in pregnancy are likely to be increased, pregnant women taking isoniazid should also take 50 mg pyridoxine per day. Insufficient

human data are available for pyrazinamide, which may best be avoided during the first trimester. Streptomycin and kanamycin are associated with eighth cranial nerve damage in the fetus.

ANTIFUNGALS

Nystatin, clotrimazole and miconazole are frequently used for the treatment of candidiasis. There are no reports of increases in malformations from their use and they can be regarded as safe to take in pregnancy. Butoconazole, terconazole and ketoconazole are unlikely to cause malformations, but have not been adequately investigated in large studies.

Fluconazole has been associated with multiple congenital abnormalities at doses of 400 mg/day or greater. The published experience with the use of smaller doses, such as those prescribed for vaginal fungal infections, suggests that the risk for adverse outcomes is low, if it exists at all.¹² In those instances in which continuous, high-dose fluconazole is the only therapeutic choice during the first trimester, the patient should be informed of the potential risk to her fetus.

The available human data suggest that itraconazole is unlikely to cause major anomalies in humans.

There are also serious risks of fetal malformations associated with the use of griseofulvin, ketoconazole, voriconazole and flucytosine. Caspofungin is classified as pregnancy category C; it is not genotoxic or mutagenic, but is embryotoxic in rats and rabbits. No controlled studies have evaluated the safety of amphotericin B in pregnancy but case reports do not suggest teratogenicity.

SPECIFIC THERAPEUTIC PROBLEMS IN PREGNANCY

INTRODUCTION

During the 19th century maternal death from puerperal sepsis was a feared and common outcome of delivery. It is now rare in industrialized countries, but infections continue to present more subtle problems for pregnant women. The unique vulnerability of the developing fetus to infection and the role of subclinical infections in preterm birth (and possibly cerebral palsy) are being unraveled.

CHORIOAMNIONITIS AND INTRA-AMNIOTIC INFECTION

Premature delivery is a continuing and serious neonatal problem. Most neonatal deaths and morbidity (in the form of chronic lung disease and neurological impairment) occur in preterm births. Algorithms have been produced to enable obstetricians to estimate the risk of preterm birth for a particular pregnancy.

A history of previous preterm birth is the greatest risk factor; this, and most of the other risk factors, are not easily modified during pregnancy. Few interventions have been shown to reduce the incidence of preterm birth, and the incidence has changed little in the last 40–50 years in Europe and the USA.¹³ Currently the incidence of birth at less than 37 weeks' gestation is 5–7% in Europe and 11% in North America. Most of the mortality and morbidity occurs in babies born before 34 weeks' gestation.

Histological chorioamnionitis and subsequent amniotic fluid infection are associated with preterm birth; this association is strongest in very preterm birth (<29 weeks). Animal models have demonstrated putative mechanisms through which infection leads to the release of proinflammatory cytokines such as interleukin-6 and tumor necrosis factor- α .¹⁴ These cytokines in turn stimulate production of arachidonic acid metabolites, including prostaglandins, leading to cervical ripening, uterine contractions and preterm birth. This process is often subclinical, but in its most acute forms is associated with maternal fever, a raised C-reactive protein and an elevated erythrocyte sedimentation rate (ESR) in the mother. Recent studies have implicated elevated levels of proinflammatory cytokines with adverse sequelae in the neonate, including the pathogenesis of fetal cerebral white matter damage and bronchopulmonary dysplasia, precursors of cerebral palsy and chronic lung disease, respectively. This has been reviewed in more detail elsewhere.¹⁵

Most chorioamnionitis is due to ascending spread of bacteria from the lower genital tract either during or before pregnancy. The organisms found most frequently in association with chorioamnionitis and amniotic fluid infection include mycoplasmas (*Ureaplasma urealyticum* and *Mycoplasma hominis*), *Bacteroides* (*Prevotella*) species, *Gardnerella vaginalis*, peptostreptococci and group B streptococci.¹⁶ Most of these organisms are found in high concentrations in the vaginal fluid of women with bacterial vaginosis, but also make up part of the normal flora in healthy women.

Bacterial vaginosis (BV) is the most common cause of vaginal discharge in women of childbearing age. The principal symptom is an offensive, fishy-smelling vaginal discharge that is often more apparent during menstruation or following unprotected intercourse. BV may resolve and occur spontaneously. In some populations its prevalence is greater than 50%, although in the UK it occurs in only 10–15% of women. It is thought to represent a disturbance of the vaginal ecosystem in which the usually dominant lactobacilli are overwhelmed by an overgrowth of predominantly anaerobic organisms including *Gardnerella vaginalis*, *Bacteroides* spp., *Mycoplasma hominis* and *Mobiluncus* spp. There is an increase in the vaginal pH from a normal below 4.5 to up to 7.0. BV is not a sexually transmitted infection and there is no benefit from treating male partners. Many observational studies have confirmed that women with BV have an increased risk of second trimester loss and preterm birth, with odds ratios between 1.4 and 6.9;¹⁷ indeed, it may be the most important cause of idiopathic preterm birth.

Several studies have evaluated the use of antibiotics to treat women in pregnancy with BV to prevent preterm birth. Some studies of selected women at high risk have shown a benefit from treatment with metronidazole, or with a combination of erythromycin and metronidazole. The largest study, however, used short courses of metronidazole orally and showed no benefit in unselected asymptomatic women, or the subgroup with a previous preterm delivery.¹⁸ Further studies are being performed, but at present no definitive conclusions can be reached on the value of such treatment. In 2007 a Cochrane review¹⁹ found that antibiotic therapy for bacterial vaginosis during pregnancy did not reduce the risk of delivery before 37 weeks. However, treatment before 20 weeks' gestation may reduce the risk of preterm birth less than 37 weeks. In women with a previous preterm birth it may decrease the risk of premature preterm rupture of membranes.

Current guidelines from the USA (Centers for Disease Control and Prevention guidelines) and the UK (British Association for Sexual health and HIV, Clinical Effectiveness Group) do not suggest screening for bacterial vaginosis in pregnancy. A Cochrane review in 2008, however, found that screening for lower genital tract infection (BV, *Trichomonas vaginalis* and candidiasis) resulted in a 'lower incidence of preterm birth for low birth weight preterm infants with a weight equal to or below 2500 g and very low birth weight infants with a weight equal to or below 1500 g were significantly lower in the intervention group than in the control group'.²⁰

Standard treatment in the UK for BV is metronidazole 400 mg every 12 h for 5 days, resulting in resolution within a few days; however, relapse occurs in as many as 30% of women within 1 month. Alternative treatments include intravaginal 0.75% metronidazole gel, 2% clindamycin cream and oral clindamycin 300 mg every 12 h for 5 days. Physicians have been wary of prescribing metronidazole during pregnancy because of reputed teratogenicity, but this has not been proven by human experience. If a woman requires treatment, it is sensible to discuss the potential risks and weigh them against the benefits. Both oral and intravaginal clindamycin have been associated with pseudomembranous colitis, a potentially fatal condition. Women who develop diarrhea following such treatment, particularly with blood, should cease treatment and seek medical advice.

PRETERM LABOR AND PRETERM PREMATURE RUPTURE OF MEMBRANES

Many of the infections that trigger preterm premature rupture of membranes and preterm birth are subclinical, without accompanying fever, maternal tachycardia, raised white cell count or raised ESR. A large multicenter UK-based study (ORACLE) of antibiotic treatment for women presenting in preterm labor has been completed recently. There was a reduction in adverse neonatal outcome for the use of erythromycin, but not amoxicillin-clavulanic acid, compared with the placebo group. There was an increase in neonatal morbidity

with amoxicillin-clavulanic acid, with 2.3% of infants whose mothers received it developing necrotizing enterocolitis (compared with 0.8% in the other groups).²¹

A Cochrane review (last updated in 2004)²² confirmed a statistically significant reduction in chorioamnionitis, numbers of babies born within 48 h and 7 days of randomization, neonatal infection and abnormal cerebral ultrasound scan prior to discharge from hospital. Symptomatic intrauterine infection should be managed by delivery and intrapartum antibiotics, as described for postpartum infection.

Antibiotics should not, however, be given in preterm labor in the absence of ruptured membranes or evidence of infection.²³

ANTIBIOTIC PROPHYLAXIS AND CESAREAN SECTION

Randomized trials provide conflicting evidence as to the value of antibiotic prophylaxis on the prevention of postoperative febrile illness and wound infection following cesarean section. While the most recent and largest study²⁴ showed no significant benefit, a Cochrane review found that prophylactic antibiotics 'reduce the risk of endometritis by two-thirds to three-quarters and a decrease in wound infections justifies a policy of recommending prophylactic antibiotics to women undergoing elective or non-elective caesarean section'.²⁵ In a 'litigation-friendly environment' obstetricians are currently advised to follow local or national guidelines. If antibiotic prophylaxis is used, ampicillin or a group 1 (first-generation) cephalosporin is a reasonable choice.

URINARY TRACT INFECTION

Asymptomatic bacteriuria occurs in 5–10% of all pregnancies. If it is left untreated, 20–30% of mothers will develop acute pyelonephritis.²⁶ A Cochrane review compared antibiotic treatment with placebo or no treatment. It found that antibiotic treatment was effective in clearing asymptomatic bacteriuria (risk ratio (RR) 0.25, 95% confidence interval (CI) 0.14–0.48), reducing the incidence of pyelonephritis (RR 0.23, 95% CI 0.13–0.41) and the incidence of low birth weight babies (RR 0.66, 95% CI 0.49–0.89) but a difference in preterm delivery was not seen.²⁷ Furthermore, screening for and treatment of asymptomatic bacteriuria in pregnancy has been shown to be cost-effective.²⁸

It is uncertain whether single-dose therapy is as effective as longer conventional antibiotic treatment²⁹ (see Ch. 54).

POSTPARTUM INFECTION

Following pregnancy the genital tract offers ideal culture conditions for many bacteria. The presence of virulent bacteria (group A and B streptococci, aerobic Gram-negative rods,

Neisseria gonorrhoeae, organisms associated with bacterial vaginosis or *Mycoplasma hominis*) increases the risk of endometritis,³⁰ as do prolonged rupture of membranes and multiple vaginal examinations.

A Cochrane review of antibiotic regimens for endometritis after delivery concluded: 'The combination of gentamicin and clindamycin is appropriate for the treatment of endometritis. Regimens with activity against penicillin-resistant anaerobic bacteria are better than those without. There is no evidence that any one regimen is associated with fewer side effects. Once uncomplicated endometritis has clinically improved with intravenous therapy, oral therapy is not needed.'³¹

SPECIFIC INFECTIONS

BACTERIAL INFECTIONS

SYPHILIS

Syphilis is a sexually transmitted infection caused by the spirochete *Treponema pallidum*. It can also be spread nosocomially through contact with infected secretions, occasionally through blood products, and transplacentally. Syphilis is common in many developing countries, where up to 10% of pregnant women may have positive serological tests. In Western Europe and the USA the incidence fell progressively over the course of the second half of the 20th century. An increase in incidence in the USA during the late 1980s was linked to substance abuse, particularly 'crack' cocaine, as was a small epidemic in Bristol in the UK in 1998. Such outbreaks, including the epidemic reported in Russia and Eastern Europe during the 1990s, reinforce the importance of continued vigilance and surveillance against this infection. Syphilis is described fully in Chapter 56, so only the aspects relevant to pregnancy are reviewed here.

Syphilis may infect the fetus at any time during gestation and can be transmitted during any stage of maternal disease; at least two-thirds of all babies born to untreated women with syphilis are infected.³² The spectrum of congenital syphilis varies, from a severe fetal infection causing intrauterine death to a neonate with symptomatic disease (early congenital syphilis), late congenital syphilis presenting after more than 2 years of age, or asymptomatic infection.

Penicillin is the treatment of choice for syphilis. Current UK guidelines recommend treating early syphilis (primary, secondary or early latent) with benzathine penicillin 2.4 million units intramuscularly as a single dose. This should be repeated after 7 days in the third trimester of pregnancy when the levels of penicillin may be reduced. Procaine penicillin G 600 000 units intramuscularly daily for 10 days can also be used. Later stages of syphilis require three doses of benzathine penicillin at weekly intervals, or 21 days of procaine penicillin. Particularly during early syphilis, a Jarisch-Herxheimer reaction may occur. This is mediated by the release of proinflammatory cytokines

in response to dying organisms, and presents as a worsening of symptoms with fever for 12–24 h after starting treatment. It does not represent an allergic reaction and may be associated with uterine contractions and preterm labor.

Women who are allergic to penicillin represent a problem. Ceftriaxone 500 mg/day intramuscularly for 10 days is now recommended as an alternative regimen. Tetracycline, a more established second-line treatment, is relatively contraindicated in pregnancy. Erythromycin is less reliable, and resistance has been reported. If erythromycin is to be used, it is best administered intravenously. Azithromycin 500 mg/day can be an option, but there are few data on its use in pregnancy. The neonate should receive treatment with penicillin. One further alternative if the risk of fetal infection is high, is to perform penicillin desensitization with assistance from a clinical allergist. Current and recent sexual partners of women with syphilis must be screened, as well as older children in the family, if the date of acquisition is unknown.

Treatment in pregnancy should be instituted before 20 weeks' gestation to prevent the development of the stigmata of congenital syphilis.³³ In one population studied in the USA, one-third of the cases of syphilis diagnosed in pregnant women were acquired during the course of the index pregnancy, suggesting that rescreening may be an appropriate policy in some populations.³⁴

The ideal treatment for syphilis in pregnancy is currently uncertain. A Cochrane review (last updated in 2009) found that none of the 29 studies included met the predetermined criteria but that none included comparisons between randomly allocated groups of pregnant women. The author concluded: 'While there is no doubt that penicillin is effective in the treatment of syphilis in pregnancy and the prevention of congenital syphilis, uncertainty remains about what are the optimal treatment regimens.'³⁵ Further studies are needed to evaluate the impact of HIV on the effectiveness of the currently recommended treatment regimens.

Stoll comprehensively reviewed the management of an infant born to a mother with reactive serological tests for syphilis.³⁶ In principle, if the mother has not received definitive treatment with penicillin, the infant *should* be treated with penicillin. The infant should be evaluated clinically, through serological tests and examination of the cerebrospinal fluid (CSF).

GONORRHEA

Neisseria gonorrhoeae is a sexually transmissible agent causing cervicitis, urethritis, endometritis, salpingitis and perihepatitis in women. In men it causes urethritis and epididymitis. In both men and women it causes proctitis and pharyngitis. Gonorrhea is common worldwide, although the incidence has decreased in developed countries since the Second World War. Infection in both sexes may be asymptomatic (see Ch. 56). Like chlamydia, gonorrhea is most common in young, sexually active women, with the incidence declining over the age of 25. Its importance in obstetrics is due to a neonatal eye

infection that, if untreated, can progress to blindness due to corneal scarring. The introduction of silver nitrate drops as prophylaxis produced a dramatic decline in the incidence of this complication.

The diagnosis is confirmed by culture. DNA detection-based tests are available and might be used for screening, but do not currently provide information about antibiotic sensitivity. *N. gonorrhoeae* has demonstrated a great ability to acquire resistance to antibiotics. It readily exchanges plasmids with other bacterial species and plasmid-mediated resistance to penicillin and tetracycline appear rapidly under selection pressure with such antibiotics. In many developing countries the price of antibiotics is prohibitive for most individuals, so that suboptimal doses are used; this encourages the development of resistant strains, which are then exported worldwide.

Chromosomal mutation has also produced moderate levels of penicillin resistance and is responsible for resistance to quinolones. Quinolones are contraindicated in pregnancy because of potential damage to developing cartilage and therefore in a penicillin-allergic woman or a woman with penicillin-resistant infection a cephalosporin such as ceftriaxone 500 mg in a single intramuscular dose, or cefixime 400 mg in a single oral dose, should be administered. Cephalosporin resistance has been reported in Japan and it is almost inevitable that further resistance will develop worldwide. A Cochrane review³⁷ (last updated 2009) found that little difference between different treatment options (amoxicillin plus probenecid, spectinomycin, ceftriaxone, ceftriaxone and cefixime) and, depending on resistance pattern, treatment with any of these antibiotics would be appropriate.

Neonates may present with ophthalmia neonatorum due to gonorrhea a few days after birth. If *N. gonorrhoeae* is cultured, topical and systemic treatment should be administered according to antibiotic sensitivities (see Ch. 53). In a similar way to *Chlamydia trachomatis* infection, gonorrhea is associated with chorioamnionitis and preterm birth.

Chlamydia trachomatis

Chlamydia trachomatis is important in pregnancy because it causes neonatal eye infection (ophthalmia neonatorum) and infant pneumonitis. Its role in miscarriage, chorioamnionitis and preterm birth is unclear, with some studies finding associations and others none. Nevertheless, chlamydia infections need to be treated at whatever stage of pregnancy they are diagnosed.

Estimates of the prevalence of genital *C. trachomatis* infection vary between 2% and 10% of women in the UK. The organism is detected much more commonly in young sexually active women, particularly those under the age of 25. The spectrum of disease varies from chronic asymptomatic infection to cervicitis, endometritis, salpingitis (pelvic inflammatory disease) and intraperitoneal spread leading to perihepatitis (Fitz-Hugh-Curtis syndrome). In men it causes non-gonococcal urethritis, which may present with urethral discharge and dysuria.

Approximately 15–25% of babies born to women with chlamydial infection develop ophthalmia neonatorum. The treatment of choice for *C. trachomatis* in the

non-pregnant woman is tetracycline, usually doxycycline or azithromycin. Tetracycline should be avoided in the second and third trimesters of pregnancy because it binds to developing bones and deciduous teeth in the fetus, causing yellow–brown staining of the teeth. A Cochrane review (last updated in 2009) concluded that amoxicillin is an acceptable therapy of genital chlamydial infections in pregnancy when compared with erythromycin and that clindamycin and azithromycin may be considered if erythromycin and amoxicillin are contraindicated or not tolerated.³⁸

The treatments suggested in UK guidelines are erythromycin 500 mg every 6 h for 7 days or erythromycin 500 mg every 12 h for 14 days, or amoxicillin 500 mg every 8 h for 7 days or azithromycin 1 g as a single dose.³⁹ Amoxicillin or azithromycin is also recommended by the US Centers for Disease Control (CDC)⁴⁰ and the draft World Health Organization (WHO) guidance for Europe.⁴¹

A test of cure should therefore be performed 3 weeks after completing treatment. It is essential that male partners are screened and treated before sexual intercourse is resumed. Neonates with ophthalmia neonatorum should be treated with tetracycline eye ointment. Because there is a risk of subsequent chlamydial pneumonitis they should also be treated with a 2-week course of erythromycin syrup.

Chlamydophila abortus

This organism, formerly classified as a strain of *Chlamydia psittaci*, causes epidemic abortion in ewes. In humans it causes an atypical pneumonia. Exposure to lambing ewes and the products of conception can lead to infection of pregnant women, resulting in intrauterine infection and abortion. It occurs most commonly in veterinarians and farm workers. All pregnant women should be advised to avoid sheep during the lambing season. Treatment is as for *C. trachomatis*.

LISTERIOSIS

Listeria monocytogenes is commonly found in the stool samples of pregnant women; however, invasive disease in pregnancy is very rare. Most maternal disease results in influenza-like symptoms and does not usually require treatment.

Vertical transmission can occur transplacentally or, more frequently, during birth from cervicovaginal secretions. Intrauterine infection often leads to premature labor, fetal distress and meconium-stained amniotic fluid. Infection with *L. monocytogenes* responds to treatment with high-dose penicillin, ampicillin or trimethoprim–sulfamethoxazole (not a first-choice drug in the first trimester or in late pregnancy). While most causes of chorioamnionitis call for the early termination of pregnancy (delivery), chorioamnionitis caused by *L. monocytogenes* can be treated medically.⁴²

GROUP B STREPTOCOCCI

Colonization of the vagina with group B streptococci (GBS) is very common in pregnancy.⁴³ The importance of this is, however, uncertain and guidelines on the screening for GBS colonization are conflicting. While CDC 2002 guidance recommends universal screening,⁴⁴ current UK guidance states that ‘routine screening (either bacteriological or risk based) for antenatal GBS carriage is not recommended’.⁴⁵ Bergeron and colleagues⁴⁶ used the polymerase chain reaction (PCR) in labor. In their hands the test had a sensitivity of 97% and a specificity of 100% and yielded results within 30–45 min.

While GBS do not usually cause morbidity in mothers, they are a common cause of neonatal infection. A Cochrane review (2009)⁴⁷ concluded that intrapartum antibiotic treatment reduces the rate of early onset GBS infection, but has no effect on other outcomes including overall morbidity and mortality.

VIRAL INFECTIONS

Specific therapeutic agents to treat viral infections systematically have not been available for more than a few years, with the exception of aciclovir for herpes simplex virus. Their role and safety in pregnancy is not fully established. The potential harm caused by intrauterine or congenital infections means that clinicians must consider the use of many such agents in pregnancy. Nevertheless, for many viral infections that can harm a fetus specific treatments are either not available (e.g. parvovirus and rubella) or have not been studied sufficiently in pregnancy (e.g. cytomegalovirus).

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is a herpes virus with the ability to establish latency. In the UK approximately 40% of pregnant women are susceptible. The incidence of primary infection in pregnancy is unknown, but estimated to be about 1%. In healthy women reactivation of latent CMV infection is unusual, but may occur in pregnancy. The exposed fetus is less likely to have severe manifestations than in primary maternal infection: the principal features are microcephaly, blindness and deafness but some affected children have sensorineural hearing loss as the only sign of congenital CMV infection. A definitive diagnosis of congenital CMV infection can be made by isolating the virus in cell culture from throat swabs, urine, blood or CSF in the first 3 weeks of life. Serological diagnosis is made by the demonstration of a rising titer of IgG antibody or specific CMV IgM antibody.

Specific antiviral agents such as ganciclovir, valganciclovir, foscarnet and cidofovir are available for CMV; however, none should be used routinely. These agents are used in immunosuppressed individuals with AIDS or following transplantation.

A trial of intravenous ganciclovir in infected infants has shown some benefit in reducing deafness, but no role for treatment in pregnancy has been established.

HERPES SIMPLEX VIRUS

Herpes is important in pregnancy because a devastating neonatal infection can occur with involvement of skin, liver and central nervous system (CNS). Neonatal mortality may reach 75%, but can be reduced to 40% if aciclovir is administered rapidly to the neonate. This syndrome is more common in the USA than the UK, with rates of 1 in 5000 and 1 in 33 000 live births, respectively. The vast majority of these cases are associated with a primary herpes infection in the mother in the weeks before delivery. The baby has no protective antibody and is vulnerable to disseminated infection or localized herpes encephalitis. The incidence of neonatal herpes is remarkably low considering the high prevalence of both symptomatic and asymptomatic genital herpes in these populations. The risk of neonatal herpes is greatest if primary infection occurs shortly before delivery, when there is no maternal IgG to cross the placenta, providing partial protection to the neonate.

In adults herpes is initially a clinical diagnosis. Typical vesicles or ulcers are seen on the genital mucosa. In primary infection lesions may be widespread, and persist for up to 3 weeks; secondary or recurrent episodes are usually localized and resolve in 3–7 days. In pregnancy recurrences may resemble primary infections, making clinical staging more difficult. Type-specific serological tests are becoming available, which may help to clarify the diagnosis. If IgG antibody to the same type of virus as is isolated on culture is present in the serum, then it is not a primary infection.

In the non-pregnant woman primary herpes is treated with a 5-day course of aciclovir 200 mg five times a day. This prevents further lesions from developing and allows current ulcers to heal. Recurrent episodes do not usually require treatment, as use of antivirals has not been shown to usefully reduce the time to healing.

For aciclovir, extensive reproductive toxicology studies in animal models before drug approval did not show a teratogenic effect.⁴⁸ Subsequent studies using a newer model showed head and tail abnormalities in rats at higher doses. It crosses the placenta. There was no evidence of teratogenicity in the prospective Acyclovir in Pregnancy Registry.⁴⁹ Less information is available for famciclovir and its active metabolite penciclovir, and valaciclovir, a prodrug for aciclovir. None is teratogenic in animal studies, and there is currently no excess of birth defects reported from their registries. The authors have used aciclovir to control symptoms in pregnant women with primary herpes following such discussions. Like any febrile illness, primary herpes may be associated with early miscarriage. Use of continuous aciclovir to suppress recurrent herpes throughout pregnancy is inadvisable.

Neonatal infection usually follows exposure to active lesions in the mother during delivery. When lesions are present the

risk increases in proportion to the time between rupture of the membranes and delivery. The risk of intrapartum mother-to-child transmission can be reduced by cesarean section provided that the amniotic membranes are ruptured for less than 4 h. Current USA guidelines⁵⁰ recommend that ‘women with active recurrent genital herpes should be offered suppressive viral therapy at or beyond 36 weeks of gestation and that cesarean delivery is indicated in women with active genital lesions or prodromal symptoms, such as vulval pain or burning at delivery, because these symptoms may indicate an impending outbreak’. Current UK guidelines do not recommend suppressive treatment and only advise cesarean section for symptomatic primary herpes infection.⁵¹ In the Netherlands cesarean section for recurrent herpes was abandoned in 1987 and there was no subsequent increase in neonatal herpes.⁵²

If primary herpes presents around the time of delivery, the pediatrician should be informed and genital swabs should be cultured from the mother and throat swabs from the baby within 24 h of birth. Intravenous aciclovir should be administered to the neonate.

HUMAN IMMUNODEFICIENCY VIRUS

The acquired human immunodeficiency virus (HIV) pandemic has been spreading around the world since before the original descriptions of AIDS in 1981. Worldwide, approximately equal numbers of men and women are infected; most affected women are of childbearing age. In some cities in sub-Saharan Africa more than 30% of pregnant women are HIV infected. In London some hospitals have a prevalence of 1% of antenatal attendees. In the UK, nearly 1000 children are born to HIV-infected women annually. Since the vast majority of HIV-infected children acquire the infection by perinatal transmission, the prevention of vertical transmission is of paramount importance in reducing the prevalence of pediatric HIV.

Vertical transmission

Mother-to-child (vertical) transmission of HIV may occur during pregnancy, during childbirth or through breastfeeding. In the absence of intervention, vertical transmission of HIV infection is reported in 15–20% of babies born to HIV-positive women in European/American populations and in 25–35% in Africa and Asia.^{53,54} Transmission is more likely if the mother has advanced HIV disease, as shown by a high viral load and a low CD4 count. Other risk factors include prolonged rupture of membranes and exposure to events that brings the fetus into contact with maternal blood such as vaginal/instrumental delivery, the use of fetal scalp electrodes and episiotomy.⁵⁴ Premature birth, low birth weight and breastfeeding are also established risk factors associated with increased risk of vertical transmission.

The exact mechanisms for perinatal transmission of HIV and the gestational age of greatest risk have not yet been determined. Viral DNA has been detected in fetal tissues as early

as 12 weeks of gestation.⁵⁵ At birth, the virus can be detected in 30–50% of infected children,⁵⁶ suggesting that the remaining 50–70% of infected infants without viral markers at birth may have been infected late in pregnancy, during delivery or after birth, mainly through breastfeeding. The additional risk of transmission through breastfeeding in infants of infected mothers, over and above transmission in utero or during birth, is estimated to be 16%.⁵⁷

The duration of breastfeeding is important and correlates with the risk of transmission. Nevertheless, in developing countries, the negative nutritional impact on overall infant morbidity and mortality of not breastfeeding may outweigh the benefit of avoiding HIV transmission from breast milk.

Preventing vertical transmission

Three interventions have been shown to reduce the risk of vertical transmission: elective cesarean section; bottle feeding; and antiretroviral treatment for the mother and neonate. In Europe and the USA the rate is currently below 2% in pregnancies in which the mother undertakes the recommended regimens to

reduce the risk of transmission. A recent audit from the UK and Ireland reported an overall transmission rate of 1.2%, and it was 0.1% in women taking triple therapy with a viral load <50 copies/mL.⁵⁸

Antiretroviral therapy

The aims of antiretroviral therapy in pregnancy are to prevent vertical transmission and maintain maternal health. Current UK guidelines for treatment of adults recommend starting combination antiretroviral therapy if there are clinical indications, or if the CD4 count is below 350 cells/mL (British HIV Association guidelines).

The safety of antiretrovirals in pregnancy has not been assessed adequately. The US FDA guidelines (Table 55.4), available at http://www.apregistry.com/forms/interim_report.pdf, rate them all as category B or C, with the exception of efavirenz which is category D. Among nucleoside/tide analogs, didanosine, emtricitabine and tenofovir are category B. Four protease inhibitors are category B: atazanavir, nelfinavir, ritonavir and saquinavir. The non-nucleoside analog drugs etravirine

Table 55.4 FDA categories for antiretroviral agents in pregnancy

Antiretroviral drug	FDA pregnancy category ^a	Placental passage (newborn:mother drug ratio)	Long-term animal carcinogenicity studies	Animal teratogen studies
Nucleoside and nucleotide analog reverse transcriptase inhibitors				
Abacavir (Ziagen, ABC)	C	Yes (rats)	Positive (malignant and non-malignant tumors of liver, thyroid in female rats, and preputial and clitoral gland of mice and rats)	Positive (rodent anasarca and skeletal malformations at 1000 mg/kg [35x human exposure based on AUC during organogenesis; not seen at 8.5x human exposure in rabbits])
Didanosine (Videx, ddl)	B	Yes (human) (0.5)	Negative (no tumors, lifetime rodent study at 0.7–3x maximum human exposure)	Negative (at 12x and 14.2x the human exposure in rabbits and rats, respectively)
Emtricitabine (Emtriva, FTC)	B	Yes (mice and rabbits) (0.4–0.5)	Negative (no tumors, lifetime rodent study at 26–31x human exposure at the recommended dose)	Negative (at 60x, 60x and 120x the human exposure in rats, mice and rabbits, respectively)
Lamivudine (Epivir, 3TC)	C	Yes (human) (~1.0)	Negative (no tumors, lifetime rodent study at 10–58x human exposure at the recommended dose)	Negative (at 35x the plasma levels of humans in both the rat and rabbit; however, embryo lethality seen in rabbits with 1x human exposure)
Stavudine (Zerit, d4T)	C	Yes (rhesus monkey) (0.76)	Positive (mice and rats, at very high-dose exposure, liver and bladder tumors [rats only] at 250x and 732x the human exposure in mice and rats, respectively)	Negative (at 399x [rats] and 183x [rabbits] human exposure based on C_{max} , although sternal bone ossification is decreased and rat neonatal mortality increased at 399x human exposure in rats)
Tenofovir DF (Viread)	B	Yes (human) (0.95–0.99)	Positive (hepatic adenomas [female mice only] at 16x human exposure)	Negative (14x and 19x the human dose based on body surface area in rats and rabbits, respectively)
Zidovudine (Retrovir, AZT, ZDV)	C	Yes (human) (0.85)	Positive (non-metastasizing vaginal epithelial tumors at 3x to 24x human exposure in mice and rats, respectively)	Positive (increased fetal malformations associated with maternal toxicity at 300x human exposure in rats. Increased fetal resorptions at 66–226x and 12–87x human exposure in rats and rabbits, respectively, with no developmental abnormalities)

Table 55.4 FDA categories for antiretroviral agents in pregnancy—cont'd

Antiretroviral drug	FDA pregnancy category ^a	Placental passage (newborn:mother drug ratio)	Long-term animal carcinogenicity studies	Animal teratogen studies
Non-nucleoside reverse transcriptase inhibitors				
Efavirenz (Sustiva)	D	Yes (cynomolgus monkey, rat, rabbit) (~1.0)	Positive (hepatocellular adenomas and carcinomas and pulmonary alveolar/bronchiolar adenomas in female but not male mice at 1.7× human exposure; no increases in tumors in rats at 0.2× human exposure)	Positive (anencephaly, anophthalmia, micro-ophthalmia, and cleft palate in cynomolgus monkeys at drug concentrations comparable to humans; no reproductive toxicities in pregnant rabbits at 0.5–1× human exposure)
Etravirine (Intelence)	B	Unknown	Carcinogenicity studies in rodents are ongoing. Not mutagenic or clastogenic in in-vitro and in-vivo assays	Negative (rats and rabbits at exposures comparable to humans)
Nevirapine (Viramune)	B	Yes (human) (~1.0)	Positive (hepatocellular adenomas and carcinomas in mice and rats at systemic exposures lower than human)	Negative (rats and rabbits at 1–1.5× human exposure. However, decreased fetal body weight in rats at 1.5× human exposure)
Protease inhibitors				
Atazanavir (Reyataz)	B	Minimal/variable (human)	Positive (benign hepatocellular adenomas in female mice at 7.2× the human exposure)	Negative (2× and 1× the human exposure in rats and rabbits, respectively)
Darunavir (Prezista)	C	Unknown	Positive (hepatic adenomas, carcinomas [male mice], thyroid neoplasms [rats only] at 0.1–0.3× and 0.7–1× human exposure in mice and rats, respectively)	Negative (at 0.5× and 0.05× human exposure in rats/mice and rabbits, respectively)
Fosamprenavir (Lexiva)	C	Unknown	Positive (hepatic adenomas and carcinomas [mice and rats]; thyroid adenomas, interstitial cell hyperplasia, and uterine endometrial adenocarcinoma [rat only]; relative human exposures varied from 0.1–0.7× [mouse] to 0.3–1.4× [rat] depending on the human dosing regimen)	Negative (at 0.8× and 2× human exposure in rabbits and rats respectively; increased incidence of abortions in rabbits at 0.8× human exposure)
Indinavir (Crixivan)	C	Minimal (human)	Positive (thyroid adenomas in male rats at 1.3× human exposure)	Negative (however, extra ribs in rats at exposures below or slightly above those in humans)
Lopinavir–ritonavir (Kaletra)	C	Yes (human) (0.20 ± 0.13)	Positive (hepatic adenomas and carcinomas at 1.6–2.2× and 0.5× human exposure in mice and rats, respectively)	Positive (no effects in rabbits and dogs [\sim 1× human exposure]; decreased fetal viability, body weight, delayed skeletal ossification and increase in skeletal variations in rats at maternally toxic doses [lopinavir 0.7×/ritonavir 1.8× human exposure])
Nelfinavir (Viracept)	B	Minimal/variable (human)	Positive (thyroid follicular adenomas and carcinomas in rats at 1–3× human exposure in rats)	Negative (in rats with comparable exposure to humans and rabbits at significantly lower exposure than humans)
Ritonavir (Norvir)	B	Minimal (human)	Positive (liver adenomas and carcinomas in male mice at 0.3× human exposure)	Positive (early resorptions, decreased fetal body weight, ossification delays, and developmental variations in the rat at maternally toxic dose [\sim 0.3× human exposure]; cryptorchidism in rats [0.22× human exposure])

Table 55.4 FDA categories for antiretroviral agents in pregnancy—cont'd

Antiretroviral drug	FDA pregnancy category ^a	Placental passage (newborn:mother drug ratio)	Long-term animal carcinogenicity studies	Animal teratogen studies
Saquinavir (Invirase)	B	Minimal (human)	Negative (at 0.29× and 0.65× human exposure [co-administration with ritonavir] in rats and mice, respectively)	Negative (at 0.29× and 0.21× human exposure [co-administration with ritonavir] in the rat and the rabbit, respectively)
Tipranavir (Aptivus)	C	Unknown	In progress	Negative (decreased ossification and pup weights in rats associated with fetal toxicity at dose exposure 0.8× human exposure)
Entry inhibitors				
Enfuvirtide (Fuzeon)	B	None based on very limited human data	Not conducted	Negative
Maraviroc (Selzentry)	B	Unknown	Negative (transgenic mice; rats at 11× human exposure)	Negative (no evidence of harm to fetus at 20× and 5× human exposure in rats and rabbits, respectively)
Integrase inhibitors				
Raltegravir (Isentress)	C	Yes (rats [1.5–2.5], rabbits [0.02])	In progress	Negative (however, supernumerary ribs at 3× human exposure in rats)

AUC, area under the curve; C_{max}, maximum concentration.

^aSee Table 55.2 for an explanation of pregnancy categories.

and nevirapine are category B. The newer agents that block viral entry – enfuvirtide and maraviroc – are category B, while raltegravir, an integrase inhibitor, is category C. A discussion of the choice of agents in a standard triple-therapy regimen is beyond the scope of this chapter, but is discussed fully in the FDA guidelines and updated by the perinatal HIV working group at <http://www.hivatis.org>. Efavirenz is associated with congenital abnormalities in Rhesus macaque monkeys and its use is not recommended, particularly in the first trimester. To date, when used in human pregnancy, no increased rate of birth defects has been reported, and the upper 95% confidence interval for the rate of reported neonatal defects is now 4.9% compared to a background rate of 2.7%.

Potential hazards for the mother and fetus include the usual side effects of triple therapy, such as increased insulin resistance and diabetes mellitus, mitochondrial toxicity and lactic acidosis. Lactic acidosis is most common with stavudine and didanosine regimens, and a fatality in the third trimester has been reported. Tenofovir has been associated with osteopenia in animal studies, but it has not been reported in exposed children. In animals it resolves after exposure stops.

A further hazard is the risk of resistant virus emerging if monotherapy is used. If monotherapy is prescribed to women with low viral loads, CD4 counts >350 cells/mL and who are clinically well, the risk of developing zidovudine resistance mutations is low. A study from London reported no new resistance developing in 80 women prescribed zidovudine monotherapy with low viral loads and high CD4 counts.⁵⁹ Many antiretroviral drugs are potent inducers and inhibitors of cytochrome P₄₅₀ enzymes. This leads to many potential drug interactions. Many should be taken with food to achieve adequate levels. A particular caution is to avoid co-administration of

proton pump inhibitors with the protease inhibitor atazanavir. Heartburn is common in pregnant women. If an antacid is needed it should be taken at least 2 h after atazanavir.

The role of single agent (mono-) therapy

The efficacy of zidovudine monotherapy in reducing vertical transmission was demonstrated in a landmark randomized, double-blind, placebo-controlled trial.⁶⁰ Treatment was started at between 14 and 34 weeks of gestation, administered intravenously during delivery, and the neonate received oral treatment for 6 weeks. The rate of vertical transmission was reduced by 67% in women treated with zidovudine (25.5% placebo versus 8.3% zidovudine). Apart from a mild self-limiting anemia, no adverse effects were observed after a 4-year follow-up.

Nevirapine is the only other single drug (other than zidovudine) that has been shown in a randomized controlled trial to significantly reduce vertical transmission. In the HIVNET 012 trial,⁶¹ 600 pregnant women were randomized to receive zidovudine during and at the onset of labor followed by 1 week of neonatal treatment, or a single 200 mg dose of nevirapine at the onset of labor with a single dose administered to the neonate within 3 days of delivery. At 14–16 weeks of age, 13.1% of the nevirapine-treated group were HIV infected, compared with 25.1% in the zidovudine group, a 47% reduction in transmission. Nevirapine monotherapy is relatively inexpensive, easy to administer and has immense potential for use in developing countries. There are concerns about the risk of resistance developing, as occurred in 23% of women in a small substudy. Current WHO guidance⁶² does not recommend monotherapy (zidovudine for 7 days) in any setting other than for infants of mothers on established triple antiretroviral therapy.

Combination therapy

Triple therapy is recommended for pregnant women with advanced HIV disease, high viral load or low CD4 counts because the risk of mother-to-infant transmission correlates with these parameters.⁶¹ Nevertheless, the marked reduction in viral load produced by triple therapy, and the resultant reduction in transmission, may be outweighed by potential and unquantified risks of these interventions on the neonate. For women with advanced HIV disease who are reluctant to expose their babies to combination therapy, zidovudine monotherapy plus an elective cesarean section is recommended.⁶³

For women who present too late in pregnancy to allow formal virological/immunological assessment, the consensus guidelines recommend a zidovudine regimen with the possible addition of lamivudine and/or nevirapine. In women who conceive while on antiretroviral therapy treatment, it should be continued, although a change to (or the addition of) zidovudine should be considered while it remains the main agent of proven efficacy and safety in human pregnancy.

A randomized controlled trial comparing breastfeeding with formula feeding under study conditions with access to clean water showed no improvement of HIV-free survival for the formula group.⁵⁷ Outside such study setting, formula or mixed feeding leads to higher overall mortality than exclusive breastfeeding. Studies are underway exploring the reduction associated with continuing maternal triple therapy after delivery to allow breastfeeding, or continuing treatment for the baby if the mother does not require treatment herself. Initial studies report a transmission rate of approximately 2% through breastfeeding with antiretroviral treatment.

HEPATITIS

In pregnancy the liver appears to be particularly vulnerable to infectious agents. Thus, hepatitis A, for which there is no specific antiviral agent, may cause fulminant, fatal infection in pregnancy, as may hepatitis E. Vaccination against hepatitis A and the use of human immunoglobulin may provide some protection if initiated in the incubation period. In non-pregnant adults ribavirin and interferon are used to treat hepatitis C, but their effects have not been studied in pregnancy. The risk of vertical transmission is low (<3%), but increases if there is a high level of maternal viremia.

Hepatitis B

Hepatitis B is a more severe infection, which may be followed by chronic carriage and disease ending in cirrhosis. Infection is transmitted sexually through blood or blood products or vertically to the fetus from an infected mother. The majority of acute infections are not clinically recognized, as only 20% of individuals develop jaundice. The earlier in life the infection occurs, the more likely the person

is to become a carrier: 80% of infants infected perinatally become carriers. Infection is particularly common in China and South-East Asia but prevalent in most tropical countries (see Ch. 48).

Pregnant women are screened for hepatitis B at booking. Treatment is available with interferon under the guidance of a liver specialist, and antiviral drugs with specific activity against hepatitis B are being introduced. However, the safety of interferon in pregnancy has not been adequately evaluated.⁶⁴ Vertical transmission can be reduced by vaccination of neonates born to mothers with hepatitis B. Hepatitis B immune globulin is also given at birth if the mother is antigen e positive. Many countries have a policy of universal vaccination of all infants.

PROTOZOAL AND FUNGAL INFECTIONS

TOXOPLASMOSIS

Maternal infection with the intracellular protozoan parasite *Toxoplasma gondii* is usually asymptomatic and the risk to an immunocompetent mother is minimal. Transplacental fetal infection occurs in 20–50% of primary infections and may cause chorioretinitis, intracranial calcifications and hydrocephalus. Diagnosis of primary infection during pregnancy depends on serological screening for *Toxoplasma*-specific IgG in pregnant women followed by confirmatory testing and, ultimately, amniocentesis or cordocentesis. Where the incidence of primary toxoplasmosis in pregnancy is low (e.g. in the USA and UK) screening is currently not recommended. Women who seroconvert during pregnancy should be treated with spiramycin (a macrolide that does not cross the placenta) and, if fetal infection is confirmed, treatment should be changed to pyrimethamine and sulfadiazine plus folate supplements (after 18 weeks' gestation).⁶⁵

Mothers should be informed that: (1) such treatment will not always prevent transmission but will reduce the risk of severe congenital malformations developing; and (2) maternal side effects and congenital abnormalities may occur as a result of the treatment.

TRICHOMONIASIS

Trichomonas vaginalis causes a severe vulvovaginitis in susceptible women. It is generally sexually transmitted, although infection may persist asymptotically for many months in women and in some men. In men it causes urethritis but is frequently asymptomatic. Male partners should be screened for sexually transmitted diseases and treated with metronidazole.

Transient infection may be transmitted to newborn female infants who have stratified squamous epithelium in the vagina, similar to that of an adult, due to the influence of high levels

of maternal estrogen in utero. These infants are susceptible to infection and may present with purulent vaginal discharge. As the influence of maternal estrogen wanes over the first few weeks of life, infection usually resolves spontaneously and specific treatment is rarely necessary.

The only established treatments for trichomoniasis are metronidazole and tinidazole. As discussed above, there is no evidence of teratogenicity from metronidazole use, and it should be used to treat symptomatic infection whatever the stage of pregnancy. Treatment of asymptomatic trichomoniasis with metronidazole did not prevent preterm birth and may cause harm.⁶⁶ A Cochrane review⁶⁷ found no evidence to support the use of metronidazole in pregnant asymptomatic women with *Trichomonas vaginalis*. It is not clear why metronidazole should cause adverse pregnancy outcomes when it is effective in clearing the infection.'

MALARIA

Malaria is prevalent throughout the tropics and is a major cause of mortality in both children and adults. *Plasmodium falciparum* causes the most severe type of malaria, which can present with hepatic and cerebral manifestations. It is transmitted between human hosts by the female *Anopheles* mosquito. *P. falciparum* has been able to develop resistance to most antimalarials, creating a need for new agents. The other strains of malaria seldom cause fatal disease, but cause considerable morbidity; they are virtually always chloroquine sensitive (see Ch. 62).

Pregnant and puerperal women are at increased risk of malaria infection. If they become infected with malaria, complications – particularly hypoglycemia and lactic acidosis – are more frequent. Infection may also trigger a miscarriage or premature labor. In hyperendemic areas the disease may present as severe anemia, with a negative blood film.

In women at risk of malaria, regular or intermittent chemoprophylaxis reduces the risk of several maternal anemia, perinatal death and low birth weight.⁶⁸ Even non-falciparum malaria has been associated with intrauterine growth retardation. Congenital malaria has been described.

The diagnosis should be suspected in anyone who has been to the tropics and presents with a febrile illness. A history of taking prophylaxis does not exclude the diagnosis, as no prophylaxis is 100% effective. A blood film should be requested and stained for malaria parasites. Repeated blood films should be taken during episodes of fever if the initial test is negative. As well as anemia there may be thrombocytopenia and elevation of liver enzymes. Fever in the tropics or in people recently returned may be caused by many other infections, including typhoid, food poisoning organisms and viral infections such as dengue fever.

In affluent countries pregnant women with suspected malaria should be admitted to hospital and monitored closely as sudden deterioration requiring intensive care may occur.

Confirmed or possible falciparum malaria is usually treated with quinine sulfate. The dose regimen and mode of administration are not affected by pregnancy. Quinine does not cause abortion or preterm labor (unless massively overdosed), but can induce hypoglycemia and lactic acidosis. Malariae, vivax and ovale malaria should be treated with standard doses of chloroquine. Vivax and ovale malaria can develop persisting forms (hypnozoites). The best method of eradication therapy in pregnancy is currently controversial and expert advice should be obtained. A treatment course of pyrimethamine-sulfadoxine may be appropriate.

Individuals living in endemic areas acquire immunity to malaria, but lose it within a few months of moving away. Therefore, anyone traveling from a non-malarial country to an endemic area should take prophylaxis (see Ch. 62 for recommendations). A randomized controlled trial in Kenya found that intermittent sulfadoxine-pyrimethamine (Fansidar) was safe and prevented severe anemia secondary to malaria in pregnancy.⁶⁹

The choice of prophylactic agent should be made after consulting current recommendations giving details of resistance patterns. Chloroquine is probably the least toxic prophylactic agent for pregnant women. Those traveling to areas of chloroquine resistance must balance the risk of malaria against the potential toxicity of prophylactic agents. It is safest to avoid travel to such areas when pregnant, but if the mother cannot be persuaded to delay travel the potential risks and benefits of chemoprophylaxis (and/or standby treatment) must be discussed. The role of artemether/lumefantrine in pregnancy is currently uncertain but we expect that initial reports about its safety in pregnancy⁷⁰ will be confirmed. The reader is strongly advised to consult the most recent local guidelines.

VAGINAL CANDIDIASIS

Over three-quarters of women have at least one episode of vaginal candidiasis during their lifetime. The organism is carried in the gut, under the nails, in the vagina and on the skin. The yeast *Candida albicans* is implicated in more than 80% of cases; *Candida glabrata*, *Candida krusei* and *Candida tropicalis* account for most of the rest (see Ch. 60). *Candida* is an opportunist, growing under favorable conditions. Symptomatic episodes are common in pregnancy; its growth is favored by the high levels of estrogen, increased availability of sugars, and subtle alterations in immunity.

In general it is better to use a topical treatment rather than a systemic one. This minimizes the risk of systemic side effects and exposure of the fetus. Vaginal creams and pessaries can be prescribed at a variety of doses and duration of treatment. For uncomplicated candidosis, a single dose treatment, such as clotrimazole 500 mg, is not adequate in pregnancy, and a longer course (e.g. 100 mg/day for 7 days) is recommended.

Sexually transmitted diseases

Sheena Kakar and Adrian Mindel

Many infections are sexually transmitted (Table 56.1). Some, including HIV, hepatitis B and C, are also transmitted by blood or blood products. Others, like human papillomavirus (HPV), herpes simplex virus (HSV) and molluscum contagiosum are also transmitted by close bodily contact.

In 2005, the World Health Organization (WHO) estimated there were 448 million cases of the four major curable sexually transmitted infections (STIs), trichomoniasis, chlamydia, gonorrhoea and syphilis, among people aged 15–49.¹ Ninety percent of cases occur in developing countries. In recent years the viral STIs, in particular HIV, have become increasingly important. The joint United Nations program on HIV/AIDS estimated that at the end of 2007 there were 33 million people living with HIV/AIDS, most in developing countries.²

The rate of spread of STIs within a community depends on several factors, including the size of the susceptible population, exposure to an infected individual, efficiency of transmission and duration of infectiousness. Epidemiological patterns of individual infections depend on the interplay between these factors and the social, economic and political environment. One of the major reasons why STIs are more common in developing nations is that a large proportion of these populations is aged 18–35, the age group considered to be at greatest risk for STI acquisition.

An example of the effect of social, economic and political changes on STIs is the epidemic growth of these infections in the former USSR. Profound social and economic changes, and a partial collapse of the health system, have been contributory. The epidemic has been fuelled by growth in the commercial sex industry, unsafe intravenous drug use and exchange of sex for drugs.

At an individual level, risk factors include early coitarche, multiple sexual partners, partners from high-risk groups, poor condom usage and drug use.

STIs have important health, social and economic consequences for the individual and the community. These include pelvic inflammatory disease (PID) leading to infertility and ectopic pregnancy; congenital, perinatal and postnatal infections; and a variety of genital tract cancers. In addition, STIs, in particular genital ulcer disease (GUD), increase the transmission of HIV.

CHLAMYDIA

These obligate intracellular bacteria have several species, two of which infect humans as their primary host – *Chlamydia trachomatis* and *Chlamydophila* (formerly *Chlamydia pneumoniae*). *C. trachomatis* can be further divided into biovars, distinct groups of biological variants, each producing a different disease spectrum. Serovariants or serovars of the trachoma biovar result in trachoma (serovars A–C) or STIs (serovars D–K). Lymphogranuloma venereum comprises the serovars L1, L2 and L3 and forms the second biovar in the *C. trachomatis* species.

EPIDEMIOLOGY

C. trachomatis has the highest prevalence of any bacterial STI in developed countries. In 2005, the WHO estimated that there were 102 million new cases of *C. trachomatis* infection in people aged 15–49 worldwide,¹ second only to trichomoniasis as the leading cause of curable STIs. In both sexes, the prevalence of infection ranges from 3–5% in low-prevalence general medical settings to 15–20% in high-prevalence STI clinics.

Since 1998, diagnoses of uncomplicated chlamydia infections in genitourinary medicine (GUM) clinics in the UK have increased by 150% from 48 726 in 1998 to 121 986 in 2007.³

In common with other STIs, risk factors include age below 25, one or more sexual partner in the recent past, inconsistent condom use, oral contraceptive use, termination of pregnancy and non-white race.

Chlamydia may result in significant complications, including PID, with resultant infertility and ectopic pregnancy, neonatal infection, epididymo-orchitis and reactive arthritis. In the UK the annual cost of chlamydia, including complications, is estimated to be at least £100 million and in the USA in 2007 the annual cost was estimated at US\$624 million.^{4,5}

Table 56.1 Sexually transmitted infections

Disease	Causative organism	Complications
Bacterial		
Gonorrhea	<i>Neisseria gonorrhoeae</i>	Pelvic inflammatory disease, bartholinitis and Bartholin's abscess, systemic dissemination, epididymo-orchitis
Chlamydia	<i>Chlamydia trachomatis</i>	Pelvic inflammatory disease, bartholinitis and Bartholin's abscess, epididymo-orchitis
Syphilis	<i>Treponema pallidum</i>	Central nervous system, cerebrovascular system and gummatous infection
Chancroid	<i>Haemophilus ducreyi</i>	Local genital destruction
Lymphogranuloma venereum	<i>Chlamydia trachomatis</i>	Local abscesses, fistulae, strictures and genital destruction, rarely meningoencephalitis, hepatitis, pneumonitis
Donovanosis (granuloma inguinale)	<i>Klebsiella granulomatis</i>	Local genital destruction, genital lymphedema, squamous cell carcinoma, bone and liver dissemination
Viral		
Genital warts	Human papillomaviruses	Genital tract tumor (mainly cervical cancer – with 'high risk' types)
Genital herpes	Herpes simplex virus type 1 and 2	Acute systemic viremia with primary HSV-2, local recurrences
Molluscum contagiosum	Molluscum contagiosum virus	
HIV	Human immunodeficiency virus types 1 and 2	Severe immune suppression, opportunistic infections
Hepatitis B	Hepatitis B virus	Fulminant hepatitis, chronic infection, cirrhosis, hepatocellular carcinoma
Hepatitis A	Hepatitis A virus	Fulminant hepatitis
Hepatitis C	Hepatitis C virus	Fulminant hepatitis, chronic infection, cirrhosis, hepatocellular carcinoma
Other infections and miscellaneous conditions		
Candidiasis	<i>Candida albicans</i> <i>Candida glabrata</i>	
Bacterial vaginosis	Reduced lactobacilli, high-concentration anaerobic bacteria	Pelvic inflammatory disease, and chorioamnionitis, prematurity, premature rupture of membranes, low birthweight
Trichomoniasis	<i>Trichomonas vaginalis</i>	Premature rupture of membranes, low birthweight
Non-specific genital infections	<i>Mycoplasma genitalium</i> , <i>Ureaplasma urealyticum</i> , <i>Mycoplasma hominis</i>	

PATHOGENESIS

The developmental cycle of Chlamydiae is unique. The bacterium infects eukaryotic cells, depending on these cells for many of the nutrients required for its growth and replication. The infectious particle of chlamydia is a metabolically inactive elementary body which attaches to epithelial cells, induces phagocytosis and, avoiding lysosomal fusion, enters the reticulate system. Within the phagosome the elementary body undergoes morphological change to form the reticulate body, the metabolically active, replicating form of chlamydia. Over the next 48–72 h the reticulate body replicates, increasing in numbers, reorganizing into elementary bodies: a mature inclusion body may contain thousands of elementary bodies. When cell death is imminent, lysosomal fusion

occurs, the cell ruptures and elementary bodies are released. The disease process is thought to result from a combination of direct tissue damage secondary to chlamydial replication, local inflammatory responses and the body's humoral and cell-mediated immune responses.

Immune responses to chlamydia control the acute infection. However, the infection evolves into a low-grade chronic infection which, unless treated, persists. One hypothesis regarding the pathogenesis postulates a delayed hypersensitivity reaction to chlamydial heat shock protein (hsp 60) which shares extensive amino acid sequence with human hsp 60. Chlamydial hsp 60 shares some antigenic sites with mycobacteria and *Escherichia coli*. These infections could sensitize patients, resulting in a primed response to chlamydial infection and greater disease severity.

DIAGNOSIS

CLINICAL

Most women with uncomplicated chlamydia are asymptomatic. Those who have symptoms present with vaginal discharge, intermenstrual or postcoital bleeding and occasionally lower abdominal pain. On examination, mucopurulent cervicitis and/or contact bleeding may be noted. Men present with dysuria and urethral discharge. Rectal infection may result in proctitis. Pharyngeal infections are usually asymptomatic.

INVESTIGATIONS

Diagnostic options include culture, antigen testing and nucleic acid amplification tests (NAATs). Although culture has the highest specificity, sensitivity is low. It requires endocervical or urethral swabs and is expensive. NAATs are cheap, have relatively easy specimen collection and transport conditions. However, sensitivities are variable and positive predictive value low (<5%) in low-prevalence populations. NAATs such as the polymerase chain reaction (PCR) and ligase chain reaction (LCR) are highly specific and sensitive but more expensive. PCR and LCR have gained popularity in male diagnosis due to non-invasive specimen collection (urine instead of urethral swab) and are comparable with other test methods.⁶ Urine may also be a suitable sample in women.⁷ Serology is available but of little diagnostic value in genital disease as it fails to differentiate between previous and current infections.

MANAGEMENT^{5,8,9}

Uncomplicated infection:

- Azithromycin 1 g orally (single dose)
- Doxycycline 100 mg orally every 12 h for 7 days.

Alternative regimens:

- Erythromycin 500 mg orally every 12 h for 7 days or every 12 h for 14 days
- Ofloxacin 200 mg orally every 12 h for 7 days
- Amoxicillin 500 mg orally every 8 h for 7 days in pregnancy.

A meta-analysis of 12 randomized controlled trials (RCTs) demonstrated equal efficacy of azithromycin and doxycycline.¹⁰ Azithromycin has a very long half-life, a large volume of distribution with excellent tissue and cellular penetration (see Ch. 22), and can be given as a single dose. It has fewer side effects than doxycycline, the most common being mild gastrointestinal disturbance. Doxycycline can also cause gastrointestinal disturbance, particularly esophagitis. Another common side effect is photosensitivity (see Ch. 30). When compliance is taken into account, though expensive, azithromycin is more cost-effective than doxycycline.¹¹

Alternative therapies have broadly comparable cure rates, but use is limited by side effects or cost. Erythromycin has been studied at 500 mg every 6 h or 500 mg every 12 h for 7–14 days. Higher dose regimens are slightly more efficacious but less effective because of gastrointestinal intolerance, with up to 50% of patients not completing the course. Ofloxacin (a fluoroquinolone) is as effective as doxycycline, with a better side effect profile, but is considerably more expensive and does not share the advantage of single-dose therapy (with azithromycin).¹² Tetracyclines are as efficacious, but have more side effects than doxycycline and have to be taken every 6 h.

Rifalazil, a new rifamycin compound, has been found to be highly active against chlamydia in cell cultures. A recent RCT demonstrated a dose-dependent microbiological and clinical cure rate comparable to azithromycin.¹³ Moxifloxacin also demonstrates activity against chlamydia in vitro. Both agents may be useful in chlamydia infections.^{14,15}

To minimize transmission, abstinence for a week after treatment completion is recommended.

PREGNANCY AND BREASTFEEDING

Doxycycline and ofloxacin are contraindicated in pregnancy, but azithromycin appears to be safe.^{8,16,17} Amoxicillin has also been evaluated in pregnancy and provides microbiological clearance despite some resistance detected in vitro. It has a better side effect profile than erythromycin, with a similar cure rate. However, it is not clear whether amoxicillin eliminates the organism or temporarily suppresses replication.

While erythromycin remains effective, its use may be limited by gastrointestinal side effects.⁸ Erythromycin estolate is contraindicated in pregnancy because of possible drug-related hepatotoxicity.

Due to concerns over efficacy of therapy in pregnancy, and possible sequelae in the neonate and mother in the event of persistent infection, a test of cure is advised 3 weeks following treatment.⁵ Data on neonatal outcomes are limited.

Amoxicillin and azithromycin may be used during breastfeeding. Erythromycin is best avoided in the early postnatal period (risk of neonatal pyloric stenosis) but is safe for use thereafter.¹⁸

RESISTANCE

There are case reports of clinically significant, multidrug-resistant chlamydial infections, causing relapse or persistence. Resistance to azithromycin, doxycycline, ofloxacin, erythromycin and josamycin has been documented in vitro.^{19,20} While this does not seem to be a widespread phenomenon, it highlights the need for increased surveillance to monitor treatment failures, and in vitro resistance of isolates.

Resistance of *C. trachomatis* depends on its ability to proliferate within the host cell, in the presence of varying

concentrations of antibiotics. Consequently, resistance is usually not absolute and described as being ‘heterotypic’. This implies that all organisms may be capable of resistance. However, only a small proportion will show resistance at any given time. It is hypothesized that this heterotypic resistance may be a by-product of undefined alterations in the growth phase or life cycle in some bacteria, rendering them refractory to antimicrobial agents. An alternative theory is that resistance may be mediated through mechanisms that exclude drugs from chlamydial cells or inclusions (e.g. an efflux pump). Further research is required in this area.¹⁹

SEXUAL PARTNERS

All sexual contacts of the index case (within 4 weeks if symptomatic or up to 6 months if asymptomatic) should be traced, screened and treated if necessary. Studies have demonstrated the advantages of partner-delivered therapy for contacts. To optimize partner notification, counseling and written information may be helpful.

SCREENING

As many infections with chlamydia are asymptomatic and sequelae can be devastating, screening programs should be implemented. Screening criteria are normally age related (18–24 years) and can include behavioral and clinical measures. Where screening programs have been implemented, prevalence has decreased. They are epidemiologically effective and cost-effective in areas with prevalence as low as 3%.^{21,22}

GONORRHEA

Neisseria gonorrhoeae is an aerobic, Gram-negative diplococcus of the genus *Neisseria*. In common with other members of this genus, its primary site of infection is mucous membranes. Gonococci and meningococci are the two major pathogenic species seen in humans. Gonococcal infections can lead to urethritis, cervicitis, proctitis or pharyngitis. Co-infection with chlamydia has been reported in 20–40% of people.

EPIDEMIOLOGY

In 2005 the WHO estimated that, worldwide, there were 88 million cases of gonorrhea in adults aged 15–49, the majority in the developing world.¹ The incidence declined in most developed countries in the 1980s; however, the incidence increased in the late 1990s and early 2000s with a recent stabilization of rates.

Gonorrhea is the second most common bacterial STI (after chlamydia) in the UK. In 2007, a total of 18 710 diagnoses

were made in UK GUM clinics, a decrease of 1% from 18 898 diagnoses in 2006, in line with the trend since 2002.¹⁵

Following a 75% decline in gonorrhea incidence in the USA, the rate now seems to have reached a plateau. In 2007, the rate was 118.9/100 000 population, with the highest rate in the South (156/100 000), only slightly higher than 2006 when the rate was 119.7/100 000.²³

Risk factors for gonorrhea are similar to most STIs. However, gonorrhea also shows a distinct ethnic minority bias in the USA and Europe, which is partly explained by accessibility to healthcare, poverty and socioeconomic status. However, differences still exist in studies attempting to control for these factors.²⁴

Men have a 20% risk of acquiring urethral infection after one episode of vaginal intercourse with an infected partner. In women the risk of acquisition is higher (50–90%). Pharyngeal to urethral infection is increasingly recognized with the growing popularity of orogenital sex. Asymptomatic infection is reported in up to 35% of women and 1–3% of men.

PATHOGENESIS

N. gonorrhoeae has two main patterns of infection. Most bacteria are limited to the mucosal surface, where they cause marked tissue damage. Some bacteria can resist the killing activity of antibodies and complement in human serum, causing disseminated infection with little or no mucosal damage. Within each infection pattern, there exists a spectrum of pathogenicity. The severity and pattern of the infection are determined by molecules expressed on the surface, including those responsible for adherence, metabolite transport and tissue toxicity, against which various antibodies are formed. Two surface molecules, pilus and opacity proteins, are responsible for adherence to cells. Both show antigenic variation, allowing them to attach to different niches and escape the host's immune responses, and show phase variation, which alters the pathogenicity of the gonococci. Once adhered to the cell, gonococci must evade neutrophil phagocytosis to survive. Pili surface proteins increase resistance to phagocytosis and killing.²⁵ Even following phagocytosis, 2% of gonococci survive.²⁶ Gonococci adhere to and invade mucus-secreting, non-ciliated cells. Inside this immune privileged site they multiply, divide, and then exit from the basal surface by exocytosis. Tissue damage caused by gonococci is thought to be secondary to extracellular products such as enzymes (phospholipase, peptidase), lipo-oligosaccharides and peptidoglycans.

Gonococci have developed a number of mechanisms to avoid killing by serum antibodies and complement. For example, blocking antibodies against a surface molecule, reduction modifiable protein (RMP), appear to inhibit IgM complement-fixing antibodies from recognizing their target on lipo-oligosaccharides.²⁷ Blocking antibodies to RMP are not only important in the development of serum resistance, but also appear to play a part in mucosal immunity, and therefore transmission. Women with antibodies against RMP

are more likely to acquire mucosal infection. Serum-resistant gonococci, however, lead to limited (if any) mucosal inflammation, correlating with their inability to trigger chemotactic response to neutrophils. Serum-sensitive gonococci, which are limited to mucosal surfaces, are thought capable of triggering a strong chemotactic response and marked mucosal inflammation.

DIAGNOSIS

CLINICAL²⁸

Symptomatic women commonly present with vaginal discharge associated with cervical infection. Dysuria, but not frequency, is seen with urethral infection and is present in 70–90% of infections. Less commonly, patients will present with intermenstrual bleeding or menorrhagia. Clinical findings can include mucopurulent cervical discharge with contact cervical bleeding and ectopy. Frequently, no signs are evident in uncomplicated infection.

In men, the most common presentation is urethral discharge, which tends to be purulent, occurring up to 14 days after infection and often associated with meatal erythema. About half of these will have dysuria. Epididymitis occurs in 1% of infections. Asymptomatic infections are less common than with chlamydia. Rectal infection via direct inoculation occurs after receptive anal sex. In women it is often asymptomatic, but up to 50% of men will have discharge or proctitis. Pharyngeal infection is asymptomatic in most cases and spontaneously resolves in about 12 weeks.

Disseminated infection is rare and presents as an arthritis–dermatitis syndrome. The arthritis may be an acute, asymmetric, destructive monoarthritis or a reactive arthropathy. Classically, the rash appears as distal, tender, necrotic pustules. Meningitis and endocarditis are infrequently described.

INVESTIGATIONS

The gold standard investigation is culture on selective media containing antimicrobials to reduce contamination. This has a high sensitivity (80–95%) and specificity. In male urethral swabs, the sensitivity of microscopy and Gram stain alone in symptomatic individuals is 90–95%, which is comparable with culture. However, sensitivity falls to 50–75% in asymptomatic infections and 50–70% in cervical infections.²⁸ Microscopy and Gram stain, therefore, have a place in rapid diagnostic testing, but cannot supplant culture. NAATs are growing in popularity with sensitivity in the range of 87–98%, but with an organism that shows increasing antibiotic resistance, culture and antimicrobial testing will always be the gold standard. Sensitivity and specificity of serological testing is very low, limiting its use in screening, case finding or diagnosis.

MANAGEMENT^{29–33}

UNCOMPLICATED INFECTIONS OF CERVIX, URETHRA AND RECTUM

Single-dose treatment with:

- cefixime 400 mg orally
- ceftriaxone 125–250 mg intramuscularly.

Alternative regimen: single-dose treatment with spectinomycin 2 g intramuscularly or other cephalosporin regimens such as:

- ceftizoxime 500 mg intramuscularly
- cefoxitin 2 g intramuscularly (with concurrent probenecid 1 g orally)
- cefotaxime 500 mg intramuscularly.

Possible oral alternatives:

- Cefpodoxime – 200 mg (British Association for Sexual Health and HIV [BASSH] recommendation) or 400 mg (US Centers for Disease Control and Prevention [CDC] recommendation)
- Cefuroxime axetil 1 g.

Patients with positive microscopy or culture, or a recent partner with confirmed gonorrhea, should receive treatment. The choice of antibiotics depends on local resistance patterns. The WHO and individual countries use sentinel surveillance systems to monitor susceptibility and guide treatment recommendations.

Since the 1950s, antibiotic resistance has been documented to several antibiotics, particularly penicillin, tetracycline and quinolones. Resistance is acquired through multiple chromosomal mutations or single-step plasmid acquisition. The antibiotics chosen should eliminate infection in 95% of those treated. Quinolone resistance has been increasingly documented worldwide, with highest levels in South East Asia and the Pacific. Quinolones are no longer recommended in these areas. In 2006, the Gonococcal Isolate Surveillance Project (GISP) in the USA recorded 22.3% of isolates resistant to penicillin, tetracycline or both, and also widespread fluoroquinolone resistance.³⁰ Consequently, fluoroquinolones are no longer recommended for gonorrhea in the USA.²⁹ Similarly in the UK, between 2006 and 2007, increased antimicrobial resistance to penicillin, tetracycline, ciprofloxacin and azithromycin was noted. None of these are currently recommended in the UK.

In the USA³⁰ and the UK³¹ gonococci remain sensitive to ceftriaxone.

In the UK, few spectinomycin-resistant isolates have been noted since 1988; however, no isolate has demonstrated spectinomycin resistance since 2005.³¹

One systematic review of studies published between 1980 and 1993 looked at single-dose antimicrobial therapy (excluding β -lactamase-sensitive penicillin and tetracycline). A total of 21 antibiotics were considered, including cephalosporins, fluoroquinolones, azithromycin, rifampicin (rifampin) and spectinomycin. The best balance of efficacy

and safety for uncomplicated gonococcal infection included ceftriaxone (125 mg), cefixime (400 mg), ciprofloxacin (500 mg) and ofloxacin (400 mg). However, the need to alter treatment depending on sensitivity patterns implies that only ceftriaxone and cefixime are currently recommended. The dose of ceftriaxone remains disputed. The Centers for Disease Control and Prevention (CDC) recommends 125 mg, but both Australian³⁴ and British guidelines³⁵ recommend 250 mg.

In general, all single-dose regimens recommended above have few side effects and are well tolerated. Disadvantages to using ceftriaxone and spectinomycin are that both have to be given intramuscularly. Many would prefer oral alternatives like cefixime. In a study regarding potential cost benefits of prescribing ceftriaxone versus cefixime, both were found to be equally cost-effective.³⁶ Given the prevalence and diversity of gonococcal resistance it is important to monitor local resistance patterns.

PHARYNGEAL INFECTION

Ceftriaxone 125 mg or 250 mg intramuscularly can be used for pharyngeal infections. Cefixime may also be used.³⁷ Spectinomycin and ampicillin have poor efficacy.

DISSEMINATED GONOCOCCAL INFECTION²⁹

- Intravenous or intramuscular ceftriaxone 1 g per day.

Alternative regimens:

- Intravenous cefotaxime 1 g every 8 h
- Intravenous ceftizoxime 1 g every 8 h
- Intramuscular spectinomycin 2 g every 12 h.

There have been no recent studies on the treatment of disseminated gonococcal infection. The above regimens have been used in clinical practice with few reported adverse effects.

All patients should be hospitalized for initial treatment and examined for endocarditis and meningitis. Parenteral therapy should be continued for 24–48 h after signs of improvement are seen, followed by oral therapy (cefixime 400 mg every 12 h or cefpodoxime 400 mg orally every 12 h) to complete a full week's course. If meningitis is present, ceftriaxone is continued parenterally for up to 2 weeks. If endocarditis is present, the drug should be taken for at least 4 weeks. Local expert opinion is advised when treating disseminated infection.

PREGNANCY AND BREASTFEEDING^{29,38}

- Intramuscular ceftriaxone 250 mg.
- Oral cefixime 400 mg.
- Oral amoxicillin 3 g given 30 min after oral probenecid 1 g.
- Intramuscular spectinomycin 2 g.

A Cochrane review of studies amongst pregnant women with gonorrhea suggests both ceftriaxone and spectinomycin are effective in microbiological clearance, while amoxicillin with probenecid may be less effective. However, study numbers were too small to state this with confidence.³⁸

Two RCTs have studied the treatment of gonorrhea in pregnancy; one compared ceftriaxone with cefixime, the other evaluated ceftriaxone, amoxicillin and spectinomycin. Microbiological cure ranged from 89% to 97%. In these two trials, all antibiotics were efficacious and no serious side effects were reported. Fluoroquinolones are not recommended in pregnancy because of reported arthropathy in animal studies.

Ceftriaxone, cefixime and amoxicillin are safe for use in lactation.¹⁸ It is unknown whether spectinomycin is secreted in breast milk and should be used with caution in nursing mothers.

SEXUAL PARTNERS

All sexual partners in the last 2–3 months should be evaluated and treated for gonococcal and chlamydial infection.

FURTHER MANAGEMENT

All patients should be screened for other STIs, particularly chlamydia, as some patients (20–40%) may have dual infection. At that co-infection level, the cost of routine dual therapy is less than testing for chlamydia. Therefore, chlamydia treatment should be routinely provided when treating gonorrhea.^{5,35}

MYCOPLASMA GENITALIUM

Mycoplasma genitalium belongs to the family Mycoplasmataceae, class Mollicutes. These bacteria are phenotypically distinct. They lack cell walls and have the smallest known genome amongst cellular organisms that can be cultured.

EPIDEMIOLOGY

M. genitalium is increasingly recognized as an important STI. In men with acute chlamydia-negative non-specific urethritis (NGU), several studies have demonstrated that the prevalence of *M. genitalium* ranges from 18% to 46%.³⁹ Infection of the rectum may occur in individuals practicing anal sex.

In women, *M. genitalium* can cause cervicitis and urethritis.³⁹ It has been detected in the endometrium of women with PID⁴⁰ and has been isolated from fallopian tubes.⁴¹ PID associated with *M. genitalium* is less likely to be symptomatic than gonococcal PID and appears clinically similar to chlamydial

PID.⁴² Further, because symptoms may be mild, women with *M. genitalium* PID may not seek treatment.⁴² Serological studies amongst women with tubal infertility indicate a possible relationship between past infection with *M. genitalium* and tubal damage.⁴³ Further studies are needed to fully understand the natural history of *M. genitalium* and its relationship with PID. It is noteworthy that most PID treatment regimens do not cover *M. genitalium*.⁴⁴

PATHOGENESIS

M. genitalium can bind to human spermatozoa and potentially be carried up into the female genital tract.⁴⁵ The ability of *M. genitalium* to elicit pathological changes in the human host depends on a complex set of interactions between the organism and immune mechanisms. *M. genitalium*'s genome consists of at least seven proteins, two of which have been studied in detail: MgPa (aka MG191 and MG140) and P110. They are required for adherence to the host cell and are highly immunogenic. The organism has also developed 'gliding motility' and the ability to express antigenic variants and other virulence-associated phenotypes, enhancing its ability to evade human defense mechanisms. Additionally, *M. genitalium* can survive within epithelial cells and attach to mucin, further contributing to its virulence.⁴⁶

DIAGNOSIS

CLINICAL

In men, the signs and symptoms are those of urethritis. In women, the clinical picture may be that of cervicitis, urethritis or PID. The infection may remain asymptomatic in both sexes.

INVESTIGATIONS

M. genitalium is difficult to culture, usually requiring complex media.⁴⁷ More commonly NAATs, particularly PCR, are used to diagnose infections.⁴⁸

Suitable specimens include urethral, vaginal and endocervical swabs; urine samples; and rectal swabs, if infection at that site is suspected. For culture, a suitable transport medium is required. For NAATs, swabs may be transported in phosphate-buffered saline or 'dry'.

MANAGEMENT

As *M. genitalium* lacks a cell wall, it is resistant to the β-lactams and cephalosporins.

The following may be used in the treatment of *M. genitalium*:^{39,44,49}

- Azithromycin 1 g orally (single dose)
- Moxifloxacin 400 mg orally every 12 h for 7–10 days.

Treatment failures have occurred with the use of azithromycin, with some strains showing resistance. This resistance is believed to have a genetic basis, with a mutation in the V region of the 23S rRNA. The basis for development of this mutation is induction of macrolide resistance by use of inappropriate dosages.⁵⁰ Consequently, patients treated with azithromycin should have a test of cure and treatment failures managed with moxifloxacin.⁴⁹

PREGNANCY AND BREASTFEEDING

Azithromycin is safe for use in pregnancy and while breastfeeding. Quinolones are contraindicated in pregnancy and breastfeeding.

SEXUAL PARTNERS

Contact tracing and treatment of partners is recommended.

NON-SPECIFIC URETHRITIS

There are several infectious causes of urethritis other than gonorrhea, chlamydia and *M. genitalium*. These include *Trichomonas vaginalis*, HSV-2, *Ureaplasma urealyticum* and *Mycoplasma hominis*. Oral pathogens are also being increasingly implicated in urethritis, including adenovirus, HSV-1 and *Streptococcus pneumoniae*. However, once gonorrhea and chlamydia have been excluded, other organisms are seldom sought. Instead, the condition is usually managed empirically. Tetracyclines, erythromycin and azithromycin are all effective:^{51,52}

- Azithromycin 1 g orally (single dose)
- Doxycycline 100 mg every 12 h for 7 days
- Erythromycin 500 mg every 6 h for 7–14 days
- Tetracycline 500 mg every 6 h for 7 days.

Moxifloxacin is active against *Ureaplasma* spp., *Mycoplasma* and *Chlamydia*, and is being evaluated as potential therapy.¹⁴

Urethritis caused by organisms such as *T. vaginalis* and HSV should be treated as detailed in subsequent sections.

PELVIC INFLAMMATORY DISEASE

There are many causes of PID and it is beyond the scope of this chapter to review these in detail. However, PID is a major complication of two sexually transmitted organisms (*Neisseria gonorrhoea* and *Chlamydia trachomatis*), together

Box 56.1 Treatment for pelvic inflammatory disease**Parenteral (inpatient) regimens****Regimen A^a**

Cefoxitin 2 g i.v. every 6 or 12 h, *or*
 Cefotetan 2 g i.v. every 12 h, *plus*
 Doxycycline 100 mg i.v. or p.o. every 12 h

Regimen B^a

Clindamycin 900 mg intravenously every 8 h, *plus*
 Gentamicin loading dose 2 mg/kg i.v. or i.m., followed by 1.5 mg/kg every
 8 h maintenance dose. Single daily dosing may be substituted

Alternative regimen^a

Ampicillin–sulbactam 3 g i.v. every 6 h, *plus*
 Doxycycline 100 mg orally or i.v. every 12 h

Outpatient treatment**Regimen A**

Ceftriaxone 250 mg i.m. in a single dose, *plus*
 Doxycycline 100 mg orally every 12 h for 14 days, *with or without*
 Metronidazole 400–500 mg every 12 h for 14 days

Regimen B

Cefoxitin 2 g i.m. plus probenecid 1 g p.o. administered concurrently
 in a single dose, *plus*
 Doxycycline 100 mg p.o. every 12 h for 14 days, *with or without*
 Metronidazole 400–500 mg p.o. every 12 h for 14 days

Regimen C

Other parenteral third-generation cephalosporin (e.g. ceftizoxime or
 cefotaxime), *plus*
 Doxycycline 100 mg p.o. every 12 h for 14 days, *with or without*
 Metronidazole 400–500 mg p.o. every 12 h for 14 days

^aOral therapy may be initiated 24 h after clinical improvement using doxycycline 100 mg every 12 h or clindamycin 450 mg/day for 14 days.

with anaerobic organisms. *M. genitalium* is increasingly implicated as a causative organism for PID.⁵³

As a definitive diagnosis is dependent on laparoscopy, many individuals are treated presumptively. This may result in overdiagnosis of PID and underdiagnosis of other causes of pelvic pain.⁵⁴ As microbiological confirmation is seldom undertaken, treatment is directed at the most likely organism(s).

High cure rates (i.e. microbiological resolution and clearance of symptoms) are achieved with most regimens (Box 56.1). A meta-analysis showed that regimens with two or more antibiotics had a better than 90% success rate.⁵⁵ However, damage to the fallopian tubes and subsequent infertility are long-term consequences, particularly where infection occurs more than once.

A recent RCT showed that the efficacy of azithromycin 1 g orally weekly for 2 weeks was comparable to doxycycline in treating mild PID⁵⁶ and may be preferred in situations where compliance is questionable or there is evidence of *M. genitalium* infection.

Moxifloxacin is currently being evaluated for use in PID as it is active against organisms causing PID, including mycoplasmas,¹⁴ and demonstrates uterine tissue concentrations sufficient to eradicate major pathogens. Other advantages are once-daily dosing and few side effects.

EPIDIDYMO-ORCHITIS

Epididymo-orchitis is a complication of gonorrhea and chlamydia, particularly in men under 35 years, and treatment should be directed at these organisms, i.e.:

- ceftriaxone 250 mg intramuscularly (single dose), *plus*
- doxycycline 100 mg every 12 h for 10 days.²⁹

In men over 35 years, treatment should be directed at urinary tract infections.

LYMPHOGRANULOMA VENEREUM**EPIDEMIOLOGY**

Lymphogranuloma venereum (LGV) is usually a disease of developing countries where it is often endemic. In developed countries, cases tend to occur in individuals with multiple sexual partners, low socioeconomic groups and urban areas. Traditionally, LGV occurred sporadically in developed countries, often secondary to sexual contact overseas. However, outbreaks have been described in several developed countries⁵⁷ amongst men who have sex with men (MSM), particularly in those with numerous casual partners. Where LGV is endemic, most patients are males in their twenties. The male-to-female ratio varies but can reach as high as 5:1 and may be due to a greater proportion of asymptomatic cases in women. However, late complications are reported more frequently in women.

PATHOGENESIS

LGV is a disease of the lymphatics. The organism induces a thrombolymphangitis and perilymphangitis in the drainage site of the primary infection. The endothelial cells lining the lymphatic vessels proliferate and central necrosis occurs. These areas coalesce to form abscesses from which fistulae or sinuses can develop. This acute inflammatory process lasts weeks to months, followed by fibrosis, resulting in further destruction of the lymphatics. Chronic edema develops secondary to lymphatic obstruction and the affected area often becomes indurated with breakdown of the overlying skin. In rectal involvement, a picture similar to Crohn's disease develops with transmural inflammation, mucosal ulceration and inflammatory strictures.

DIAGNOSIS**CLINICAL**

LGV is divided into three stages:

- Stage 1 is the development of a painless non-scarring ulcer or papule, usually on the glans penis, vaginal wall or labia. It occurs 3–12 days after sexual contact and often

heals unnoticed. Lesions can occur in the urethra, cervix or rectum, leading to urethritis, cervicitis or proctitis, respectively. Lymphangitis develops in the field of drainage.

- Stage 2 manifests as tender lymphadenopathy in the inguinal and/or femoral region. In two-thirds of cases this is unilateral. The area can feel matted, with ulceration and sinus formation. When inguinal and femoral regions are affected, the taut inguinal ligament forms a groove, which is said to be pathognomonic of LGV. This stage is often associated with fever. Meningoencephalitis, hepatitis, pneumonitis, erythema nodosum and erythema multiforme have been described. The time between the primary lesion and lymphadenopathy is 10–30 days, but may be up to 6 months.
- Not all cases progress to stage 3, where widespread destruction of surrounding areas results in proctocolitis, abscess formation, fistulae and strictures. This is more common in females and MSM. Alternatively, a lesion (esthiomene) develops when the primary infection has involved the lymphatics of the scrotum, penis or vulva. Lymphangitis, lymphatic obstruction and fibrosis result in induration, enlargement and ulceration of affected parts. This destructive process is most commonly seen in women.

INVESTIGATIONS

Investigations need to exclude other causes of GUD and other coexisting STIs. Various techniques can be used to assess lymph node aspirates or ulcer base exudates, including culture, immunofluorescence, enzyme immunoassay (EIA) and PCR. Alternatively, serological testing including microimmunofluorescence, complement fixation or enzyme-linked immunosorbent assay (ELISA) may be used. Culture is the most specific method but its sensitivity is poor (50–85%). Culture and immunofluorescence are labor intensive and expensive. EIA is relatively easy but has poor sensitivity and requires confirmation by another method. PCR, used in non-LGV chlamydia, has not been used to any great extent in LGV. PCR has high sensitivity and specificity, but is expensive. Of the serological tests, microimmunofluorescence is one of the most sensitive and specific. It can distinguish serotypes, making it the diagnostic test of choice if available.

MANAGEMENT

Studies regarding the treatment of LGV are few. Assessment of treatment outcome is difficult because spontaneous resolution can occur. Various guidelines suggest the following:^{5,58,59}

- first-line therapy: doxycycline 100 mg orally every 12 h for 21 days
- erythromycin base 500 mg orally every 6 h for 21 days.

Early treatment is essential to limit the chronic phase. Resolution of symptoms should occur within a few days, although healing may take several weeks. Complications such as fistulae, sinuses or strictures may require surgery, always under antibiotic cover.

Treatment of MSM remains the same as that for heterosexuals.

PREGNANCY AND BREASTFEEDING

Erythromycin base is safe for use in pregnancy and lactation. Doxycycline is contraindicated in pregnancy.¹⁸

SYPHILIS

The causative organism of syphilis is *Treponema pallidum*, subspecies *pallidum*, a spirochetal organism belonging to the genus *Treponema*. The genus includes three other human pathogens, *T. pallidum* subspecies *pertenue* (the cause of yaws), *T. pallidum* subspecies *endemicum* (the causative organism of bejel) and *Treponema carateum* (the causative organism of pinta).

EPIDEMIOLOGY

The incidence of syphilis in the developed world fluctuated dramatically during the 20th century. It was extremely common throughout Europe in the early part of the century. Following the First World War, social stability, improvements in living standards and healthcare resulted in a decline in incidence. However, this was short lived. During, and immediately after, the Second World War the incidence increased. The introduction of penicillin and improvements in healthcare resulted in a dramatic decline in syphilis in the 15 years following the Second World War. During the 1960s and 1970s, there was an increase in many parts of the world, particularly in MSM. However, as a consequence of the HIV epidemic, the 1980s saw widespread promotion of safer sex messages, leading to dramatic declines in syphilis, particularly in Europe, North America and Australia. In the late 1990s, Eastern Europe and some inner cities in North America saw an increase in incidence secondary to poverty, unemployment, poor healthcare and social breakdown.

In the USA, between 1990 and 2000, the rate of primary and secondary syphilis declined by 90%. However, from 2001 to 2007 the rates increased annually, predominantly among men (from 3/100 000 to 6.6/100 000).²³

In sub-Saharan Africa and South and South East Asia, syphilis remains a major public health problem with an estimated 6 million new diagnoses in both regions in 2005.¹

PATHOGENESIS

Treponemes enter the body via microabrasions caused by trauma during sexual intercourse and then migrate into the dermis where they attach to the surface of cells. They do not enter the cell, but penetrate the endothelial junctions and tissue layers. There is localized infection at the site of invasion, usually resulting in a local lesion (chancre). The organism then disseminates throughout the body. Late complications are due to a chronic inflammatory reaction which continues over many years. Cardiovascular syphilis is characterized by lymphocytic and perivascular infiltrates, resulting in an obliterative endarteritis. The pathological changes of neurosyphilis again reflect a chronic inflammatory reaction with lymphocytes and plasma cells infiltrating the meninges and perivascular areas, resulting in degeneration of neural cells. *T. pallidum* has an immune evasiveness, which is its key to success as a pathogen. This may partly be due to sequestration in immune sanctuary sites masking the organism's surface by host proteins, or paucity of outer membrane proteins acting as antigenic targets. Some immunogenic proteins appear to be under the cell surface and associated with the periplasmic leaflet. Additionally, the proteins are usually present in small numbers, further restricting their potential as immune targets.

DIAGNOSIS

CLINICAL

The incubation varies from 9 to 90 days (average 21 days) and the clinical features can be divided into three stages:

- Primary infection (chancre) occurs at the site of local inoculation. Chancres are usually painless ulcers, accompanied by local lymphadenopathy, and heal within 3–10 weeks.
- The secondary stage corresponds with dissemination of the infection, characterized by skin and mucous membrane lesions and constitutional symptoms. In many individuals, latency is established without any signs or symptoms of early infection; they may go on to develop the late complications of infection.
- Late complications include cardiovascular, neurological or gummatous disease. Cardiovascular problems include aortitis, aortic incompetence and aortic aneurysms. The second major late complication is neurological syphilis involving the brain and/or spinal cord. Gummatous disease represents a hypersensitivity reaction characterized by nodules consisting of necrotic tissue surrounded by mononuclear cells and proliferating connective tissue. They can occur in any tissue or organ, but most commonly occur in skin or bone.

Infection is completely curable in the primary, secondary and early latent stages. However, cardiovascular and/or neurological damage is irreversible, although progression can be

prevented with treatment. The natural history of untreated syphilis is variable: around 10% develop cardiovascular disease, 10% neurological disease and 10% gummatous disease.

INVESTIGATIONS

Syphilis can be diagnosed through direct visualization of the organism or by serological testing. Direct visualization may be possible in primary and secondary syphilis. Specimens may be obtained from primary chancres or mucous membrane lesions. The organism can be viewed under dark-field microscopy of serous exudate placed on a saline-moistened slide. Treponemes can be seen as motile spirochetes, characteristically said to display 'corkscrew' and 'angular' motion, with 15–20 coils. Specimens may also be examined with fluorescent antibody stains, a method that can also be used on biopsy and autopsy specimens.

The mainstay of syphilis diagnosis is serology. There are two types of serological tests: non-treponemal and treponemal.

Non-specific antibodies directed towards anticardiolipin, cholesterol and lecithin form the basis for the non-treponemal tests. They can be detected in serum and are related to disease activity. However, these tests also become positive in response to other conditions, including acute viral and mycoplasmal infection, vaccination, pregnancy, and connective tissue disorders. Two tests commonly used are the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma regain (RPR) test.

Treponemal tests are specific. However, once positive they tend to remain so, and consequently detection of antibodies indicates past or present infection. Three tests are commonly used: fluorescent treponemal antibody absorption test (FTA), *Treponema pallidum* hemagglutination assay (TPHA)⁶⁰ and a variation of TPHA, the *Treponema pallidum* particle agglutination assay (TPPA). Antibodies can be detected in serum and cerebrospinal fluid (CSF). In early infection no antibodies are present and the first test to become positive is usually the FTA.

There has been an increase in availability of the treponemal EIA for the detection of IgM and IgG treponemal antibodies. EIA for treponemal IgM antibodies is particularly helpful in the diagnosis of suspected early syphilis as they are almost invariably detectable 2 weeks after infection. IgG antibodies become detectable by the fourth or fifth week of infection.⁶¹

MANAGEMENT

Treatment aims to eliminate infection and prevent complications and onward spread. Since its introduction in the late 1940s, penicillin has revolutionized the management of syphilis and remains the mainstay of treatment, although no RCTs have been conducted. Despite its widespread use, *T. pallidum* remains sensitive to penicillin. Treatment choices are predicated on convenience of dosage, CSF penetration,

concomitant HIV infection and allergy. Benzathine penicillin is convenient to use, but has poor CSF penetrance.⁶² Some experts prefer procaine penicillin, particularly when used with probenecid, which delays renal excretion and prolongs the half-life of penicillin and has good CSF penetration.⁶³

PRIMARY, SECONDARY OR EARLY LATENT SYPHILIS IF THE CSF IS NEGATIVE^{5,61,64}

Treatment is procaine penicillin 1.2 g (600 000 units) intramuscularly daily for 10 days with probenecid 500 mg every 6 h. An alternative is single-dose benzathine penicillin G 1.8 g intramuscularly.

If the patient is allergic to penicillin the following regimens may be employed:

- Doxycycline 100 mg orally every 12 h for 21 days⁶⁵
- Azithromycin 2 g orally⁶⁶ (single dose)
- Erythromycin 500 mg orally every 6 h for 14 days
- Ceftriaxone 500 mg intramuscularly daily for 10 days
- Amoxicillin 500 mg orally every 6 h for 14 days (with probenecid 500 mg every 6 h for 14 days).

Ceftriaxone should be used with caution in individuals with history of anaphylactic reaction to penicillin.

Patients treated with alternative regimens must be monitored carefully for treatment failure. There are few reports of treatment failure with azithromycin.⁶⁷ A Cochrane review comparing azithromycin with penicillin is currently underway.

In individuals whose compliance to alternative regimens is questionable or follow-up unlikely, desensitization and subsequent treatment with benzathine penicillin may be recommended.

CARDIOVASCULAR, GUMMATOUS OR NEUROSYPHILIS^{5,61,64}

Choices include intramuscular procaine penicillin 1.2 g (600 000 units) daily and probenecid 500 mg every 6 h for 17 days, intramuscular benzathine penicillin G 1.8 g weekly for 3 weeks or doxycycline 100 mg orally every 12 h for 28 days.

THE JARISCH–HERXHEIMER REACTION

An influenza-like reaction with headache, myalgia and fever sometimes occurs within 24 h of starting therapy, believed to be due to rapid reduction in treponemal load which can be managed with simple antipyretics. Occasionally this reaction may cause severe complications in late syphilis, particularly where the cerebral vasculature or the aorta is involved. Systemic steroids such as prednisolone 30 mg/day for 3 days, commencing the day before treatment, are useful.

SYPHILIS IN HIV-POSITIVE PATIENTS^{5,61,64}

Treatment of syphilis in HIV-positive individuals remains an area of dispute. Some experts believe all HIV-positive patients should be treated as for late syphilis. Others believe treatment remains the same as for HIV-negative patients.

PREGNANCY AND BREASTFEEDING

Procaine penicillin and benzathine penicillin are both suitable for treatment in pregnancy and while breastfeeding. Doxycycline is not recommended. Erythromycin 500 mg orally every 6 h for 21 days is suitable in patients allergic to penicillin. If erythromycin is used, the baby should be treated with procaine penicillin as erythromycin does not reliably ensure cure of an infected fetus.⁵ There is little or no evidence to recommend a change in antibiotic treatment schedule amongst pregnant women.^{64,68}

CONGENITAL SYPHILIS

Infants under 2 years should receive aqueous crystalline penicillin 100 000–150 000 U/kg per day, administered intravenously as 50 000 U/kg (30–60 mg) per dose, every 12 h for the first 7 days of life, and every 8 h thereafter for a total of 10 days, as recommended by the CDC. The BASHH also recommends intravenous benzyl penicillin sodium 100 000–150 000 U/kg per day as per the CDC regimen. Alternatively, procaine penicillin G may be administered in a daily single dose of 50 000 U/kg intramuscularly for 10 days.^{5,69}

CHANCROID

Chancroid is an important cause of GUD in developing countries. The causative agent is *Haemophilus ducreyi*, a Gram-negative anaerobic coccobacillus.

EPIDEMIOLOGY

In 1995, the WHO estimated the annual incidence of chancroid to be 7 million.⁷⁰ The burden of this infection is predominantly in some developing countries where it is endemic. Several studies in the late 1990s suggested the prevalence of chancroid had decreased. A larger proportion of GUD is attributable to reactivation of HSV in HIV-positive populations. Mixed infections with HSV, syphilis or both are also common (17.4% [13.1–21.5% at 95% confidence intervals]).⁷¹

In developed nations, incidence and prevalence are low, with occasional outbreaks described in Canada and the southern states of the USA, often associated with exchange of sex for money or drugs and the use of crack cocaine or alcohol. Recently there has been a significant decline in prevalence in the USA, with only 23 reported cases in 2007.⁷²

H. ducreyi is transmitted mainly through sexual contact, with lower socioeconomic groups at greatest risk. Infection is twice as common among uncircumcised men as in circumcised men. Commercial sex workers (CSWs) with subclinical disease form a reservoir of infection, but there is no evidence for asymptomatic carriage. If untreated, the infection is thought to last about 45 days.

The presence of GUD, particularly chancroid, is an important risk factor in transmission of HIV. The mechanism behind this is thought to be *H. ducreyi* recruiting CD4 cells and macrophages to the genital surface, providing an increased target population of cells for HIV to infect.

PATHOGENESIS

H. ducreyi penetrates the epidermis through an abrasion or trauma. It incites a predominantly Th1 response, with recruitment of CD4 and CD8 lymphocytes, macrophages and granulocytes to the infection site. The initial lesion is commonly intraepidermal and organisms can be found within polymorphs and the interstitium. More virulent strains of *H. ducreyi* can withstand phagocytosis and killing by neutrophils. In addition to cellular immune response, a humoral immune response is elicited, with antibodies targeted particularly against lipo-oligosaccharides. The role of these immune responses in the pathogenesis of chancroid is not fully understood.

DIAGNOSIS

CLINICAL

Chancroid has an incubation period of 3–10 days. Men usually present with a genital ulcer or tender inguinal lymphadenopathy. Women present with dysuria, dyspareunia, vaginal discharge and pain or bleeding on defecation, depending on the infection site.⁷³ The ulcer can be single or multiple. Women often have a number of discrete ulcers, whereas over half of affected men will only have a single ulcer. The ulcer classically has ragged, undermined edges, a necrotic base with purulent exudate and bleeds easily on contact. It is non-indurated with little surrounding inflammation. Pain is characteristic, but less common in women. Ulcers occur at sites of trauma: in men, either on the internal or external surface of the prepuce, frenulum or coronal sulcus; in women, on the fourchette, labia, vestibule or clitoris. Ulcers may extend into the vagina and have been described on the cervix.

Associated painful inguinal lymphadenopathy occurs in about 50% of cases, being unilateral and extensive. Buboes form, become fluctuant and rupture, leading to extensive ulceration. Superinfection of these and primary ulcers by anaerobic organisms can lead to phagedenic ulceration and extensive tissue destruction. In men, phimosis may occur as a late complication, often requiring circumcision.

INVESTIGATIONS

Currently the ‘gold standard’ for diagnosis is culture of swabs taken from the base of the ulcer. Pus aspirated from a bubo can also be cultured, but has a lower yield as the number of organisms is low. For optimum results, a selective culture medium is required, for example gonococcal agar base, supplemented with fetal calf serum or charcoal. With these methods, sensitivities of at least 80% are reached. Gram staining samples may reveal Gram-negative coccobacilli with occasional chains. However, this is only 50% sensitive when compared with culture. PCR is the most sensitive method (>95%) but is only commercially available as a combined test for *H. ducreyi*, *T. pallidum* and HSV. Some laboratories have developed in-house PCR tests, but these are not Food and Drug Administration (FDA) approved.

Serology is available in the form of an ELISA, although it is unable to distinguish between new and old infection. Other causes of GUD should be considered and excluded.

MANAGEMENT^{5,74}

- Azithromycin 1 g orally (single dose)
- Erythromycin 500 mg orally every 6 h for 7 days
- Ciprofloxacin 500 mg orally every 12 h for 3 days
- Ciprofloxacin 500 mg orally (single dose)
- Ceftriaxone 250 mg intramuscularly (single dose)
- Spectinomycin 2 g intramuscularly (single dose).

With the emergence of plasmid-mediated antimicrobial resistance, tetracyclines, penicillins, streptomycin, chloramphenicol and sulfonamides are no longer reliable. Trimethoprim also shows widespread resistance, although the mechanism behind this has not been characterized. Intermittent resistance to ciprofloxacin and erythromycin has been described in several isolates worldwide, although in insufficient numbers to limit their use. If *H. ducreyi* is not eradicated from the ulcer within 72 h of commencing therapy, clinical failure can be anticipated.

All regimens recommended above have been proven effective in RCTs.^{75,76} A small study demonstrated cure rates of 93.7% and 93.3% with ciprofloxacin and erythromycin, respectively, but only 53.3% with co-trimoxazole.⁷⁷ The advantage of azithromycin and ceftriaxone is they are single-dose regimens. The option of using ciprofloxacin in a single dose has also been evaluated, with cure rates of 92%, compared to erythromycin, with cure rates of 91%.⁷⁸ Some studies

raised concern regarding single-dose regimens in HIV-positive patients. In one study 30% of patients administered ceftriaxone failed treatment.⁷⁹ Treatment failures have also been described with azithromycin.⁷⁵ Single-dose regimens should be used cautiously, particularly in HIV-positive patients. The CDC recommends that single-dose regimens should only be used in HIV-positive individuals if follow-up is ensured.⁵ Fluctuant buboes are managed by repeated aspiration of pus through adjacent healthy skin, a safe and effective procedure.

PREGNANCY AND BREASTFEEDING

Fluoroquinolones cannot be used in pregnancy and lactation, or in children. Azithromycin, erythromycin or ceftriaxone is the treatment of choice.

FOLLOW-UP

Patients should be reassessed after treatment completion to ensure healing has occurred. Re-epithelialization will be evident by day 7, although complete healing depends on initial ulcer size. Failure to respond may be due to antibiotic resistance or the presence of a co-infection. Sensitivity testing and exclusion of syphilis and HSV are warranted.

CONTACT TRACING

Contact tracing is necessary for any sexual contact in the 10 days prior to symptom onset. Contacts should be examined and treated if necessary. Active tracing and treating contacts and condom promotion programs make eradication of *H. ducreyi* achievable, a goal with high priority due to the enhanced HIV transmission.

DONOVANOSIS (GRANULOMA INGUINALE)

Donovanosis is a form of GUD seen predominantly in tropical countries and caused by the Gram-negative bacillus *Klebsiella granulomatis* (formally classified as *Calymmatobacterium granulomatis*).⁸⁰

EPIDEMIOLOGY

Recently, donovanosis has been seen in small endemic foci in only a few geographical areas; in particular, Papua New Guinea (PNG), southern Africa, North East Brazil, French Guyana and remote Australian aboriginal communities. Outbreaks have also been identified in parts of South

Africa.⁸¹ However, the numbers of cases in PNG⁸² and in Australia have decreased dramatically following successful elimination programs.⁸³ Most cases occur via sexual transmission, with men outnumbering women by up to 6:1,⁸⁴ and are associated with poor personal hygiene.⁸⁵ Vertical transmission has been reported, as has primary infection, in children. There appears to be a genetic component to donovanosis, with individuals with HLA-B57 being more susceptible and those with HLA-A23 having some resistance to infection.⁸⁶

PATHOGENESIS

Organisms gain entry via trauma or abrasions. A small firm nodule containing 'Donovan bodies' occurs at the site of inoculation and is considered classic for the disease. 'Donovan bodies' consist of large mononuclear cells in which intracytoplasmic inclusion bodies contain the bacteria. These inclusion bodies rupture, releasing infective organisms.

DIAGNOSIS

CLINICAL

At the site of primary inoculation, a small, non-tender papule or subcutaneous nodule forms; this either ulcerates or becomes a hypertrophic growth. The ulcer can become necrotic and destructive, leading to the formation of extensive scar tissue. The primary ulcer, in contrast to chancroid, is painless and can be single or multiple; however, like chancroid, it bleeds easily on contact and often has a distinctive odor. Genitals are affected in 90% of cases. Exogenous ulcers are found in 6% of cases, usually associated with primary disease. Sites include the oropharynx, neck and chest. Inguinal lesions occur in 10% of cases secondary to spread of infection from lymph nodes to overlying skin.

Some cases may resolve, but others develop into a chronic form leading to extensive tissue destruction. Other complications include hemorrhage, genital elephantiasis secondary to lymphoedema, squamous cell carcinoma and, rarely, dissemination to bone and liver. Disseminated disease is seen more frequently in pregnancy.

INVESTIGATIONS

Suitable samples include swabs or scrapings from the base of ulcers or tissue biopsy. These are stained with Giemsa or Gram stain and studied under a direct microscope. Donovan bodies (Gram-negative with bipolar staining) are found within histiocytes and are characteristic of infection (seen in 60–80% of suspected cases). *K. granulomatis* has been cultured but culture is not yet used in routine practice; neither is PCR nor serology.⁸⁷

MANAGEMENT

All patients with proven or clinically suspected donovanosis from endemic areas should be treated, with therapy continuing until the ulcer has healed.

The following regimens have been evaluated in prospective studies.^{5,84,87–91}

- Azithromycin orally 1 g weekly or 500 mg daily
- Erythromycin orally 500 mg every 6 h
- Doxycycline orally 100 mg every 12 h
- Trimethoprim-sulfamethoxazole orally 160/800 mg every 12 h
- Norfloxacin orally 400 mg every 12 h
- Gentamicin (intramuscular or intravenous) 1 mg/kg every 8 h
- Ceftriaxone (intramuscular or intravenous) 1 g daily.

Australian antibiotic guidelines recommend azithromycin. As lengthy therapy is often required, this may be one of the most cost-effective regimens. Like chancroid, there is some evidence that patients with HIV may not respond to first-line therapy and may require longer courses of antibiotics.⁸¹

Sexual contacts of the index case should be assessed and treated in order to reduce transmission of donovanosis, as well as HIV, in endemic areas.

PREGNANCY AND BREASTFEEDING

Azithromycin, erythromycin and ceftiaxone are safe for use in pregnancy and while breastfeeding. Doxycycline and ciprofloxacin and contraindicated. Pregnancy is a relative contraindication to the use of sulfonamides.

BACTERIAL VAGINOSIS

Bacterial vaginosis (BV) is a syndrome characterized by alteration in normal bacterial flora found in the vagina, from a predominance of lactobacilli, to high concentrations of anaerobic bacteria (*Gardnerella vaginalis*, *Prevotella* spp., *Mycoplasma hominis*, *Mobiluncus* spp.). It presents with an offensive vaginal discharge and is believed to be associated with PID, and an increased risk of preterm labor and chorioamnionitis in pregnant women.

EPIDEMIOLOGY

The infection is common in most countries, with highest reported rates in women in rural parts of sub-Saharan Africa (over 50%), followed by CSWs and women attending STI clinics (24–37%).^{92,93} Higher prevalence appears to be related to ethnicity, being sexually active and having symptoms.⁹⁴ A recent UK study indicated a prevalence of BV amongst asymptomatic pregnant women of 3.54%⁹⁵ and a study in Burkina Faso indicated a prevalence of 6.4% amongst women attending antenatal clinics.⁹⁶ BV appears to double women's risk of HIV acquisition.⁹⁷

PATHOGENESIS

The pathogenesis of BV is unclear. Inoculation studies in human and animal models, together with epidemiological data, suggest that sexual intercourse may introduce a set of bacteria that in some women set in motion a chain of events leading to alteration in bacterial flora and subsequent BV. Lack of inflammation in vaginal epithelial cells suggests that BV is due to a change in bacterial flora and composition of vaginal fluid rather than a true infection. Practices like 'douching' of the vagina are associated with BV and may play a role in pathogenesis.⁹⁸ Another factor thought to influence the host's susceptibility to infection is the predominant strain of lactobacillus present. Some strains produce hydrogen peroxide, which may inhibit growth of anaerobic rods, *Gardnerella*, *Mobiluncus* and *Mycoplasma*. These lactobacilli are found more frequently colonizing the vagina of normal women than those with BV and women with these strains are less likely to develop BV.

DIAGNOSIS

CLINICAL

BV is asymptomatic in many women. The characteristic symptom is a malodorous thin, white, homogeneous vaginal discharge, coating the walls of the vagina.

BV is associated with chorioamnionitis, preterm labor, low birthweight, premature rupture of membranes,⁹⁹ postpartum PID (following cesarean and vaginal delivery), post-abortion PID and PID following gynecological surgery. It is not clear if treating women with asymptomatic BV reduces their risk of developing PID.

INVESTIGATIONS

The diagnosis of BV is based on the presence of symptoms and signs. Cultures for specific bacteria are of limited use as these form part of normal vaginal flora. Diagnostic criteria consist of three of the following four signs:

1. Characteristic, white adherent vaginal discharge
2. Vaginal pH <4.5
3. Fishy odor (from release of amines) when vaginal fluid is mixed with 10% potassium hydroxide
4. Presence of clue cells.¹⁰⁰

Clue cells are vaginal squamous cells covered with bacteria giving them a stippled appearance. They can be visualized by placing a drop of vaginal fluid and normal saline on a slide and viewed microscopically. Gram staining vaginal fluid will also reveal clue cells, in addition to large numbers of Gram-negative or Gram-variable coccobacilli.

Commercially available diagnostic kits have not been validated for diagnosis.

MANAGEMENT

BV can remit spontaneously. Even with treatment, it may recur in up to one-third of women. Consequently, women with BV who are symptomatic, undergoing surgical procedures or are pregnant should be treated to reduce anaerobic flora.^{101,102}

RECOMMENDED REGIMENS

- Metronidazole 400–500 mg orally every 12 h for 7 days
- Metronidazole 2 g orally (single dose)
- Metronidazole gel (0.75%) intravaginally daily for 5 days
- Clindamycin cream (2%) intravaginally daily for 7 days
- Clindamycin 300 mg orally every 12 h for 7 days
- Tinidazole 2 g orally (single dose).

Metronidazole and clindamycin (oral and intravaginal preparations) have been evaluated in several RCTs and appear to have similar efficacy with cure rates at 1 month of 71–89%. A systematic review of oral and intravaginal preparations in non-pregnant women showed that at 4 weeks post therapy, cumulative cure rates were 78% for oral metronidazole, 82% for intravaginal clindamycin and 71% for intravaginal metronidazole.¹⁰³ One RCT comparing oral metronidazole with clindamycin showed no difference in short-term cure rates (94–96% at 7–10 days).¹⁰⁴ Comparison of metronidazole 2 g statim with 500 mg every 12 h for 7 days suggests that the single dose may be less effective.¹⁰⁵ Both metronidazole and clindamycin (intravaginal applications) have demonstrated similar efficacy in restoring lactobacilli at 21–30 days after initiation of therapy.¹⁰⁶

Clindamycin has few side effects but has been associated with pseudomembranous colitis and vaginal candidiasis. Up to two-thirds of women treated with oral metronidazole will experience side effects, mainly gastrointestinal. Intravaginal metronidazole preparations are equally effective, have fewer side effects, but may be more expensive.¹⁰⁷

The UK guidelines recommend tinidazole 2 g (single dose). An RCT found tinidazole 2 g per day for 2 days or 1 g per day for 5 days to be significantly more effective than placebo,⁹⁶ though more expensive than metronidazole.¹⁰¹

Although the recurrence rate among women treated for BV is high, there is no evidence from several placebo-controlled trials to support treatment of male sexual partners.

TREATMENT OF BV IN PREGNANCY AND BREASTFEEDING

Several RCTs regarding treatment of BV in pregnant women with a history of preterm labor indicate that this group should receive oral metronidazole or clindamycin early in the second trimester as both drugs are efficacious and safe.^{108–110}

Evidence does not support the use of intravaginal clindamycin to prevent preterm labor in women with BV. In fact, its use in the latter half of pregnancy has been associated with low birthweight and neonatal infections.¹¹¹

There is a suggestion that treating BV in the first 20 weeks of pregnancy may have a beneficial effect on preterm labor.¹¹² However, there are insufficient data to support treatment of all asymptomatic pregnant women.

Metronidazole enters breast milk and high doses should be avoided. Small amounts of clindamycin enter breast milk. It is prudent therefore to use intravaginal treatment during lactation.

TEST OF CURE

Only pregnant women with BV require test of cure. They should be retested after 1 month to assess requirement for further treatment.

PROPHYLACTIC THERAPY

Data on the use of prophylactic treatment before gynecological procedures and insertion of intrauterine contraceptive devices are limited. Currently there is insufficient evidence to support its use.

ALTERNATIVE MEDICATIONS

Various alternative treatments are currently available, including acidifiers, yoghurt and lactobacillus preparations but data supporting their use are limited.

GENITAL HERPES

EPIDEMIOLOGY

Genital herpes is caused by infection with one of the two herpes simplex viruses (HSV): HSV-1 or HSV-2. Most genital infections are caused by HSV-2 as a consequence of direct genital-to-genital spread. In some countries, particularly in the developed world, HSV-1 accounts for a considerable proportion of cases.¹¹³ HSV-1 is spread to the genitals during orogenital sex. Individuals infected genetically with HSV-1 or HSV-2 may remain asymptomatic,¹¹⁴ although most shed the virus sporadically and can infect their sexual partners.¹¹⁵

Several seroepidemiological studies have been conducted. These showed that among pregnant women, HSV-2 seroprevalence ranged from 7% to 50%,¹¹⁶ in STI clinics from 15% to 75%^{116,117} and among CSWs from 74% to 96%.

The presence of HSV-2 antibodies is related to age at coitarche, number of lifetime sexual partners, increasing age, ethnic origin, socioeconomic status, gender (women more commonly infected than men) and previous STIs.^{118,119}

PATHOGENESIS

HSV enters the body via the skin or mucous membranes of the genital tract. The virus is then taken up by sensory nerve cells and transported retrogradely to sensory or autonomic ganglia. The virus remains in the sensory neurons, where it may reactivate, and then be taken via anterograde transport to the cutaneous surface, where viral replication occurs. This results in either asymptomatic viral excretion or clinical recurrence of the disease.¹²⁰ The nature of the latent virus and cause of recurrences remain to be fully elucidated.

DIAGNOSIS

CLINICAL

Most individuals exposed to HSV remain asymptomatic.¹²¹ Amongst individuals who do develop symptoms, the first episode is usually more severe than recurrences. Individuals may present with symptoms suggestive of viremia with headache, fever and myalgia.¹²² Local symptoms include genital pain, dysuria and sometimes vaginal or rectal discharge. The first sign of infection is erythema followed by vesicles, which soon rupture to superficial ulcers that eventually heal. The lesions are often excruciatingly painful and the entire illness may last 2–4 weeks. The lesions may occur anywhere on the genitalia and draining lymph glands are often painfully enlarged.¹²²

Recurrences are usually shorter, often consisting of a single lesion or small group of lesions on the external genitalia, usually healing within 7–10 days.¹²² Many individuals with recurrent herpes have prodromal or warning symptoms consisting of neuralgia-type pain. Frequency of recurrences is variable: HSV-2 infections tend to recur more often than HSV-1 and lesions recur more often in the first year of infection. Some individuals may have 12 or more recurrences per year.¹²³

INVESTIGATIONS

HSV may be grown in cell culture from specimens such as vesicle fluid or material from the base of ulcers. Additional methods of identification include direct immunofluorescence, cytology (where typical cytological changes can be seen) and PCR. The use of PCR for the diagnosis of HSV has many advantages, including increased sensitivity, less dependency on collection and transport conditions, as well as stage of the outbreak. It can also be potentially quicker than viral culture.^{124,125}

Serological tests can be divided into group-specific and type-specific. Group-specific serological tests will indicate whether the individual has previously been exposed to either of the two HSV viruses, whereas type-specific serology will differentiate between the two viruses. A number of EIA tests are currently available for type-specific serology. However,

the most reliable technology is Western blot.¹²⁶ IgG antibodies take approximately 6–8 weeks to develop and consequently are of little use in primary infection. However, as many individuals are asymptomatic, type-specific serological tests should be used cautiously.

MANAGEMENT

Several nucleoside analogs are available for the management of genital herpes. These include aciclovir, valaciclovir (prodrug of aciclovir) and famciclovir (prodrug of penciclovir, converted to the active agent in the liver). Both aciclovir and penciclovir have similar modes of action^{127,128} (see Ch. 2). However, pharmacokinetic differences exist between these agents (see Ch. 37).

FIRST-EPIISODE GENITAL HERPES

All three nucleoside analogs have been evaluated for treatment of first-episode genital herpes. Numerous RCTs of intravenous, oral and topical aciclovir have demonstrated considerable efficacy in reducing constitutional symptoms, preventing new lesion formation and reducing the duration of lesions by many days.^{129–131} Intravenous and oral therapy appear to be better than topical. Oral valaciclovir and famciclovir have similar efficacy to aciclovir.

Recommended regimens are:

- aciclovir 200 mg five times daily for 5–10 days
- aciclovir 400 mg every 12 h for 5–10 days
- valaciclovir 500 mg every 12 h for 5–10 days
- famciclovir 250 mg every 8 h for 5–10 days.

Note: Although the 400 mg dose of aciclovir can be administered every 8 h, rather than every 12, this has not been the subject of any randomized controlled trial.

Treatment should be initiated as early as possible, resulting in a significant reduction in the duration of lesions, symptoms and viral shedding. None of the drugs has any effect on the likelihood of frequency of subsequent recurrences. The efficacy of all three agents appears to be similar, although the superior bioavailability of valaciclovir and famciclovir allows for less-frequent dosing schedules.

RECURRENT GENITAL HERPES

There are two approaches to managing recurrent genital herpes. Drugs can be used intermittently to treat each episode (intermittent therapy) or continuously over a period of time to prevent episodes from occurring (suppressive therapy).

Intermittent therapy

Intermittent therapy reduces the duration of each episode and may be useful for individuals with severe but infrequent recurrences. It may also be beneficial during the prodrome

when it may abort episodes. All three available drugs have been evaluated in RCTs and have demonstrated similar efficacy.^{132–135}

Doses for intermittent treatment

- Aciclovir 200 mg five times daily for 5 days.
- Valaciclovir 500 mg every 12 h for 5 days.
- Famciclovir 125 mg every 12 h for 5 days.

Recently, the trend is to use shorter regimens (1–3 days) for intermittent therapy.^{136–138} The efficacy of these regimens appears similar to that of the 5-day regimens with the advantage of fewer days of treatment without increased toxicity.

Suppressive therapy

Suppressive therapy is particularly useful for individuals having frequent recurrences. Most individuals on suppressive therapy will have no recurrences. All three drugs have similar efficacy,^{139–141} although the superior bioavailability of valaciclovir and famciclovir allows for less-frequent dosing schedules. Many patients treated with suppressive therapy will also have an improvement in psychosexual morbidity.¹³⁴

Doses for suppressive therapy

- Aciclovir 200 mg every 6 h or 400 mg every 12 h.
- Valaciclovir 500 mg once daily for individuals with 10 or fewer recurrences per year; 500 mg every 12 h for individuals with more than 10 recurrences per year.¹⁴¹
- Famciclovir 250 mg every 12 h.

Treatment should continue for a year and then stopped to see if recurrences are occurring with similar frequency and to determine the need for further therapy. Suppressive therapy does not appear to affect the natural history of recurrences. Individuals on treatment should be advised that viral shedding may still occur, and consistent condom use will reduce the risk of transmission.

PREGNANCY

None of the drugs has been formally evaluated during pregnancy. However, the inadvertent use of aciclovir during pregnancy did not demonstrate any adverse events.^{142,143}

Primary herpes in pregnancy

Women acquiring primary herpes during pregnancy should be treated with aciclovir or valaciclovir as described above. If the mother has primary herpes, the risk of mother-to-child transmission is 30–50%.¹⁴⁴ The risk increases significantly if the outbreak occurs in the third trimester.¹⁴⁵ Neonatal herpes is a devastating infection (see Ch. 55).

Cesarean birth before membrane rupture significantly reduces the risk of intrapartum transmission to the infant.^{5,146}

Recurrent herpes during pregnancy

The risk of transmission from mother to child with recurrent genital herpes is very low (<1%).¹⁴⁵ However, women with recurrent genital herpes are often extremely anxious about the risk and may request antiviral therapy or even elective cesarean section. Suppressive therapy in the last month of pregnancy decreases the risk of recurrences during that period^{147,148} and may be more cost-effective when compared to cesarean delivery.¹⁴⁹ If lesions or prodromal symptoms occur at the onset of labor, cesarean section is recommended to minimize the risk of viral exposure to the infant, even if suppressive therapy has been used.⁵

GENITAL WARTS

EPIDEMIOLOGY

Over 40 human papillomavirus (HPV) infections can involve the genital tract. These may be divided into those with low oncogenic transforming potential and those with high transforming potential. Types with low transforming potential are associated with condylomata acuminata (genital warts), whereas those with high transforming potential are associated with subsequent development of cervical cancer and other genital tract tumors. All HPV types found in the genital tract are transmitted by sexual intercourse.¹⁵⁰

The true prevalence of these infections is unknown, as a large number of individuals are asymptomatic with no reliable serological tests available currently. However, the incidence of genital warts has increased in Europe, North America and Australia.¹⁵¹ Using PCR-based methods, HPV infection has been detected in 1.5–44.3% of women with normal Papanicolaou (Pap) smears and 3.5–46.4% of men.¹⁵² These data are difficult to interpret as many of the studies were small, detection techniques varied and the population groups were different. Finally, recent studies suggest that genital warts and HPV infection may be more common in HIV-positive populations.^{153,154}

PATHOGENESIS

HPV infects the stratified squamous epithelium of the genital tract. The infection does not result in cell lysis; rather, infected cells are shed from the surface of the skin or mucous membranes. This means that no viral proteins are released, and consequently immune response is limited. It takes approximately 6 months after infection for natural immunity to develop.¹⁵⁵ T-cell function appears to be critical in modifying the effects of HPV and allows for persistence or spontaneous regression. Individuals with depressed cellular immunity often have persistent and proliferative lesions.¹⁵⁶

In benign lesions, HPV remains extrachromosomal. However, in cervical and other genital tract tumors, viral DNA is incorporated into the host chromosome.¹⁵⁵

DIAGNOSIS

CLINICAL

Most individuals infected with genital tract HPV remain asymptomatic. Some will develop genital warts which, in women, can occur on the vulva, vagina or cervix; in men, they occur on the penis, scrotal skin and occasionally within the urethra. In both sexes, perianal and anal warts can occur. Internal warts in women tend to be asymptomatic. HPV infections associated with cervical intraepithelial neoplasia are usually asymptomatic.

INVESTIGATIONS

No routine diagnostic tests are available for detecting HPV. While DNA amplification tests have been used in research and epidemiological studies, their use in routine clinical management is yet to be fully evaluated.

MANAGEMENT

There are no agents that specifically eradicate HPV or limit its replication. Treatments are directed at obliterating genital warts or removing dysplastic lesions. Several ablative techniques can be used, including cryotherapy, electrocautery, laser therapy or surgical removal.

Choice of treatment depends on the site and number of warts, availability of individual methods, operator expertise, cost and side effects. Success rates for all these treatments appear to be similar, with initial removal of warts achievable in most cases, although relapse is common.

Several chemical treatments are also used, including the anti-mitotic drug podophyllin and its purified counterpart, podophyllotoxin. The advantage of podophyllotoxin is that it does not contain any of the toxic ligands present in podophyllin, its consistency and strength can be guaranteed, and it is suitable for self-application on external warts. Podophyllin should be applied once or twice weekly for 3–6 weeks. Podophyllotoxin is applied every 12 h for 3 days, repeated in 7-day cycles. Complete clearance occurs in 50–90% of cases.^{157,158} Relapses occur in up to 38% of cases.^{159,160} Neither drug is recommended during pregnancy nor for treatment of lesions on the cervix.

Use of imiquimod, an immune-modulating agent that acts by inducing interferon- α and - γ and recruitment of CD4 $^{+}$ T lymphocytes, results in ‘immune-induced’ regression of warts and HPV DNA.^{161,162} The 5% cream should be applied three times a week¹⁶³ for up to 16 weeks. Clearance occurs in 56–62% of cases.^{161,164} An RCT suggested that use of imiquimod for 4 weeks may be just as effective in lesion clearance as the 8- to 16-week regimen, as well as being more cost-effective.¹⁶⁵ Imiquimod sometimes causes local irritation^{161,164} and recurrences do occur.

There is limited evidence to suggest recurrences may be less in individuals treated with imiquimod than with other treatment modalities.¹⁶⁴ A meta-analysis of RCTs comparing curative effects of 5% imiquimod and 0.5% podophyllotoxin on genital warts demonstrated a similar curative effect.¹⁶⁶

Finally, trichloracetic acid (TCA) or bichloracetic acid in 80–90% solutions may be used. It is recommended these solutions be applied to warts weekly for up to 6 weeks. These methods carry a risk of local irritation due to low viscosity of the solutions and are best applied by trained healthcare workers.¹⁵²

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is an infectious skin condition characterized by umblicated papules of up to 5–10 mm. The infective agent is a pox virus, but little is known about its life cycle and pathogenesis due to its inability to grow in tissue culture. Infection is mainly found in two population groups: children and young adults. Transmission of the virus is via skin-to-skin contact, which is reflected in the distribution of lesions in these two groups: most lesions in children are on the trunk and upper limbs and in adults on the buttocks, thighs and perineal area. The exception to this is HIV-positive adults where lesions are widespread, larger and often affect the face. Adults with atypical lesions should be offered HIV testing.

Diagnosis of molluscum contagiosum is clinical. Lesions may resolve spontaneously over a period of months and treatment can leave residual scarring. The decision to treat must therefore be discussed carefully with the patients. Options include extrusion or chemical ablation of the central core of the papule; topical creams including podophyllotoxin, TCA, acidified nitrite, an imiquimod analog; or physical ablation with cryotherapy.^{167,168}

VIRAL HEPATITIS

Hepatitis A and B (and occasionally C) can be acquired sexually. These infections are discussed in Chapter 48.

TRICHOMONAS VAGINALIS

This flagellated protozoan is found in the genitourinary tract of both sexes. It is transmitted primarily by sexual intercourse and in women is often found in association with other STIs. HIV is thought to have a two- to four-fold increased transmission rate in the presence of trichomoniasis.¹⁶⁹ Also, vaginal trichomoniasis has a demonstrated association with HIV seroconversion.¹⁷⁰ Finally, trichomoniasis has several adverse pregnancy outcomes including premature rupture of membranes and/or delivery and low birthweight.^{171,172}

EPIDEMIOLOGY

In 2005, the WHO estimated the worldwide incidence of trichomoniasis in adults at 248.5 million.¹ The infection is very common in CSWs (up to 60% prevalence) and in individuals with multiple sex partners, poor personal hygiene, previous STIs and from low socioeconomic groups.

The incubation period is from 5 to 28 days. Transmission from men to women is greater than from women to men: 67–100% and 14–60%, respectively.¹⁷³

PATHOGENESIS

Infection with *T. vaginalis* elicits a cellular and humoral immune response. An initial event is the influx of polymorphonuclear leukocytes. There is evidence that molecules of the organism act as a chemoattractant for these cells.¹⁷⁴ Leukocytes can then kill these organisms and the fragments are phagocytosed by macrophages. A second line of attack is complement mediated: C3 binds to the organism, activating the alternative complement pathway leading to its death.¹⁷⁵ Multiple environmental factors are thought to influence susceptibility of *T. vaginalis* to complement-mediated lysis. Iron has been shown to induce resistance to lysis, probably by induction of cysteine protease, which degrades C3.¹⁷⁶ Antibodies (IgA, IgG, IgM) against a number of different surface molecules are found both locally and in serum. The level of protection in resolving the initial infection and protecting against future reinfection has not been defined.

DIAGNOSIS

CLINICAL

The main site of infection in women is the vaginal epithelium. The urethra is often involved. Paraurethral glands may also be infected but endocervical infection is rare. In men, the urethra is the most common site infected, although the organism has also been isolated from external genitalia, epididymal aspirates and the prostate. Between 20% and 50% of infected women are asymptomatic. Symptoms include vaginal discharge, which can be malodorous, and vulval itch. Abdominal pain is described but may be secondary to co-infection with other organisms. On examination, patients may have vulval and vaginal erythema, with a small percentage having erythematous cervicitis, sometimes described as a ‘strawberry’ appearance; 5–15% of women will have no signs of infection.^{175,177} Men often present on contact tracing and, like women, up to half will have no symptoms. Symptoms include dysuria and/or urethral discharge. Some men may have balanitis. Spontaneous resolution and prolonged asymptomatic infections often occur in men.

INVESTIGATIONS

Direct microscopy of a ‘wet’ preparation (saline and vaginal discharge) in 50–70% of cases in women and 30% in men will demonstrate characteristic jerky movements caused by the beating of the organism’s anterior flagella, and an increased number of polymorphonuclear leukocytes. Microscopy must be performed within 10–20 minutes of collection or the organisms will lose viability. Culture remains the ‘gold standard’ and can diagnose up to 95% of cases in women and 60–80% in men.^{178,179}

PCR tests have been developed to detect *T. vaginalis*; however, their commercial availability is limited.

MANAGEMENT^{5,180}

- Metronidazole 2 g orally (single dose).
- Metronidazole 400 mg (or 500 mg) orally every 12 h for 5–7 days.
- Tinidazole 2 g orally (single dose).

Metronidazole or its related compounds remain the mainstay of treatment with a 95% cure rate if both partners are treated.¹⁸¹ Reasons for failure include reinfection, non-compliance and co-infections. Some organisms are capable of living under aerobic conditions, but there are currently no effective treatments for these organisms. Prolonged courses, higher doses and parenteral administration have all been tried with some reports of success.

In individuals reporting hypersensitivity to nitroimidazoles, desensitization with antihistamines and/or steroids may be employed prior to treatment.^{182,183}

Treating asymptomatic trichomoniasis during pregnancy does not appear to reduce the incidence of preterm labor. However, women with symptoms should always be treated.¹⁸⁴ Metronidazole is safe in pregnancy and during lactation.

CANDIDIASIS

Up to 89% of genital tract candidal infections are caused by *Candida albicans*. The remainder are caused by non-*albicans* species, the most common being *Candida glabrata*.¹⁸⁵

EPIDEMIOLOGY

Over 70% of women will have one or more episodes of vulvovaginal candidiasis in their lifetime, half of whom will have a recurrence.¹⁸⁶ However, frequent recurrences are uncommon. Factors predisposing women to infection include pregnancy, diabetes mellitus, the oral contraceptive pill, intrauterine contraceptive devices, steroids and HIV infection.^{187,188} Candidiasis is not usually sexually transmitted and is uncommon in circumcised men.

PATHOGENESIS

C. albicans is a common bowel commensal, gaining access to the vagina via the perianal area. Whether it is ever a vaginal commensal is disputed.¹⁸⁹ How and why the organism causes inflammation is unclear, although there are a number of recognized predisposing factors. A possible mechanism relates to the production of proteases and phospholipases by *Candida* organisms.¹⁹⁰

DIAGNOSIS

CLINICAL

In women, candida causes a vulvovaginitis, characterized by vulval pruritus and a white curdy vaginal discharge. On examination there may be vulval and/or vaginal erythema. Discharge is white and often adheres to the vaginal walls.¹⁹⁰ However, many women present with atypical features and laboratory confirmation is important, particularly if other STIs are possible. Infected males usually present with an acute balanoposthitis.

INVESTIGATIONS

A 'wet mount' microscopic examination of vaginal fluid may reveal yeast cells and mycelia.¹⁹⁰ On Gram staining, the cells and mycelia stain Gram-positive. *Candida* species can readily be cultured on Sabouraud's medium. Newer diagnostic methods are being developed for rapid diagnosis of vaginitis by *Trichomonas vaginalis*, *Candida* spp. and *Gardnerella vaginalis*. They are based on the principle of visual aggregation of latex particles bound to specific antibodies to surface antigens.¹⁹¹

MANAGEMENT

Topical agents with activity against *Candida* include imidazole agents and nystatin. They are available in the form of creams or pessaries for intravaginal and vulval use. Imidazole agents commonly used are miconazole, clotrimazole or econazole. Several dosing options are available with apparently similar efficacy (over 80%) and a low relapse rate. Nystatin is used less as it is less effective and messy. Recommended topical agents for vulvovaginal candidiasis are listed below:

- Clotrimazole vaginal tablet 500 mg (single dose)
- Clotrimazole pessaries or 200 mg/day for 3 days
- Clotrimazole pessaries 100 mg/day for 6 days
- Clotrimazole cream 5 g (single dose)
- Miconazole pessaries 200 mg/day for 3 days
- Miconazole pessaries 100 mg/day for 7 days
- Miconazole pessaries 100 mg/day for 14 days

- Miconazole vaginal ovule 1200 mg (single dose)
- Econazole pessaries 150 mg/day for 3 days
- Fenticonazole pessary 600 mg (single dose).

The oral azole agents (ketoconazole, fluconazole and itraconazole; doses below) have efficacy similar to topical agents^{192–195} and are preferred by many women. Also, single-dose oral fluconazole has been shown to be cost-effective:

- Fluconazole* 150 mg (single dose)
- Itraconazole* 200 mg every 12 h for 1 day.

RECURRENT VULVOVAGINAL CANDIDIASIS

Recurrent candidiasis is defined as four or more episodes of symptomatic vulvovaginal candidiasis with positive microscopy and/or culture, documented on two such occasions with partial resolution of symptoms in between episodes.^{196,197} While RCT evidence is lacking, the following regimens may be used to manage the condition.

Recommended treatment^{196,198,199}

- Fluconazole 150 mg orally every 72 h (3 doses) followed by a maintenance dose of 150 mg weekly for 6 months
- Clotrimazole 500 mg pessary twice weekly for 2 weeks ± clotrimazole 1% vaginal cream every 12 h or clotrimazole 200 mg nocturnally for 6–12 nights followed by a maintenance regimen of clotrimazole 500 mg pessary weekly.

Alternative regimens:

- Clotrimazole pessary 500 mg weekly
- Fluconazole* 50 mg orally daily
- Itraconazole* – suppression: 100 mg orally daily; maintenance: 100–200 mg orally weekly
- Ketoconazole* 100 mg orally daily.

CANDIDAL BALANITIS

Topical use of azoles is usually successful.

TREATMENT OF NON-ALBICANS CANDIDA SPECIES

Most are usually susceptible to available azoles. *Candida krusei* may demonstrate an intrinsic resistance to fluconazole.²⁰⁰

Although there are no RCTs, it is generally believed that longer courses of azoles may be needed.

*Avoid in pregnancy/risk of pregnancy/breastfeeding.

*Avoid in pregnancy/risk of pregnancy/breastfeeding.

CHAPTER

57 Leprosy

Diana Lockwood, Sharon Marlowe and Saba Lambert

Leprosy is one of the oldest recorded diseases. In 1988 the World Health Organization (WHO) proposed to eliminate leprosy (i.e. <1 case per 10 000 population) by the year 2000; however, in 2007, 258 133 new cases were reported globally by the WHO.

In 1873 the Norwegian Armauer Hansen showed that leprosy was caused by *Mycobacterium leprae*, which invades the skin and nerves, causing a chronic granulomatous disease with peripheral neuropathy and skin lesions.

Outside endemic areas, doctors often fail to diagnose leprosy, with unfortunate consequences for the patients: for example, in the UK, 40% of new cases have severe neuropathy at diagnosis. Early recognition of leprosy is important because the infection is curable and prompt treatment can reduce nerve damage and associated stigma.

EPIDEMIOLOGY

Leprosy remains a public health problem in 24 countries, mainly in the tropics. The top seven endemic countries are India, Brazil, Indonesia, Democratic Republic of Congo, Madagascar, Bangladesh and Nepal: 54% of the detected cases worldwide are found in India¹ (Fig. 57.1).

M. leprae is transmitted via the nasal discharge of untreated lepromatous patients and enters another human subject through the nasal mucosa, with subsequent hematogenous spread to the skin and peripheral nerves. Some literature suggests transmission via broken skin^{2,3} or blood-borne, or by way of soil as the mycobacteria are known to survive in the environment for up to 46 days.⁴ Leprosy is a uniquely human disease with no animal reservoir except the nine-banded armadillo; although this animal is frequently infected or seropositive for *M. leprae*, there have been few reports of transmission from this animal to humans.

In England and Wales, where leprosy is a notifiable disease, a total of 1358 cases have been registered since 1951.⁵ There are still 128 individuals who are on treatment or under surveillance. Since 1993 approximately nine new cases per year have been diagnosed. Half of the new cases in the UK

are found in immigrants from the Indian subcontinent and there are a few cases in Caucasians who have lived in leprosy-endemic areas for prolonged periods (8–42 years).⁶ Patients originating from Brazil have also been seen recently at the Hospital for Tropical Diseases. The epidemiological pattern of leprosy in the UK is influenced by both migration patterns and levels of leprosy in migrants' home countries. As leprosy has a long incubation period (2–10 years), patients can present long after leaving endemic areas.

PATHOGENESIS

Leprosy manifests in a spectrum of disease forms, ranging from the tuberculoid to the lepromatous (Fig. 57.2).⁷ The varied clinical manifestations of leprosy are determined by the host's response to the leprosy bacillus: tuberculoid (TT) patients have a uniform clinical, histological and immunological response manifesting as limited clinical disease, granuloma formation and active cell-mediated immunity; lepromatous (LL) patients have multiple clinical signs, a high bacterial load and low cell-mediated immunity. Between these two extremes there is a range of variations in host response; these comprise borderline cases (BT, BB, BL)⁸ (Table 57.1). Immunologically, borderline cases are unstable and polar tuberculoid and lepromatous cases are stable.

CLINICAL FEATURES AND SPECTRUM OF DISEASE

Patients present with skin or nerve lesions, or a combination of both. Leprosy affects only the peripheral nerves – never the central nervous system. A patient may present with a macular hypopigmented skin lesion, weakness or pain in the hand due to nerve involvement, facial palsy, acute foot drop or a painless burn or ulcer in an anaesthetic hand or foot.

Leprosy: prevalence rates, beginning of 2007

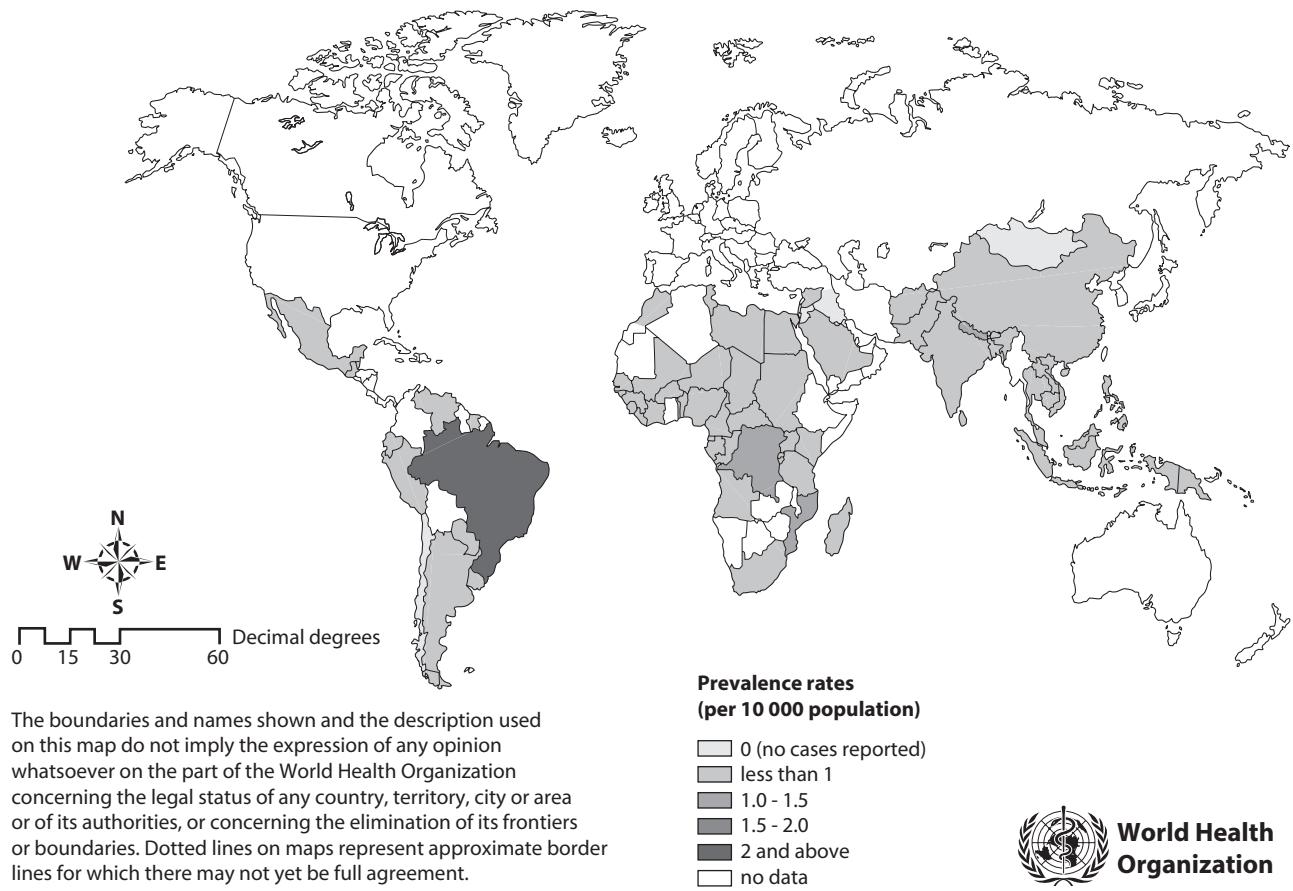

Fig. 57.1 Global leprosy prevalence, beginning of 2007.¹ Adapted from WHO. Leprosy – global situation. *Wkly Epidemiol Rec.* 2008; 83(33): 293–300 and 2008;83(50):459.

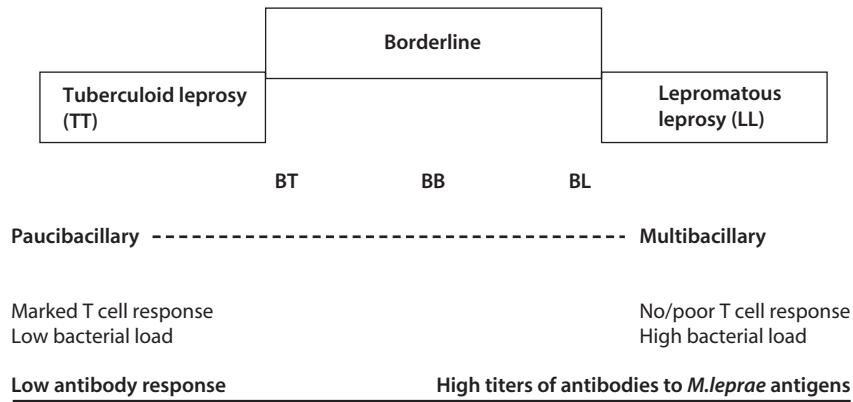

Fig. 57.2 Leprosy – a spectrum of disease.

Table 57.1 Characteristic features of different types of leprosy

	TT	BT	BB	BL	LL
Skin lesions	Single, well-defined, hypopigmented, erythematous macule	Few, asymmetric, well-demarcated macules	Few asymmetric, less well-demarcated and shiny	Many symmetric shiny macules and plaques	Many symmetric erythematous, shiny macules, papules and nodules
Sensory impairment in lesions	Marked	Marked	Moderate	Slight neuropathy	Late 'glove and stocking'
Peripheral nerve involvement	Single peripheral nerve trunk	Several and asymmetric	Multiple	Multiple and symmetric	Multiple, late, symmetric

TT, tuberculoid; BT, borderline tuberculoid; BB, mid-borderline; BL, borderline lepromatous; LL, lepromatous.

Patients may also present with painful eyes as a first indication of lepromatous leprosy. The diagnosis of leprosy should be considered in anyone from an endemic area who presents with typical skin lesions, neuropathic ulcers or a peripheral neuropathy.

DIAGNOSIS

BACTERIOLOGICAL AND HISTOLOGICAL EXAMINATION

In a suspected case, slit skin smears are taken to look for acid-fast bacilli. *M. leprae* on the smears are counted and the bacterial index calculated on a logarithmic scale. A negative result does not exclude leprosy, as tuberculoid lesions may contain no detectable bacteria. *M. leprae* cannot be cultivated on artificial media, but can be grown with difficulty in nude mice and the nine-banded armadillo with a 14-day doubling time and at low temperatures (30–33°C). Sequencing of the *M. leprae* genome revealed that it has lost approximately one-third of the genes possessed by *M. tuberculosis*.⁹

Histopathological evaluation is essential for accurate classification of leprosy lesions and is the best diagnostic test in a well-resourced setting, both for confirming and for excluding the diagnosis of leprosy. The presence of granulomata and lymphocytic infiltration of dermal nerves in anesthetic skin lesions confirms the diagnosis. A nerve biopsy may be required in cases with no visible skin lesions.

SEROLOGICAL TESTS AND POLYMERASE CHAIN REACTION

Recent advances have been made in serological diagnostic tests. Antibodies to the *M. leprae*-specific antiphospholipid 1 (PGL-1) are present in 90% of patients with untreated lepromatous disease, but in only 40–50% of patients with paucibacillary disease and 1–5% of healthy controls.¹⁰ An easy to use immunohistochemical assay, the ML Flow test, based on PGL-1 detection, is being assessed by a Brazilian team.¹¹ Polymerase chain reaction (PCR) for detection of *M. leprae* encoding specific genes or repeat sequences is potentially highly sensitive and specific, since it detects *M. leprae* DNA in 95% of multibacillary and 55% of paucibacillary patients. Currently PCR is not used in clinical practice.¹⁰

TREATMENT

The management of leprosy consists of treating the *M. leprae* infection with antibiotic chemotherapy, management of the immune-mediated reactions, prevention of nerve damage and education.

CHEMOTHERAPY

TREATMENT OF INFECTION

Multidrug therapy (MDT) with a combination of dapsone, rifampicin (rifampin) and clofazimine is the current treatment for infection with *M. leprae*. Following the resistance to dapsone-only regimens, the WHO introduced MDT in 1982. MDT is very successful, with a high cure rate, few side effects and low relapse rates (relapse is defined as the reappearance of signs of activity and/or appearance of new lesions and/or bacteriological positivity during or after surveillance). Relapse rates as low as 0.1% per annum have been recorded.¹² In a review of the outcome of MDT of more than 67 000 Indian patients from 1983 to 1992, Lobo showed that only 0.3% of all paucibacillary and multibacillary cases relapsed and that 2.7% of all patients were recorded as treatment failures.¹³ Lobo also found that 92.2% of patients completed satisfactory treatment, were declared cured and released from treatment.

The benefits of MDT include the prevention of drug resistance and better patient compliance due to a fixed duration of therapy. Another advantage is that field workers review patients and supervise the taking of their monthly medication (Table 57.2). The WHO reduced the recommended treatment period for multibacillary disease from 24 to 12 months, but many advocate 24 months for patients with a BI (the logarithmic scale used to assess response to MDT in skin smears) of >4 at diagnosis.¹⁴ One option would be to treat such patients until their skin smears are negative or to keep them under regular review. MDT is safe in pregnancy and in breastfeeding mothers.^{15,16} Children should receive reduced doses of the drugs.

Dapsone

Dapsone is bacteriostatic and effective against a wide range of bacteria and protozoa.¹⁷ In 1947, Cochrane used 1.25 g of subcutaneous dapsone twice weekly to successfully treat leprosy patients.^{18,19} This effectiveness was confirmed in

Table 57.2 Multidrug regimens for treatment of *M. leprae* infection

Regimen	Drug	Dosage	Frequency	Duration
Paucibacillary	Dapsone	100 mg	Daily (self-administered)	6 months
	Rifampicin	600 mg	Monthly (supervised)	
Multibacillary	Dapsone	100 mg	Daily (self-administered)	1 year
	Clofazimine	50 mg	Daily (self-administered)	
	Clofazimine	300 mg	Monthly (supervised)	
	Rifampicin	600 mg	Monthly (supervised)	

Malaysia with a reduced subcutaneous dose of 200–400 mg. At the same time, research in Calcutta,²⁰ Nigeria^{21,22} and the French West Indies reported good results with an oral preparation.²³ By 1951, the standard treatment for leprosy was oral dapsone, 100 mg/day, and was used widely as monotherapy in the 1950s and 1960s. However, in the late 1960s two important problems developed: primary and secondary dapsone resistance:

- Primary resistance refers to resistance in patients who have never been exposed to dapsone.
- Secondary resistance refers to relapse in patients who have previously been treated with dapsone.

Dapsone acts as other sulfonamides, by competing with *para*-aminobenzoic acid for the enzyme dihydropteroate synthetase and therefore inhibiting the synthesis of dihydrofolic acid (see Ch. 2). A dose of 100 mg of dapsone is weakly bactericidal against *M. leprae* and after a few weeks of starting dapsone therapy active lesions start to improve.

Side effects are rare with dapsone and include mild hemolysis and dapsone allergy, occurring within the first few months of treatment. Dapsone allergy usually starts 3–6 weeks after starting the drug, with fever, pruritus and a dermatitic rash. Unless dapsone is stopped immediately, the syndrome may progress to exfoliative dermatitis; hepatitis, albuminuria, psychosis and death have also been recorded.²¹ Treatment is to stop dapsone and treat with corticosteroids for several weeks. The incidence of dapsone allergy is estimated at one per several hundred patients. Although dapsone-induced peripheral neuropathy has been reported in some diseases, there have been few reports of it occurring in leprosy.

Clofazimine

Clofazimine was first used for the treatment of leprosy as monotherapy in the early 1960s and continued until the mid 1970s. To date there has been only one reported case of resistance.²⁴

Clofazimine is bacteristatic and slowly bactericidal against *M. leprae*, similar to dapsone.²⁵ Clofazimine is active against other mycobacteria, this effect being more pronounced in vitro than in vivo, but the mechanism of its action against *M. leprae* is unknown. The speed of response is similar to that of dapsone but slower than that of rifampicin. At doses greater than 1 mg/kg per day, clofazimine exhibits increasing anti-inflammatory activity.²⁶

The main problems encountered with clofazimine are increased skin pigmentation and dryness, which occur as the drug becomes clinically effective. This ichthyosis is reversible and slowly resolves on stopping the drug. Pigmentation can also be seen in the cornea and conjunctival and macular areas of the eyes. Clofazimine is lipophilic and is therefore deposited in fatty tissue and cells of the reticuloendothelial system. Autopsies carried out on patients who had been on clofazimine therapy revealed large quantities of the drug in mesenteric lymph nodes, adrenal glands, subcutaneous fat, liver, spleen, small intestine and skin but not in the central nervous system.²⁷

Rifampicin (rifampin)

Rifampicin is used mainly for the treatment of tuberculosis and leprosy, although it also inhibits the growth of other bacteria²⁸ (see Ch. 27).

Rifampicin is bactericidal and the most effective anti-leprosy drug, rendering the patient non-infectious within days of commencing therapy.²⁹ Resistance has been shown to be due to tightly clustered mutations in a short region of the *rpoB* gene.³⁰

Few serious side effects have been related to rifampicin, which may be due to its monthly dosing regimen, and no cases of resistance have been recorded in leprosy patients. The most common reported side effect is hepatotoxicity, which has (rarely) resulted in death. Early symptoms are anorexia, vomiting and jaundice associated with a two- or three-fold increase in hepatic transaminases. The elevated transaminases may be transient and return to normal despite continuing therapy.

A 'flu-like' syndrome has been reported with intermittent rifampicin therapy and consists of chills, fever, headache, myalgia and arthralgia. This syndrome has a reported incidence of 0.3% in the WHO/MDT report of complications. Rifampicin also produces a red–brown discolouration of urine, feces, saliva, sputum, sweat and tears; patients should be informed that this is inconsequential and will last only 24–48 h.

Other regimens instead of MDT

Following the success of MDT there has been research into the use of other drugs that are more potent than, and as effective as, MDT, but which require a shorter duration of therapy. Other antibiotics currently available as second-line therapy to MDT are minocycline, ofloxacin, clarithromycin and moxifloxacin.

Minocycline

Minocycline has strong bactericidal activity against *M. leprae* due to its lipophilic properties, which allow it to penetrate the outer capsule and cell wall of the organism.³¹ Data from a clinical trial carried out in Mali in 1992 showed that 100 mg minocycline daily caused marked clinical improvement by 1 month. After 2 months of treatment there was a significant decrease in bacterial index, indicating that minocycline was very effective at killing *M. leprae* bacilli.³²

The main side effect observed in minocycline-treated leprosy patients is hyperpigmentation, presenting as a patchy blue–black color at the site of skin lesions, especially on the legs and feet.³³ Dizziness is a specific side effect of minocycline and other mild adverse effects include gastrointestinal symptoms of nausea, abdominal pain or diarrhea, and headache³⁴ (see Ch. 30).

Ofloxacin

Ofloxacin is a fluoroquinolone derivative with strong bactericidal activity against *M. leprae*.³⁵ A clinical trial in Côte d'Ivoire, studying the efficacy of a daily dose of 400 mg of ofloxacin,³⁶

showed definite clinical improvement after 22 doses, 99.9% of initially viable organisms being dead at day 22.

Clarithromycin

Clarithromycin is a macrolide with potent bactericidal activity against *M. leprae*, both in mice and in lepromatous patients. A study in Mali showed that 500 mg of daily clarithromycin was as effective as 100 mg of daily minocycline. Of the 12 patients treated with clarithromycin alone, 5 (42%) showed definite clinical improvement and 6 (50%) showed marked clinical improvement after 1 month of treatment. This treatment also resulted in significant reductions in bacterial index after 3 months.³² Mouse studies have reported additive effects of clarithromycin and minocycline, but this has not been confirmed in human trials.³⁷

Moxifloxacin

Moxifloxacin, another quinolone, was recently tested in the Philippines. Eight multibacillary leprosy patients were given a single 400 mg dose of moxifloxacin, which resulted in significant killing of *M. leprae*, ranging from 82% to 99%, mean 91%. No viable bacilli were detected with an additional 3 weeks of daily therapy.³⁸

Single-dose therapy

A single-dose MDT is now available for single-lesion paucibacillary patients: rifampicin 600 mg, ofloxacin 400 mg and minocycline 100 mg (ROM). A large, multicentered, randomized controlled, double-blind trial carried out in India to test single-dose ROM versus 6 months of paucibacillary MDT in single-lesion cases demonstrated that 51.8% of patients treated with ROM showed marked clinical improvement compared with 57.3% of those on WHO/MDT for patients with paucibacillary disease. Although this result showed that the WHO regimen was statistically better than single-dose ROM for single-lesion cases, ROM may still be appropriate for field situations.³⁹ ROM given as a single monthly dose for 24 months was shown in a small Philippines study to be as effective as MDT in the treatment of multibacillary leprosy.⁴⁰

Other drug regimens

In the mouse model, the combination of minocycline and ofloxacin has been found to be almost as bactericidal as rifampicin, and the combination of rifapentine, moxifloxacin and minocycline significantly more bactericidal than the ROM regimen.⁴¹

Urgent research is needed targeting patients with rifampicin-resistant leprosy. One proposed regimen was an initial 6-month intensive phase (moxifloxacin 400 mg, clofazimine 50 mg, clarithromycin 500 mg and minocycline 100 mg – daily for 6 months), followed by an additional 18-month continuation phase (moxifloxacin 400 mg, clarithromycin 1000 mg and minocycline 200 mg – once monthly for an additional 18 months).⁴²

TREATMENT OF NERVE DAMAGE

Nerve damage refers to peripheral sensory or motor neuropathy. Patients may present with nerve damage or develop nerve function impairment during or after MDT.

A large field study in Ethiopia looked prospectively at 650 patients treated with WHO/MDT and followed them up for 11 years (1988–1999). In this study 55% of patients had some nerve function impairment at diagnosis and 12% developed new impairment after starting MDT; 33% had no initial impairment and never developed neuropathy. Patients with no initial nerve impairment who later developed nerve damage and were treated with corticosteroids within 6 months of symptoms (defined as acute neuropathy) had full recovery in 88% of nerves. Corticosteroids were also successful in treating 51% of patients who had chronic or recurrent nerve damage. Chronic neuropathy was defined as nerve function impairment occurring within 3 months of stopping corticosteroids and recurrent neuropathy as new nerve impairment occurring at least 3 months after stopping corticosteroids.⁴³

Current treatment for patients presenting with new nerve damage of ≤6 months' duration is corticosteroids in addition to MDT. Oral prednisolone is started at 40 mg/day and reduced over 4–6 months depending on clinical response.

The Bangladesh Acute Nerve Damage Study (BANDS) showed that there was a delay in patients presenting for treatment, and this could be as long as 12 months after initial symptoms started. The prevalence of nerve function impairment was seven times greater in multibacillary than paucibacillary patients and twice as high in men as in women. Of the patients presenting with nerve damage, almost 12% had a sensory neuropathy and just over 7% had a motor neuropathy. The nerve most commonly affected was the posterior tibial nerve (sensory neuropathy), followed by the ulnar nerve.⁴⁴

The TRIPOD trials (Trials in the Prevention of Disability in Leprosy) showed that the use of low-dose prophylactic prednisolone during the first 4 months of MDT for leprosy reduces the incidence of new reactions and nerve function impairment in the short term, but the effect is not sustained at 1 year.⁴⁵ A recent Cochrane review concluded that evidence from randomized controlled trials does not show a significant long-term effect for either long-standing nerve function impairment or mild sensory impairment. However, the evidence was very thin and better studies are needed. A 5-month corticosteroid regimen was significantly more beneficial than a 3-month corticosteroid regimen.⁴⁶

TREATMENT OF REACTIONS

Leprosy is complicated by immunological phenomena called reactions: reversal reactions (type 1 reactions); ENL reactions (erythema nodosum leprosum, or type 2 reactions). The clinical features of these reactions are listed in Table 57.3.

Table 57.3 Clinical features of leprosy reactions

	Reversal reactions	ENL reactions
Immune response	T-cell mediated	Immune complex deposition
Type of leprosy affected	BT, BB and BL	BL and LL
Clinical features	<i>Skin lesions:</i> erythema, swelling, tenderness <i>Peripheral nerve lesions:</i> pain/tenderness, increased weakness, increased sensory loss	<i>Skin lesions:</i> transient crops of small, painful red nodules, lasting 2–3 days <i>Other signs:</i> fever, malaise, lymph node enlargement, arthritis, iritis, orchitis, neuritis

BB, mid-borderline; BL, borderline lepromatous; BT, borderline tuberculoid; ENL, erythema nodosum lepromatous; LL, lepromatous.

These sudden episodes of acute inflammation occur in approximately 30% of leprosy patients. This is due to immune reactions against antigenic components liberated from the bacilli. Patients can present in reaction before MDT, and a significant proportion of patients develop reactions within the first 6 months of treatment. There is also an increase in the incidence of reactions in postpartum patients. However, reactions can also occur after successful MDT and are probably due to persistence of *M. leprae* antigens.

Patients may suffer from recurrent reactions or repeated reactions after treatment, resulting in increased suffering and disability.

Treatment of reversal reactions

Reversal reactions are characterized by edema, inflammation and an increase in lymphocytic infiltration in skin and/or nerves of borderline patients. Reversal reactions are due to delayed hypersensitivity at sites of localization of *M. leprae* antigens. They are characterized by CD4 cell activation and production of tissue-damaging T-cell and macrophage cytokines. Mild reactions can be treated with aspirin (600–1200 mg every 4 h). Moderate and severe reactions are treated with prednisolone.

Prednisolone

Oral prednisolone has proved to be an effective treatment for severe reactions. Steroid treatment should be started within the first 6 months of an episode of reaction or nerve function impairment to be effective.^{47–49} Starting doses may be as high as 60 mg and tapered over several months to prevent further nerve damage; a starting dose of 40 mg is usually sufficient to suppress inflammation in the skin or nerves. The response to treatment can be seen by a decrease in skin inflammation over a few days. In a study looking at motor nerve conduction velocity, Naafs et al confirmed that there is a good response to several months of steroid therapy with remyelination and nerve regeneration.⁵⁰

Prednisolone has many effects on cytokines, but it down-regulates proinflammatory cytokines, mainly by inhibition of nuclear factor kappa B (NF-κB)-induced transcription

of cytokine mRNA. Little et al assessed the in-vivo effects of prednisolone in reversal reaction (RR) patients: they found that 1 month of prednisolone treatment reduced cellularity, cytokine production (interferon-γ, interleukin-12) and inducible nitric oxide synthetase in skin lesions of RR patients.⁵¹

Prednisolone is the drug of choice for severe reversal reactions, although about 30% of patients do not respond to therapy or need a protracted course of corticosteroids. Other established immunosuppressant drugs might have a role in treating reactions. A pilot study in Nepal showed equivalent outcomes whether treated with an azathioprine–prednisolone combination or prednisolone alone.⁵² Ciclosporin (cyclosporine) also showed a similar result and further trials are ongoing.⁵³

Treatment of ENL

ENL presents as a systemic illness: a patient with ENL may be very sick with high temperatures, painful subcutaneous nodules, peripheral edema and inflammation of the nerves, eyes, joints, muscles, bones and testes. In ENL, antigen–antibody complexes are deposited in the tissues with the activation of complement and migration of neutrophils into lesions.

For mild cases aspirin may be used, but many cases require treatment with prednisolone and an increased dose of clofazimine (up to 300 mg) or thalidomide. Thalidomide is the treatment of choice for severe ENL but its availability and teratogenicity limit its use.

Thalidomide

Thalidomide was first synthesized in 1954 and marketed as a hypnotic in 1956. It is now being used for its anti-inflammatory properties in ENL⁵⁴ and other diseases.⁵⁵ Thalidomide has two main actions: a potent depressant effect on the central nervous system and an immunomodulatory effect in inflammatory disease. Sampaio et al showed that it selectively inhibits transcription of the inflammatory cytokine tumor necrosis factor-alpha (TNF-α)⁵⁶ by accelerating the degradation of mRNA encoding the protein.⁵⁷ Thalidomide also enhances cell-mediated immunity by directly stimulating cytotoxic T cells and increasing the production of interleukin-10.⁵⁸

Thalidomide has been used for treatment of ENL since the early 1960s. In 1965, Sheskin⁵⁹ reported that six patients with ENL responded well to thalidomide, and this was confirmed with other studies.⁶⁰ It has also been shown that the raised serum TNF-α levels in ENL are lowered by thalidomide.⁶¹ Thalidomide shortens the ENL reaction. It acts rapidly, with improvement occurring after 8 h, although it may take up to 48 h before the patient becomes afebrile. The dose used is 400 mg/day in 2–4 divided doses, with a gradual reduction to 50 mg/day. Thalidomide is the most effective drug for ENL but must be strongly discouraged in women of childbearing age unless using double contraception; it is absolutely contraindicated in pregnancy. All patients should be given specific advice (Box 57.1) before commencing thalidomide therapy. If thalidomide is either not available or contraindicated, prednisolone is used to treat ENL.

Box 57.1 Advice for female patients before commencing thalidomide therapy

- Do not share tablets with anyone else
- Use double contraception whilst on therapy
- Seek medical advice at the first sign of amenorrhea
- An abortion should be considered if pregnancy is confirmed

There have been no reports of thalidomide causing accelerated nerve damage in leprosy. However, when used in other conditions such as Behçet's disease, thalidomide is known to cause an axonal sensory neuropathy and there is evidence to suggest more widespread effects of the nervous system.^{62–65} Other side effects that occur with thalidomide include a widespread rash developing 6–12 days after starting the drug, drowsiness, constipation, xerostomia, increased appetite, nausea and loss of libido.⁶⁶ It can also rarely result in menstrual abnormalities, increased urinary secretion of corticosteroids, myxedema and a euthyroid state in previous thyrotoxicosis.⁶⁷

CHEMOPROPHYLAXIS AND IMMUNOTHERAPY

In the 1960s and 1970s chemoprophylaxis with dapsone and acedapsone was investigated. However, as dapsone showed varying protection to contacts of leprosy patients and there were anxieties about dapsone resistance, this regimen was curtailed. In the 1980s–1990s rifampicin, used either alone or in combination with other drugs, was found to have chemoprophylactic efficacy.⁶⁸ An intervention study in highly endemic Micronesia using a single dose of ROM as chemoprophylaxis showed an apparent reduced leprosy incidence in the first 3 years in the blanket group. Whether this is due to a delayed development of leprosy or a complete clearance of infection needs to be determined.⁶⁹ A recent study in Bangladesh⁷⁰ randomized 28 092 close contacts of newly diagnosed leprosy patients to a single dose of rifampicin or placebo with a follow up of 4 years. The overall reduction in incidence of leprosy using a single dose of rifampicin in the first 2 years was 57% (close to that achieved with longer dapsone treatment). However, the difference was no longer significant in the third and fourth years. Further studies are needed to raise the efficacy of rifampicin.

A meta-analysis of 14 trials showed that chemoprophylaxis gives approximately 60% protection against leprosy. Leprosy chemoprophylaxis may be an effective way of reducing incidence and is more cost-effective if it is given only to household contacts.⁷¹ Current UK practice is for all childhood contacts of newly diagnosed patients to be given rifampicin prophylaxis (1 mg/kg). At present chemo- and immunoprophylaxis are not cost-effective measures for wide usage because there is no means of identifying all persons who are at high risk of developing leprosy and the prophylactic measures are not close to 100% efficacy.

To date no specific vaccine has been developed to prevent infection by *M. leprae*, although there is good evidence that bacille Calmette–Guérin (BCG) has protective efficacy. Large field trials in Uganda, Burma, Papua New Guinea and India have all demonstrated a protective efficacy varying from 20% to 80% with BCG vaccines. Adding *M. leprae* antigen to BCG does not increase the efficacy of the vaccine.⁷²

ONGOING MANAGEMENT AND PREVENTION OF COMPLICATIONS

Education concerning factual information such as mode of transmission, treatment and complications is essential for all patients and health providers. Education is also important in equipping patients with knowledge on how to adapt their lifestyle to prevent the development of complications (e.g. comfortable footwear and cessation of smoking in order to care for the anesthetic limb).

LEPROSY AND HIV

There were concerns that an interaction between HIV and *M. leprae* infection would result in an increased incidence of leprosy cases. However, studies in Uganda, Mali, Ethiopia and South India have not shown an increased prevalence of leprosy cases associated with HIV infection.^{73–75}

An association has been found between HIV infection and complications of leprosy. In a case-controlled study in Uganda, Kawuma et al⁷³ found that HIV seropositivity was a significant risk factor for developing reactions and neuritis; an unusual finding because reversal reactions are associated with an increase in CD4 cells. Similarly, Sampaio et al found that HIV-infected patients with low CD4 counts had normal granuloma formation with numerous CD4 cells.⁷⁶

Treatment of a leprosy patient with concurrent HIV infection does not differ from that of a seronegative leprosy patient and reactions should be managed with corticosteroids or thalidomide as appropriate.

Since the introduction of highly active antiretroviral therapy (HAART) in the management of HIV, leprosy is being increasingly reported as part of the immune reconstitution inflammatory syndrome (IRIS).⁷⁷ It is possible that the immune response to *M. leprae* in an HIV-infected person is suppressed before starting HAART and that leprosy manifests as IRIS with the sudden reversal of this suppression and the rise in CD4 count.⁷⁸ Further studies are needed to understand the clinical and pathological features in HIV and leprosy co-infection.

CONCLUSION

MDT has been a success story in both the treatment of *M. leprae* infection and the mobilization of many people involved in treatment, surveillance and leprosy control

programs. In 1982 MDT was implemented in endemic areas and since then more than 90% of registered cases have received treatment, 14 million patients have been cured and global prevalence has declined.

The current treatment for leprosy reactions is still not optimal, with a significant number of patients not responding to prednisolone and some ENL patients requiring chronic thalidomide therapy. Researchers are still looking for different immunosuppressant drugs with efficacy in the treatment of reactions (e.g. azathioprine and ciclosporin A).

The stigma associated with the diagnosis of leprosy is still a very real problem and the management of someone with the disease should include discussion of their psychosocial status and education for the patient and their family.

58 Tuberculosis and other mycobacterial infections

L. Peter Ormerod

Tuberculosis (TB) has been increasing significantly on a worldwide basis over the last decade, to such an extent that the World Health Organization (WHO) proclaimed it a global emergency in 1995. The WHO 2007 estimates are that there are 9.27 million new clinical cases at a rate of 139/100 000 per annum, 1.3 million deaths each year, and two billion persons infected in the world as judged by a positive tuberculin skin test.¹ This increase has been seen both in the developing world and in developed countries, reversing the historical continuous decline seen since the Second World War. The reasons for the increase are different in the developing and developed worlds.

In developed countries, particularly in Europe, the increases are due to an increasing proportion of the cases of TB occurring in ethnic minority groups who have come from countries of high prevalence and who consequently have very high TB rates. The rates in the native population continue generally to decline. In England and Wales, incidence increased nearly 70% between 1987 and 2008, but only 21% of cases are now in the White ethnic population, with over 73% of cases being foreign born.² Rates in ethnic minority groups are 25–40 times higher than in the White ethnic group.² Similar trends have been seen in most European countries, with the increase being due to immigrants and refugees/asylum seekers from high-prevalence countries. In the USA the increase seen between 1985 and 1990, which was partly due to HIV co-infection, but also due to social factors and the dismantling of TB programs, has been significantly reversed but (as in Europe) an increasing proportion of cases are now in the foreign born.³

In developing countries the increase is largely due to the lack of funding, marked population increases and the associated economic and social deprivation. To this is now added the effect of HIV co-infection. Although first described in the USA,⁴ its largest impact so far has been in sub-Saharan Africa where TB rates doubled between 1985 and 1991 in some countries (e.g. Malawi and Zambia⁵), and have continued to rise almost exponentially since. This dual epidemic, which has hit largely younger, economically active adults (and children), has further fuelled deprivation, social pressures and economic collapse. Although currently only 12% of TB worldwide is HIV associated,¹ this proportion is expected to rise over the next 5–10 years as dual infection increasingly occurs in South Asia, which, because of the much larger populations of these countries, will have a much greater numerical effect.¹

In this chapter the principles underlying the development of short-course treatment will be set out, together with recommendations based on those principles for individual patients and sites of disease. The complexities of treatment of HIV-infected patients with particular relation to highly active antiretroviral treatment (HAART) are also discussed. Such treatments, as well as prophylactic therapy in both HIV-negative and HIV-positive individuals, need to be within the context of a monitored TB control program. Multidrug-resistant (MDR) and extensively drug-resistant (XDR) TB are challenging TB control, particularly in resource-poor settings, and their management will be discussed. Trials, including quinolones, are ongoing to see if 6-month short-course chemotherapy can be reduced to 4 months. New drugs are also in development and will be briefly summarized. Finally, treatment of the opportunist mycobacteria that cause human disease is also considered.

SCIENTIFIC BASIS OF SHORT-COURSE CHEMOTHERAPY

Each of the main antituberculosis drugs varies in its capacity to kill bacteria, to sterilize lesions and to prevent the emergence of drug resistance. Killing capacity is measured by early bactericidal activity,⁶ sterilizing ability by a low relapse rate after cessation of treatment and a low culture-positive rate at 2 months of treatment.⁷ The efficiency of a drug in preventing the emergence of drug resistance is more difficult to assess and is largely derived from the interpretation of clinical studies.⁷

Isoniazid (H) is the most potent bactericidal drug and kills more than 90% of bacilli within 7 days, acting on metabolically active bacilli. It is also quite effective at preventing the emergence of drug resistance. Rifampicin (rifampin; R) is another effective bactericidal drug, with a potent sterilizing effect and a good ability to prevent the emergence of drug resistance. In addition to acting on rapidly dividing bacilli it kills so-called ‘persisters’, which remain inactive for long periods but have intermittent periods of metabolism, with only a short drug exposure. This gives it its potent

sterilizing efficiency. Although bactericidal, pyrazinamide (Z) is used mainly for its sterilizing ability; it is particularly effective at killing intracellular mycobacteria sequestered inside macrophages in an acid environment.⁶ Streptomycin (S) and ethambutol (E) are less potent drugs, with ethambutol probably being bactericidal only at a high concentration. They are less effective at preventing the emergence of resistance to rifampicin and isoniazid.

The efficacy of regimens based on rifampicin, isoniazid and pyrazinamide has been extensively studied by many controlled trials of different durations and dosing schedules. With this type of regimen it is possible to convert over 90% of sputum smear-positive patients to culture-negative at 2 months, to cure greater than 95%, and to have a relapse rate of less than 5%. The studies from which various aspects of treatment can be deduced, and on which later chemotherapy recommendations are based, are set out in Table 58.1.⁸⁻¹⁹

A duration of 6 months seems to be the shortest period for a regimen based on isoniazid and rifampicin that will give an acceptably low relapse rate. If the duration is reduced below 6 months higher relapse rates and lower cure rates are found, which are not acceptable for developed countries. Studies in Singapore and Hong Kong comparing 2, 4 and 6 months of pyrazinamide with rifampicin and isoniazid for 6 months showed that pyrazinamide is needed only for the initial 2 months. Conversely, however, if pyrazinamide is not used or cannot be

tolerated, then a 9-month regimen of rifampicin and isoniazid is required, supplemented by ethambutol for the initial 2 months.

The trials described in Table 58.1 covered a spectrum of dosing schedules from daily treatment throughout, a daily initial phase followed by a twice or thrice weekly continuation phase, or twice or thrice weekly dosing throughout. All of these schedules gave relapse rates of less than 5% during periods of follow-up between 6 and 30 months after cessation of treatment. The dosing schedule used therefore depends on a balance of cost, side effects and tolerance, drug availability and organizational aspects.

When rifampicin was omitted from the regimen in the continuation phase because of cost constraints, a 6-month total duration gave higher relapse rates and inadequate sterilization. Before the HIV epidemic regimens with an extended continuation phase of isoniazid for 6 months with either ethambutol or thiacetazone (Th) had been tested. A regimen of 2SHRZ/6HTh had been shown to be very effective when combined with admission to hospital for the initial 2 months.^{20,21} This is no longer viable as a 'cheaper' regimen because of the rate of drug reactions to thiacetazone in HIV-positive patients (*see later*) and the costs of initial hospital care. If rifampicin is not used in the continuation phase then there is a significantly increased failure rate if the organism is found to have initial isoniazid resistance.

Regimens of various durations of between 2 and 4 months have been studied in sputum smear-negative tuberculosis.

Table 58.1 Six-month short course regimen trials for the treatment of pulmonary tuberculosis

	Regimen	No. of patients	Bacteriological relapse (%)	Reference
Daily throughout				
United Kingdom	2SHRZ/4HR 2EHRZ/4HR	125 132	1 2	8 8

E, ethambutol; H, isoniazid; R, rifampicin; S, streptomycin; Z, pyrazinamide. The number in front of the letters represents the duration of treatment in months. The number in brackets after the letters represents the number of doses per week.

For those with positive initial cultures, relapse rates of 32% with 2 months' treatment,²² 7–13% with 3 months' treatment,^{22,23} and 4% with 4 months' treatment have been reported.^{22,23} The results of the 4-month regimen varied with the initial sensitivities of those with a positive culture. For initially sensitive organisms, the relapse rate was 2%, but rose to 8% for those with initial resistance to isoniazid and/or streptomycin.²³

RECOMMENDED REGIMENS

The recommendations made by various expert bodies are founded on the substantial body of evidence for pulmonary tuberculosis, and take into account the likelihood of drug resistance in the target population. The recommendations of the National Institute for Health and Clinical Excellence are set out in Table 58.2.²⁴ Where there are variations between these recommendations and those of the European Respiratory Society,²⁵ the American Thoracic Society²⁶ and the World Health Organization,²⁷ these are also shown in Table 58.2.

In the UK, a 6-month regimen comprising isoniazid, rifampicin, pyrazinamide and ethambutol for 2 initial months, followed by rifampicin and isoniazid for a further 4 months, is recommended for adult respiratory tuberculosis,

including isolated pleural effusion and mediastinal lymphadenopathy, irrespective of the bacteriological status of the sputum.²⁴ A 6-month regimen is therefore recommended for sputum smear-negative disease. Where a positive culture for *M. tuberculosis* has been obtained but susceptibility results are outstanding at 2 months, the initial four-drug phase should be continued until full susceptibility is known, but the total duration of treatment does not need to be extended. Ethambutol is included to cover the possibility of initial isoniazid resistance because of its increasing prevalence.²

If a patient cannot tolerate pyrazinamide, then the treatment required to give a suitably high cure rate is 9 months of rifampicin and isoniazid supplemented by 2 months of initial ethambutol.²⁸ Routine daily pyridoxine is not required but should be given to people at higher risk of peripheral neuropathy: those with diabetes mellitus, chronic renal failure, alcohol dependency, malnourishment and the HIV positive.²⁴

NON-PULMONARY TUBERCULOSIS

Non-respiratory tuberculosis has been subject to fewer controlled clinical trials than respiratory tuberculosis, but there are sites where evidence-based advice can be obtained.

Table 58.2 Recommended regimens for treatment of tuberculosis

Type of tuberculosis	American Thoracic Society	European Respiratory Society	National Institute for Health and Clinical Excellence
Adult			
New smear positive pulmonary or New extensive smear-negative pulmonary) 2RHZ(E/S)/4HR or 0.5RHZ(S/E)/1.5RHZ(E)(2)/4HR(2) (DOT) or 2RHZ(E/S)(3)/4RHZ(E/S)(3) DOT	2RHZ(E)/4HR or 2RHZ(E)/4HR(3)	2RHZ(E)/4HR or 2RHZS(3)/4HR(3) DOT
Extensive non-respiratory) 2RHZ(E/S)(3)/4RHZ(E/S)(3) DOT		
Non-extensive smear-negative pulmonary	2RHZ/4HR	As above	As above
Adult meningitis	Presumed as extensive non-respiratory but not specified	Presumed as extensive non-respiratory but not specified	2RHZ(E/S)/10HR
Children			
Pulmonary/lymph node	As adult	As adult	As adult
Central nervous system	2RHZ(S)/10HR	As adult	2RHZ(E)/10HR
Miliary	As above	As adult	2RHZ(E)/4HR
Bone/joint	As above	As adult	2RHZ(E)/4HR
Drug resistance			
Isoniazid	2RZE/4RZE or 2RE/10RE	Not specified	2RZES/7RE DOT or 2RZE/10RE
MDR-TB	Individualized	Individualized	Individualized
Other resistances	Not specified	Not specified	See Table 3

DOT, directly observed therapy; E, ethambutol; H, isoniazid; R, rifampicin; S, streptomycin; Z, pyrazinamide. The number in front of the letters represents duration in months. The number in parentheses after the letters represents the number of doses per week. The 2009 WHO guidelines recommend the use of 2RHZE/6HE should stop, and a weak recommendation to consider 4RHE as the continuation phase in areas with proven or suspected isoniazid resistance rates of over 5%.

LYMPH-NODE TUBERCULOSIS

The third British Thoracic Society lymph node trial showed that a 6-month regimen was just as effective as a 9-month regimen.^{29,30} From this trial,^{29,30} and from earlier lymph node studies,^{31,32} the course of lymph node disease is variable. In 10–15% of cases nodes may enlarge, abscesses may form, and new nodes may develop, both during and after treatment. These are usually without any bacteriological evidence of relapse or recurrence, and in the absence of a positive culture should not in themselves be taken as failure of treatment³¹ or relapse.³² The 6-month regimen recommended for respiratory tuberculosis is therefore also recommended for lymph node disease.²⁴

BONE/JOINT TUBERCULOSIS

Approximately half of all cases are in spinal sites. This form of tuberculosis has been the subject of a number of controlled clinical trials, with 6 months of therapy being shown to give good results.^{33–36} These studies also showed that chemotherapy can be fully ambulant in nearly all cases of tuberculosis of the thoracic and lumbar spine, with surgery reserved for the few patients with evidence of spinal cord compression or instability.^{33–36} The 6-month regimen recommended for respiratory tuberculosis is therefore advised for bone and joint tuberculosis.²⁴

PERICARDIUM

A 6-month regimen of rifampicin and isoniazid supplemented by 3 months initial pyrazinamide and streptomycin has been shown to be highly effective.^{37,38} The continuation of streptomycin and pyrazinamide after 2 months is not likely to confer additional benefit, so the 6-month regimen preferred for respiratory disease is recommended.²⁴ Trials have shown that corticosteroids confer additional benefit in this form of tuberculosis (*see later*).^{37,38}

CENTRAL NERVOUS SYSTEM

There is lack of evidence from controlled trials but management in centers treating large numbers suggests that rifampicin and isoniazid for 12 months, supplemented by pyrazinamide and a fourth drug for at least the first 2 months, will give good results.³⁹ Isoniazid, pyrazinamide and prothionamide/ethionamide penetrate the cerebrospinal fluid well, but rifampicin penetrates less well.⁴⁰ Ethambutol and streptomycin penetrate the cerebrospinal fluid in adequate concentrations only when there is active meningeal inflammation early in the treatment. Although the risk of

ethambutol ocular toxicity at the recommended dosage of 15 mg/kg is low,⁴¹ ethambutol should be used with caution in unconscious patients (Stage III) as visual acuity cannot be tested. Intrathecal administration of streptomycin is unnecessary. The fourth drug in the initial phase of treatment can be ethambutol,⁴⁰ streptomycin⁴⁰ or ethion(prothion) amide.⁴² In the UK a 12-month regimen of rifampicin and isoniazid, supplemented by 2 months initial pyrazinamide and ethambutol, is recommended for both meningitis and tuberculoma,²⁴ prolonged to 18 months if pyrazinamide is not given or cannot be tolerated. Additional corticosteroids are of benefit (*see later*).

OTHER SITES

There are few clinical trial data for other sites. In the UK, by extrapolation from respiratory disease and the more common non-respiratory data, the 6-month regimen recommended for respiratory disease is advised;²⁴ it is also advised for tuberculosis in multiple sites, or for miliary (classic or cryptic) disease.⁴³ Because of the high rates of blood-borne spread to the meninges in miliary tuberculosis, lumbar puncture is recommended in such cases so that the correct duration of therapy can be determined.²⁴

CORTICOSTEROIDS AS AN ADJUNCT TO THERAPY

Clinical trial data support a beneficial effect of corticosteroids in addition to the recommended antituberculosis chemotherapy for pericarditis,^{37,38} for TB meningitis^{40,44} and for endobronchial disease in children.⁴⁵ There are clinical, but no clinical trial, data of possible benefit in pleural effusions,⁴⁶ in tuberculosis affecting the ureter,⁴⁷ in patients with extensive pulmonary disease⁴⁸ and in suppression of hypersensitivity reactions to antituberculosis drugs.⁴⁸

TREATMENT IN PREGNANCY

Pregnancy in patients taking rifampicin is not an indication for termination. Standard treatment should be given to pregnant women, the risk to both mother and fetus being greater if suboptimal treatment is given.⁴⁹ None of the first-line drugs has been shown to be teratogenic in humans, but the reserve drugs (*see later*) ethionamide and prothionamide may be and are best avoided. Streptomycin and other aminoglycosides are potentially ototoxic to the fetus and should be avoided in pregnancy. Women may breastfeed normally whilst taking antituberculosis drugs. Patients on rifampicin-containing regimens should be told of the reduced effectiveness of oral contraceptives and be given contraceptive advice.

TREATMENT IN CHILDREN

Recommended dosages of isoniazid vary substantially. The British Thoracic Society,⁵⁰ the International Union against Tuberculosis and Lung Diseases,⁵¹ and the WHO²⁷ recommend 5 mg/kg up to a maximum dose of 300 mg/day. Other organizations such as the American Thoracic Society²⁶ and the American Academy of Pediatrics⁵² recommend 10 mg/kg up to a maximum of 300 mg. Pharmacokinetic studies⁵³ show that 5 mg/kg gives serum levels 60–100 times the minimum inhibitory concentration and satisfactory clinical outcome is achieved.⁵⁴ Dosages should generally be rounded up to easily given volumes of syrup or appropriate strengths of tablet.

The 6-month regimen advised for adults should be used for children with respiratory tuberculosis including hilar lymphadenopathy.²⁴ Ethambutol should also be included for the first 2 months. A recent literature review concluded that use of a 15 mg/kg dosage of ethambutol, in children aged 5 years or older, required no more precautions to be taken than for adults.⁵⁵ The same review also concluded that ethambutol could be used in younger children without undue fear of side effects.⁵⁵

No controlled trials examining the treatment of extra-pulmonary tuberculosis in children have been reported. Recommendations are therefore made by extrapolation from adult trials. Treatment of tuberculous lymphadenopathy, pericarditis, bowel disease, bone and joint disease and other end-organ disease using the 6-month regimen advised for adults is recommended.²⁴ For disseminated and congenital tuberculosis, treatment should also last 6 months unless there is evidence of any central nervous system involvement, when a 12-month regimen is advised.²⁴ Meningitis should be treated with 12 months of isoniazid and rifampicin supplemented by 2 months initial pyrazinamide plus either ethambutol or streptomycin.^{24,26,40,51}

DRUG-RESISTANT TUBERCULOSIS

MOLECULAR BASIS

Advances in molecular genetics over the last 15 years have demonstrated the mechanisms of resistance to specific anti-tuberculosis drugs, and in general these come about because of mutation at a small number of sites in the chromosome. Isoniazid resistance has been linked to mutations in either the *inhA* gene which codes for an enzyme involved in mycolic acid synthesis in the cell wall⁵⁶ or the catalase peroxidase gene (*katG*).⁵⁷ For streptomycin, resistance is due to changes in ribosomal S12 protein (*rpsL*) and 16S ribosomal RNA;⁵⁸ for fluoroquinolones the mutation is in the DNA gyrase A gene (*gyrA*);⁵⁹ rifampicin resistance is due to point mutations in the *rpoB* gene in the RNA polymerase B subunit⁶⁰ and has allowed the development of a molecular probe to detect this

resistance, which is a key component of MDR-TB (see below). Pyrazinamide resistance is due to mutations in the *pncA* gene.⁶¹ Ethambutol resistance is due to mutations in the *embB* region, specifically codon 306.⁶²

EPIDEMIOLOGY

Drug resistance is an increasing problem in developed countries because an increasing proportion of cases come from people originally infected in underdeveloped countries. For underdeveloped countries themselves problems are increasing because of economic and population pressures on TB control services, variable drug availability, inadequate programs and the difficulties of service delivery.⁶³ The incidence of drug resistance has to be differentiated into primary resistance (that found in previously untreated patients) and secondary or acquired resistance (that found in those with a history of treatment). Resistance to first-line antituberculosis drugs is found in all countries, with higher rates in underdeveloped countries, in parts of countries where there is economic collapse, or in certain populations (e.g. the Russian prison population⁶³). Resistance rates to isoniazid of >5% are now common in most underdeveloped countries, and the drug resistance rates of minority ethnic groups in developed countries often follows that of their country of origin. Drug resistance data in the UK are monitored by Mycobnet, a section of the Public Health Laboratory Service Communicable Disease Surveillance Centre, which has monitored trends prospectively since 1993. The current levels of isoniazid resistance are 6% (HPA 2009) overall.² Risk factors for drug resistance include prior treatment, HIV infection and foreign birth. In the UK, the national treatment guidelines²⁴ have been designed with these factors in mind.

Combined resistance to rifampicin and isoniazid, with or without additional drug resistances (so-called MDR-TB), is a particular concern and is found worldwide. Certain countries (such as the Baltic republics, Russia, the Dominican Republic and Côte d'Ivoire) are 'hotspots' with an incidence greater than 5%.⁶³ MDR-TB occurred infrequently in England and Wales between 1982 and 1991, being found in only 0.6% of isolates.⁶⁴ It rose to nearly 2% in the early 1990s but fell to 1.3% in 2005,⁶³ representing approximately 50 cases, two-thirds of which occurred in Greater London. In England and Wales the risk factors for MDR-TB are those for drug resistance in general, but are even more pronounced:⁶⁵

- Previous treatment 12.63 (OR 8.20–19.45)
- HIV infection 3.52 (OR 2.48–5.01)
- Age younger than 65 years 2.53 (OR 1.74–4.83)
- Foreign born 2.46 (OR 1.86–3.24)
- Male sex 1.38 (OR 1.16–1.65).

Clinical suspicion of acquired resistance should also be raised by failure of clinical response to treatment or by prolonged sputum smear or culture positivity, particularly at 3 months or later, while on treatment.

Now added to problems of drug resistance is the recognition of XDR-TB, brought to prominence by the Tugela Ferry outbreak,⁶⁶ which is now described in more than 45 countries.⁶⁷ Initially defined as high-level resistance to three or more of the six classes of reserve drugs,⁶⁸ in addition to rifampicin and isoniazid, this definition has been revised to resistance to quinolones and one injectable other than streptomycin (kanamycin, amikacin or capreomycin).⁶⁹

Because of the rates of drug resistance, every effort should be made to obtain bacteriological confirmation of the diagnosis. In addition to proving the diagnosis, drug susceptibility information comes only from positive culture. Three sputum samples, obtained on separate mornings, should be sent for pulmonary cases. In patients unable to produce sputum, fiberoptic bronchoscopy and washings from the appropriate lung segment(s) has a good yield.⁷⁰ Pus obtained from neck glands and other sites, and fluid from serous sites (pleura, peritoneum and pericardium) should also be sent for culture. Surgeons performing biopsies on lesions in which tuberculosis is suspected should be reminded that half of the sample should be sent for TB culture without preservative such as formalin.²⁴

A risk assessment, using the factors above, should be made for the likelihood of drug resistance in all cases. If concerns are raised as to the possibility of MDR-TB or XDR-TB, rapid molecular tests for rifampicin resistance are available on either sputum microscopy-positive or culture-positive material. These can be performed rapidly and are >95% accurate. If a test reports rifampicin resistance in a patient with *M. tuberculosis*, the patient should be managed as if he or she has M(X)DR-TB, pending the results of full susceptibility tests, as ‘isolated’ rifampicin resistance accounts for less than 10% of rifampicin resistance, and rifampicin resistance for MDR-TB in more than 90%. Separate isolation criteria are also advised for suspected or proven MDR-TB.^{71,72}

TREATMENT OF DRUG-RESISTANT TUBERCULOSIS

Various short-course chemotherapy studies have allowed assessment of the efficacy of ‘standard’ chemotherapy in patients with prior initial drug resistance.⁷³ In these trials, patients with initial isoniazid and/or streptomycin resistance had a failure rate of 17% when given a 6-month regimen of rifampicin and isoniazid; the failure rate was 12% in those treated in the 2-month initial phase. As the number of drugs given in the regimen and the duration of rifampicin treatment increased, the failure rate fell, reaching only 2% of those receiving 4–5 drugs, including rifampicin throughout, in a 6-month regimen. The key exception was that of rifampicin resistance, where the outcome was much poorer.⁷³

Such a policy is appropriate in underdeveloped countries where routine drug susceptibility data are not available, but in developed countries it is thought preferable to modify treatment on the basis of the drug resistance data.²⁴ The recommendations are set out below and summarized in Table 58.3.

SINGLE DRUG RESISTANCE

Streptomycin

Some of the drug resistance encountered, particularly in ethnic minority groups, is to streptomycin alone. Streptomycin is now seldom used, and the efficacy of the regimen recommended for both pulmonary and non-pulmonary disease is not affected.

Isoniazid

If isoniazid resistance is known about before treatment, a regimen of rifampicin, pyrazinamide, ethambutol and streptomycin for 2 months, followed by rifampicin and ethambutol for

Table 58.3 Management of drug resistance in tuberculosis

Resistance	Non-MDR-TB regimen	Comment
Streptomycin	2RHZ(E)/4RH	Standard treatment unaffected
Isoniazid	2RZSE/7RE if known pretreatment 2RZE/7-10RE	Fully supervised (DOT)
Pyrazinamide	Usually <i>M. bovis</i> If had 2RHZE: stop ZE then 7RH If had 2RHZ: then 2RHE/7HR	
Ethambutol	2RHE/7HR	Standard treatment unaffected
Rifampicin	Uncommon: see text. Manage as MDR-TB until full susceptibilities known; if true: 2HZE/16HE	
Streptomycin/isoniazid	As for isoniazid resistance during treatment	Fully supervised (DOT)
Other combination	Individual regimen needed	See text

E, ethambutol; H, isoniazid; R, rifampicin; S, streptomycin; Z, pyrazinamide. The number in front of the letters represents the duration of treatment in months.

7 months, has given good results when fully supervised.⁷⁴ For the usual scenario of isoniazid resistance being reported after treatment has started, isoniazid should be stopped and ethambutol and rifampicin given for 12 months, supplemented by 2 months initial pyrazinamide.²⁴

Pyrazinamide

See *Mycobacterium bovis* infection later (p. 758).

Ethambutol

This is uncommon; the standard regimen minus ethambutol (2RHZ/4HR) should be used.

Rifampicin

Isolated rifampicin resistance accounts for less than 10% of rifampicin resistance, 90% or more being due to M(X) DR-TB. Rifampicin resistance should be managed as for M(X)DR-TB until full first- and second-line susceptibilities are available. If true isolated rifampicin resistance is shown, a regimen of 18 months of ethambutol and isoniazid, supplemented by 2 months initial pyrazinamide, is recommended.²⁴

COMBINED NON-MDR RESISTANCE

Streptomycin and isoniazid

This is the most common dual resistance. Management should be as for isoniazid resistance found after treatment commencement but fully supervised throughout.²⁴

Other combinations

These are uncommon. An individualized regimen is required and should be discussed with an experienced clinician.

MDR-TB AND XDR-TB

Where MDR-TB is suspected, using the risk criteria set out earlier, molecular methods are available for rapid detection of rifampicin resistance using genetic probes on culture material⁷⁵ and increasingly on direct microscopy-positive samples.⁷⁶ Treatment is complex, time-consuming, demanding on both the physician and the patient, must be individually planned^{77,78} and is likely to need the inclusion of reserve drugs (Table 58.4). There are also additional infection control measures required to prevent nosocomial outbreaks.^{71,72} Such treatment should be carried out only in the following circumstances:

- The physician has substantial experience in managing complex resistant cases
- Only in a hospital with appropriate isolation facilities
- In close liaison with the appropriate mycobacteriology service.

Table 58.4 Reserve drugs that may be needed for multidrug-resistant tuberculosis

Injectable	Tablet
Streptomycin	Ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, moxifloxacin
Amikacin	Ethionamide or prothionamide
Kanamycin	Clarithromycin or azithromycin
Capreomycin, linezolid, meropenem/co-amoxiclav	Cycloserine, rifabutin, thiacetazone, PAS sodium, clofazimine
PAS, p-aminosalicylic acid.	

For this to happen, the patient may need to be transferred to an appropriate unit. All treatment, both as an inpatient and as an outpatient, must be closely monitored because of increased toxicity, and must be directly observed throughout to prevent the emergence of further drug resistance. Consideration may also need to be given to resection of pulmonary lesions under drug cover.⁷⁹ Criteria for removal from isolation have been set out.^{71,72}

The principles of treating such patients are to start treatment with five or more drugs to which the organism is (or is likely to be) susceptible, including one injectable if possible, and to continue these until cultures become negative. Drug treatment should then be continued with at least three drugs to which the organism is susceptible on in-vitro testing for a further minimum of 9 months. This may extend up to or beyond 24 months depending on the drug susceptibility profile, which drugs are available, and the patient's HIV status.⁷⁸

MYCOBACTERIUM BOVIS

Infection with *M. bovis* cannot be differentiated clinically from *M. tuberculosis* infection, and can only be diagnosed on culture. In the UK, only some 40 cases per year are diagnosed, now accounting for less than 1% of bacteriologically confirmed *M. tuberculosis* complex cases.² Of 210 isolates reported, 200 were in patients of White ethnic origin, of whom over three-quarters were aged over 50 years, suggesting reactivation of disease acquired earlier in life.⁸⁰ Commercial molecular DNA- or RNA-based tests cannot differentiate between *M. bovis* and *M. tuberculosis*, emphasizing the role of culture. Non-commercial molecular methods exist for the identification of *M. bovis*, such as identification of mutations of the *pncA* gene.⁸¹

The main difference between *M. bovis* and *M. tuberculosis* is the presence of pyrazinamide resistance in the former. This influences recommended drug regimens because the inclusion of pyrazinamide is required for an effective 6-month regimen and is nullified by the presence of pyrazinamide resistance. If a four-drug initial phase has been given, then a 7-month continuation phase of rifampicin and isoniazid can be used (see Table 58.3).²⁴ Once the diagnosis has been made,

the pyrazinamide should be stopped, 9 months of rifampicin and isoniazid given, supplemented by 2 months initial ethambutol (*see Table 58.3*).²⁴ If against national guidance a person has had only a three-drug initial regimen (2RHZ), then 2RHE/7HR will need to be given from that point.

Contact tracing of human contacts of human *M. bovis* disease should follow the recommendations given for human contacts of *M. tuberculosis*.²⁴ Where studies of human contacts of cattle with *M. bovis* disease have been undertaken, little evidence of transmission (as judged by tuberculin testing and no evidence of disease) has been found.⁸² Recent advice on contact tracing of human contacts of cattle, largely based on first principles, has been published.²⁴

BCG

Bacille Calmette-Guérin (BCG) is an attenuated strain of *M. bovis* and is therefore pyrazinamide resistant. There are differences between the UK^{24,72} and the USA²⁶ in its use, with the USA putting a much lower emphasis on its use and efficacy. In the UK, BCG was advocated in unvaccinated children aged 10–13 years and in anyone thought to be at higher risk⁷² such as:

- previously unvaccinated tuberculin-negative household contacts of pulmonary disease
- tuberculin-negative unvaccinated new immigrants from high-prevalence countries
- neonates of African–Asian ethnic origin
- tuberculin-negative previously unvaccinated healthcare workers.

The UK unselective BCG vaccination program for those aged 10–13 years stopped in 2005 following review by the Joint Committee on Vaccination and Immunisation and later supported by NICE,²⁴ whose economic appraisals showed it to be grossly uneconomic, either as a vaccination, even with a 15-year protective efficacy, or as a safety net vaccination system for those high-risk individuals who had missed prior BCG.²⁴

The complications of BCG vaccination are local abscess and ulceration at the vaccination site and local lymph node disease. Complications are almost always due to faulty vaccination technique, with subcutaneous rather than intradermal administration. These may resolve spontaneously but over a prolonged period.

Antibiotic therapy with isoniazid,⁸³ rifampicin and isoniazid, and macrolides⁸⁴ have all been advocated. Surgical removal of regional nodes is rarely required. Disseminated BCG infection after vaccination is rare, but occurs in people with immune deficiency and has been reported in HIV infection. Prospective studies, however, have so far failed to show increased complications overall in asymptomatic neonates, and at the moment the WHO still recommends vaccination in developing countries for all neonates unless they have clinical evidence of AIDS.

Instillation of BCG into the bladder has been found to be very effective in the management of transitional cell carcinoma.

Complications can occur, with mycobacterial dissemination, and focal forms of disease localized to both the urinary tract and other sites.⁸⁵ These complications require treatment as for *M. bovis* because of the pyrazinamide resistance (*see Table 58.3*).

DELIVERY OF THERAPY

Adherence is the major determinant of outcome in treating tuberculosis,⁸⁶ both the compliance of the patient in taking medication as prescribed and the compliance of the physician in prescribing the correct regimen and monitoring it. Respiratory physicians are more likely to prescribe the standard chemotherapy than other clinicians, and drug reactions are more common with non-standard regimens.^{87,88} In the UK it is advised that only physicians with full training and expertise in managing tuberculosis, and who have direct working access to TB nurses or health visitors, should manage respiratory tuberculosis.²⁴ It is further recommended that they also manage the drug treatment of non-respiratory tuberculosis, and manage children jointly with a general pediatrician, unless they are a specialist infectious disease pediatrician trained in tuberculosis.²⁴

Tuberculosis cases should be managed by a team as part of a district policy that covers all aspects of management, including notification of disease to the proper authorities, chemotherapy, compliance and contact tracing.⁸⁹ A minimum of one full-time TB nurse or health visitor plus full clerical support is recommended for every 50 notifications per annum per district,⁵⁰ with a higher ratio of staff if there are significant numbers of ‘hard to reach’ individuals.

ADHERENCE MONITORING

Monitoring patient adherence with medication is a vital part of management, and is carried out by TB nurses or health visitors, together with checking on the accuracy and continuity of prescribing. An assessment of the likelihood of adherence should be made for all patients at the onset of treatment.²⁴ For patients not on directly observed therapy (DOT; *see below*) tablet checks and urine tests for rifampicin should be carried out at least monthly throughout chemotherapy. If non-compliance is detected in patients being allowed self-administered therapy, they should be switched to supervised (DOT) therapy, and an assessment made of the possibility of acquired drug resistance. This may require repeat cultures and susceptibility tests, and consideration of molecular tests for rifampicin resistance.

COMBINATION TABLETS

Combination tablets are extremely useful in patients taking daily therapy and prevent the deliberate or accidental consumption of a single drug, which in active disease can

very easily lead to acquired drug resistance. They have the further advantage that compliance can be checked by using the orange/pink coloration of urine of the rifampicin component, which can be inspected for either visually or in the laboratory. Rifater (Hoechst Marion Roussel), for use in the initial phase of treatment, contains rifampicin, isoniazid and pyrazinamide, and Rifaxin (Hoechst Marion Roussel) combine rifampicin and isoniazid for use in the continuation phase. In some studies of combined preparations, the dosages of isoniazid, rifampicin and pyrazinamide^{90,91} have varied slightly from those in Rifater currently available in the UK (isoniazid 50 mg, rifampicin 120 mg, pyrazinamide 300 mg). The bioavailability of the drugs in combination tablets is similar to that of the same doses given individually,⁹⁰ and gives satisfactory clinical results.⁹¹ The slight variations in dosage are therefore not thought to be important in combined preparations of proven bioavailability. Because of the similarity in name (rifampicin, Rifaxin, Rimactazid, Rifaxin, Rimifon and Rifater), care must be taken in writing and dispensing prescriptions. Care is also needed with computer-generated prescribing, because if the system does not recognize the name it may default to rifampicin alone, leading to monotherapy.

For the above reasons, for patients on daily therapy in the UK, combination tablets are recommended to aid compliance and to prevent monotherapy.²⁴

PRETREATMENT SCREENING

Liver function should be checked before treatment of clinical cases: modest elevations of the hepatic transaminases (ALT/AST) are not uncommon in the pretreatment liver function tests of people with TB. Detailed advice on the monitoring of liver function and hepatotoxicity is available.⁹²

Renal function should be checked before treatment with either streptomycin or ethambutol. If possible these drugs should be avoided in renal failure, but if their use is required serum concentrations should be monitored and substantial dosage reductions made unless dialysis is used.²⁴ Because of its rare, but possible, toxic effects on the optic nerve, visual acuity should be tested using a Snellen chart before ethambutol is given.⁹³ Patients should have reasonable visual acuity and ideally be able to report symptoms, although the use of ethambutol in children appears to be safe.⁵⁵ A patient should be told to stop the drug immediately if symptoms occur and report to the physician, and this should be documented. In those with language difficulties or in small children this advice should be given to carers and family members. With increasing evidence to support the use of third-generation quinolones (moxifloxacin and gatifloxacin) in TB from data from trials in Africa (*see later*), some clinicians are substituting moxifloxacin for ethambutol, where either renal or visual impairment makes the use of ethambutol as the fourth drug in the initial phase problematic. Such use, however, has not yet reached national/international guidance.^{24–27}

DIRECTLY OBSERVED THERAPY

Concerns about patient adherence, its effects on relapse and the development of drug resistance, has led to the WHO advocating directly observed therapy (DOT) in the form of short-course chemotherapy or DOTS. With this method of treatment, the ingestion of every dose is monitored by a nursing or lay observer. DOT can be given daily but an intermittent regimen, with appropriate dosage adjustments, is often more convenient as doses can be scheduled to avoid weekends. A regimen of rifampicin, isoniazid, pyrazinamide and either ethambutol or streptomycin thrice weekly for 2 months, followed by thrice-weekly rifampicin and isoniazid for a further 4 months, is advised in the UK.^{24,50}

The strategy of universal DOT, although strongly advocated by the WHO⁹³ and bodies such as the International Union against Tuberculosis and Lung Diseases,⁹⁴ has not been tested by randomized controlled studies. Cohort studies against historical control groups receiving self-administered therapy in different countries have shown DOT to improve outcomes (e.g. cure rates).^{95–97} Decision analyses have also suggested that both selective and universal DOT strategies are more cost-effective than conventional self-administered therapy.^{98–100} However, when DOT was compared in a controlled way directly with self-administration it actually performed less well overall, although subgroups had differing results.¹⁰¹ Critics of universal DOT, which they call ‘supervised pill swallowing’, say that the success of DOT programs is derived from the substantial financial and technical investment in tuberculosis programs that DOT represents and not the DOT element itself.¹⁰² Even in the USA there have been dissenting analyses of DOT effectiveness.¹⁰³

Authors who admitted initial prejudice in favor of DOT conceded that treatment completion rates of over 90% could be obtained with a much lower proportion of DOT than that proposed by the advocates of universal DOT.¹⁰³ The US Centers for Disease Control and Prevention (CDC) recommend that DOT treatment should be considered for all patients, but that if more than 90% of the patients in an area are completing self-administered therapy, selective DOT in unreliable patients is an alternative.¹⁰⁴

In the UK, where tuberculosis is (or should be) treated by experienced physicians working in direct conjunction with tuberculosis nurses or health visitors²⁴ and as part of a district plan,^{72,90} DOT is recommended for selective use in people with an adverse adherence assessment. This includes patients who are homeless, alcohol or other drug abusers, vagrants, seriously mentally ill, patients with multiple drug resistances and those with any history of non-compliance with antituberculosis medication, either previously or shown during treatment monitoring.^{24,72}

NOTIFICATION AND CONTACT TRACING

All cases of tuberculosis, whether respiratory or non-respiratory, should be notified to the proper authorities. The purpose of notification is two-fold:

1. It allows proper epidemiological data to be collected and outbreaks detected, so that treatment services can be planned and monitored.
2. Contact tracing procedures are activated by notification, and so it is essential that all cases, including active cases diagnosed after death, are notified.

Failure to notify could lead to failure to screen appropriate close contacts, which could result in contacts requiring treatment for active disease, or those eligible for BCG vaccination or chemoprophylaxis being denied the appropriate intervention. Detailed guidance, recently updated, is available in the UK.²⁴ The emphasis on aspects of contact tracing in the UK, where BCG vaccination is more widely advised,²⁴ is different from that in the USA, where there is greater emphasis on chemoprophylaxis (*see below*) and less on BCG vaccination.²⁶

TUBERCULOSIS IN HIV-POSITIVE PATIENTS

The incidence of tuberculosis in HIV-positive individuals is much higher than in those who are HIV negative,²⁴ and the mortality rate in such patients is also higher.¹ The classic type of tuberculosis with upper zone pulmonary disease tends to occur less commonly in patients as the CD4 lymphocyte count declines. In this context patients are more likely to have non-cavitatory disease, or mediastinal lymphadenopathy, disseminated disease, to be sputum smear-microscopy negative or even have a normal chest X-ray.^{105,106} A high index of suspicion for TB needs to be maintained in symptomatic HIV-positive individuals, especially in those born in high TB prevalence settings.

Although small studies have suggested that standard 2RHZE/4RH regimens, particularly if adequately supervised, are equally effective in HIV-positive and HIV-negative patients,¹⁰⁷ there have been no controlled trials of adequate power in HIV-positive patients to show differences of efficacy between regimens. As HIV-positive individuals have the same drug resistance rates as the population that they come from, the four-drug initial phase should always be used, unless there are risk factors for MDR-TB (*see above*). If cultures remain positive at 3 months in HIV-positive patients, compliance and drug absorption should be assessed in detail.

In patients with dual infection there is no doubt that the priority is to treat the tuberculosis, especially in sputum smear-positive cases where there is also a public health element. TB treatment is also important in reversing the potentially deleterious effects of tuberculosis on the progress of the HIV infection suggested by in-vitro and in-vivo studies.¹⁰⁸ The treatment of TB in HIV-positive patients is becoming more complex because of:

- increased drug reactions to both TB drugs and highly active antiretroviral drugs in such patients
- a move to earlier treatment of HIV-positive individuals with HAART, at higher CD4 counts for the initiation of treatment, and an increasing number of drug treatment options¹⁰⁹

- drug–drug interactions with TB drugs, HAART and other drugs, e.g. conazoles, particularly due to rifampicin interactions.¹¹⁰

These will be discussed briefly here and in Table 58.5; however, the complexities, with particular emphasis on drug interactions, are set out fully in reference 110:

1. Reactions to antituberculosis drugs are more common in HIV-positive individuals, in whom severe adverse reactions can occur to any drug. This has been the case particularly with thiacetazone, causing Stevens–Johnson syndrome in 10%, with a 10% mortality, leading to its withdrawal from routine use in Africa.^{111,112}
2. The range of anti-HIV drugs is widening all the time. These now include:
 - a. nucleoside reverse transcriptase inhibitors (NRTIs): abacavir, enteric-coated didanosine, emtricitabine, lamivudine, stavudine, tenofovir, zidovudine
 - b. non-nucleoside reverse transcriptase inhibitors (NNRTIs): efavirenz, nevirapine, etravirine, TMC-278
 - c. protease inhibitors (PIs), including boosted combinations with low-dose ritonavir: amprenavir, atazanavir, atazanavir–ritonavir, darunavir–ritonavir, fosamprenavir, fosamprenavir–ritonavir, indinavir, lopinavir–ritonavir, nelfinavir, ritonavir, saquinavir, saquinavir–ritonavir, tipranavir–ritonavir
 - d. integrase inhibitors and entry inhibitors: elvitegravir, raltegravir, maraviroc, enfuvirtide (T-20).
3. Important drug interactions occur. Ketoconazole can inhibit rifampicin absorption if given at the same time, which could lead to TB treatment failure.¹¹³ Rifampicin and isoniazid interact with the azole antifungal drugs, reducing serum concentrations of flu- and itraconazoles to suboptimal levels.^{113–115} The most important area, however, is the interaction with rifampicin, the current key sterilizing drug in TB regimens, which is a potent inducer of the CYP3A P₄₅₀ enzyme through which the PIs, NNRTIs and some other anti-HIV drugs are metabolized (Table 58.5). As a general rule, rifampicin can be used with all NRTIs and with efavirenz (with an increased dose of efavirenz), but not with other NNRTIs. Rifampicin cannot be used with PIs (single or boosted) or with integrase inhibitors, but can be used with T20 inhibitors and with maraviroc (doubled dose of maraviroc). Rifabutin in reduced dosage can be used with most PIs (except saquinavir).

The data to support rifabutin-containing regimens, as opposed to rifampicin-containing regimens, for TB are weak. If at all possible a 6-month rifampicin-based regimen should be used.¹¹⁰ Treatment supervised for 5 days per week with conventional dosages, including at least 56 doses of pyrazinamide and 182 doses of rifampicin–isoniazid, is thought to be adequate.¹¹⁰ Prolongation of the rifampicin–isoniazid continuation phase to 9 months is needed in HIV-positive individuals if there is pyrazinamide intolerance, and should be considered for those still culture-positive for *M. tuberculosis* after 2 months' treatment.¹¹⁰ If rifamycins cannot be tolerated for

Table 58.5 Drug interactions between TB and antiretroviral drugs

Antiretroviral drug/class	Rifampicin	Rifabutin	Clarithromycin
Nucleoside reverse transcriptase inhibitors (NRTIs)			
	No interaction	No interaction	No interaction
	Dose as normal	Dose as normal	Dose as normal
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)			
Efavirenz	Rifampicin standard dose Efavirenz 800 mg if >50 kg, 600 mg if ≤50 kg	Rifabutin 450 mg Efavirenz standard	No interaction Dose as normal
Nevirapine	Do not use	Few data, do not use	Dose as normal
Etravirine	Do not use	Few data, do not use	
TMC-278	Do not use	Double dose TMC-278	
Protease inhibitors (PIs), including boosted			
	Do not use	Some but not all can be used with reduced rifabutin dose (see ref. 111)	Dose as normal
Integrase inhibitors and entry inhibitors			
Elvitegravir/raltegravir	Do not use	No data	
Maraviroc	Double maraviroc dose	No data	
Enfuvirtide	Dose both as normal	Dose both as normal	

some reason, HIV-related TB can be treated with a non-rifamycin-containing regimen; however, this strategy has an inferior efficacy with high relapse rates^{116,117} and should only be contemplated in patients with serious toxicity to rifamycins, and where desensitization or reintroduction has failed, or in those with rifamycin-resistant isolates.

Because of the complexities of managing such dually infected patients, detailed liaison between the TB and HIV services is needed, and drug levels of both antituberculosis and antiretroviral drugs may need monitoring. A detailed view on the complexities, with particular emphasis on drug interactions, is found in reference 110 (*see also* Ch. 6).

NEW TRIALS AND NEW DRUGS IN DEVELOPMENT

A 6-month regimen of rifampicin and isoniazid, supplemented by an initial 2 months of pyrazinamide and ethambutol, remains the ‘gold standard’ treatment.^{24–27} It does, however, have unacceptably high relapse rates, at least by developed country standards, if the regimen is shortened in duration,¹¹⁸ certainly for smear- and culture-positive disease. Moxifloxacin is highly active against *M. tuberculosis*, with activity equivalent to that of isoniazid¹¹⁹ and early bactericidal activity exceeding that of isoniazid between days 2 and 7 of therapy.¹²⁰ These data and data on the murine model, showing that substitution of moxifloxacin for isoniazid, dramatically increasing sterilizing activity and allowing a 4-month regimen,¹²¹ have led to the

potential role of it and other third-generation quinolones in shortening treatment duration coming under extensive investigation. Three phase IIb studies have now reported. The IIb study reported in 2006 only showed equivalence to ethambutol in the sterilizing ability of the regimen over 2 months¹²² using the usual 2-month culture conversion method. A more recent analysis of the phase II Oflotub study data,¹²³ however, showed that the two newer fluoroquinolones, moxifloxacin and gatifloxacin, may have the ability to potentially shorten the duration of therapy to 4 months. This study also showed that serial sputum colony counts and the time to culture conversion have the potential to be quantitative predictive ‘endpoints’ in phase II trials of the newer antituberculosis medications (*see below*).¹²³ The most recent to report¹²⁴ from Brazil also showed superiority in culture conversion rates for the moxifloxacin-containing regimen.

Two phase III studies are underway to test the regimen shortening potential of moxifloxacin and gatifloxacin. These are actively recruiting in Africa and are soon to be expanded to other sites. The Oflotub study by the WHO¹²⁵ is comparing standard 6-month short course chemotherapy (2RHZE/4RH) with a 4-month regimen of rifampicin, isoniazid and gatifloxacin, supplemented with 2 months initial pyrazinamide (2RHZGati/2RHGati). This study of 1836 patients should have completed treatment by summer 2009, and report the 1-year outcome in mid-2010. The REMOX study¹²⁶ is comparing standard treatment (2RHZE/4RH) with a 6-month regimen substituting moxifloxacin for ethambutol (2RHZMoxi/4RH), and a further 4-month regimen

of rifampicin, isoniazid and moxifloxacin, supplemented by 2 months initial pyrazinamide (2RHZMoxi/2HRMoxi). This is actively recruiting in multiple sites in Africa, with further sites being added.

Other novel agents are under development, some of which will shortly come to phase II and possibly phase III studies. These include the following:

- PA-824 (TB Alliance/Chiron) is a nitroimidazopyran that inhibits the synthesis of proteins and cell-wall lipids. This drug has a narrow spectrum of activity, no cross-resistance with current antituberculosis drugs and a unique mechanism of action. It has bactericidal activity against both replicating and static organisms,¹²⁷ and has good sterilizing activity.¹²⁸ It is currently in phase II testing.¹²⁹
- OPC-67683 (Otsuka) is a further nitroimino-oxazole that has advanced to phase II testing. Cross-resistance with PA-824 is anticipated, but it may be up to 20 times more potent.¹³⁰ Preliminary data from the murine model suggest that substituting OPC-67683 for isoniazid in the standard treatment regimen resulted in greater activity and more rapid culture conversion.¹³⁰
- TMC207 (Tibotec) is a diarylquinoline (previously R207910) that selectively inhibits mycobacterial F1F0 ATP synthetase. This is a new class of drug, without cross-resistance with other classes of antituberculosis drugs. TMC207 has time-dependent bactericidal activity in vivo and in vitro, and substitution for any of the three main first-line drugs increases potency. It has a particularly impressive synergy with pyrazinamide.¹³¹ Although well absorbed orally, one potential drawback is that it has a drug–drug interaction with rifampicin which reduces the bioavailability of TMC207 by 50%.¹³²
- Diamine SQ109 (Sequella) is a novel 1,2-ethylenediamine ethambutol analog that acts on cell-wall inhibition by a yet to be understood mechanism. In vitro it has activity against rifampicin- and isoniazid-resistant isolates, demonstrates synergy with isoniazid and rifampicin, and has a high sterilizing activity in the mouse model, with drug levels in the lungs and spleen exceeding the minimum inhibitory concentration.¹³³ It is currently in phase I testing.
- Pyrrole LL-3858 Sudoterb (Lupin) is a substituted pyrrole; early data suggest activity against both susceptible and MDR strains.¹³⁴ In the mouse model, used as a single drug it is bactericidal, and in combination significantly enhances the sterilizing ability of the standard RHZ regimen.¹³⁴ Less information is available than for some other drugs due to commercial considerations, but this drug is also in phase I testing.

These, and the other drugs which may follow them,¹²⁹ will need a series of controlled clinical trials, such as were done a generation ago by the British Medical Research Council¹¹⁸ to establish the best regimens, durations and combinations. Their use will have to be strictly limited to such trials to prevent indiscriminate or uncontrolled use which could lead to an even worse version of XDR-TB emerging, until

their utility and roles are established. The more recent data from the Oflotub study may give us additional ‘endpoints’ to monitor.¹²³

TREATMENT OF LATENT TB INFECTION, FORMERLY KNOWN AS CHEMOPROPHYLAXIS

PRINCIPLES

A proportion of people with tuberculosis infection, as judged by a positive tuberculin skin reaction or now confirmed by an interferon- γ release assay (IGRA), are thought to have a small number of dormant bacilli, perhaps in the order of 10^3 or 10^4 . The administration of one or two drugs for a shorter period of time than for disease – chemoprophylaxis or preventive therapy – is likely to kill these organisms and hence reduce the chance of progression to disease. It is therefore very important to differentiate between disease and infection:

- In tuberculosis infection, the tuberculin skin test (and IGRA test if available) is positive, the chest radiography is normal, and the patient is asymptomatic and has no clinical findings.
- In tuberculosis disease, the skin test is usually positive and there are clinical signs and symptoms or radiographic changes present. (*Note:* neither commercially available IGRA test is currently licensed for use in diagnosis.)

This matter is further complicated in HIV-positive individuals, where anergy to tuberculin does not necessarily mean tuberculosis infection has not occurred, and it becomes difficult to differentiate between disease and infection. Most latent TB infection (LTBI) treatment is secondary (i.e. after infection, as judged by a positive tuberculin test or IGRA, has occurred). Occasionally it may be given before evidence of infection, to prevent infection occurring (e.g. in the neonate of a sputum smear-positive mother); this is primary chemoprophylaxis.

REGIMENS

Although multiple drug regimens are required for the treatment of disease in order to prevent the emergence of drug resistance, it is not illogical to use a one- or two-drug regimen for prophylaxis. Individuals who are receiving chemoprophylaxis are thought to have a low organism burden, in the order of 10^3 to 10^4 . The chance of spontaneous resistance developing to a single drug is in the order of 10^{-5} to 10^{-7} . The chance of drug resistance developing is therefore very low, particularly if a two-drug regimen is used. For instance, when mass isoniazid chemoprophylaxis was given to Inuit communities there was no increase in isoniazid-resistant disease.¹³⁵

Many randomized placebo-controlled trials of isoniazid chemoprophylaxis have been conducted.¹³⁶ Alaskan studies

showed that the maximal effect was achieved by durations up to 12 months and that there was no additional benefit from more extended treatment.¹³⁷ Where the rate of new infection was low, protection lasted for more than 15 years.¹³⁸ A multicenter study by the International Union against Tuberculosis and Lung Disease (IUATLD)¹³⁹ showed that for small radiographic lesions (<2 cm) 6 months of treatment with isoniazid was just as effective as 12 months, and for larger lesions (>2 cm) 6 months of isoniazid provided considerable protection. A later meta-analysis of 77 000 persons, in 11 different placebo-controlled studies (including reference 139), however, clearly shows no additional protective efficacy with isoniazid durations of over 6 months, only increased toxicity.¹⁴⁰

As with chemotherapy for disease, compliance with therapy is important, particularly because individuals on chemoprophylaxis are clinically well and so have less incentive to complete medication: the Alaskan studies also showed that to obtain the full benefit from chemoprophylaxis, more than 60% of treatment must be taken.¹³⁷ There is also concern about increased isoniazid hepatotoxicity for durations over 6 months. In the later US Public Health Service studies the probable isoniazid hepatitis rate was approximately 1%.¹³⁶ There was, however, a clear relationship with age: no cases under 30 years, rising to 2.3% in patients over 50 years. The hepatitis rate was lower in the IUATLD trial¹³⁹ at 0.27% for 6H and 0.52% for 12H, but was still higher than the rate of 0.1% in the placebo-treated group.¹³⁹

These concerns have led to a search for alternative and shorter regimens. Rifampicin has been shown to have a greater sterilizing effect in animal studies,¹⁴¹ either alone or with pyrazinamide, than has isoniazid. A placebo-controlled prophylaxis study from Hong Kong in patients with silicosis suggested that rifampicin alone for 3 months had similar efficacy to rifampicin and isoniazid for 3 months or isoniazid alone for 6 months.¹⁴² In UK studies the use of rifampicin and isoniazid combined for 3 months showed a significant decrease in childhood tuberculosis.^{143,144} Using these data, and others from experimental studies, the American Thoracic Society/CDC recommended a regimen of rifampicin and pyrazinamide for 2 months (2RZ) rather than isoniazid alone for 6 months.¹⁴⁵ The predictable toxicity of the 2RZ regimen⁷² led to severe hepatotoxic reactions and fatalities¹⁴⁶ and the withdrawal of this recommendation.¹⁴⁷

In the USA either rifampicin for 4 months (4R) or isoniazid for 9 months (9H) is now recommended,¹⁴⁶ despite the meta-analysis on isoniazid preventive therapy showing no additional benefit of regimens longer than 6 months, only increased toxicity,¹⁴⁰ and there being no controlled trial data to support 4R. In the UK, either 6H or 3RH is recommended,²⁴ both having 'A' category data or SIGN 1+¹⁴⁸ evidence to support their use. There is also evidence to support 6R for contacts of isoniazid-resistant disease^{149,150} and is recommended for this category in the UK.^{24,72}

IN HIV-NEGATIVE PERSONS

In the UK, where there is greater emphasis on BCG, and where prior BCG vaccination modifies the tuberculin response, the following groups are recommended for consideration of treatment for LTBI, based on either incidence of active TB in persons with a positive tuberculin test or from selected clinical conditions (Box 58.1)²⁴ and for certain conditions with a high relative risk of tuberculosis (Box 58.2).

Treatment of LTBI should be offered in the following settings:

- Neonates of mothers with sputum-smear positive TB as a primary measure until shown to be tuberculin negative at age 6–8 weeks.
- Children aged between 4 weeks and 2 years of age in contact with sputum smear-positive TB, either as a primary measure (no prior BCG) or if inappropriately tuberculin positive (prior BCG).
- TB contacts aged up to 35 years with an inappropriately positive Mantoux test confirmed by a positive IGRA test.
- New entrants aged under 16 years from countries with a TB prevalence of 40/100 000 per annum or greater with a positive Mantoux test confirmed by a positive IGRA test.
- New entrants aged 16–35 years from sub-Saharan Africa, or countries with a TB rate of 500/100 000 per annum or greater, with a positive Mantoux test confirmed by a positive IGRA test.

Persons for whom chemoprophylaxis is recommended, but who do not receive it or decline to take it, should have radiographic follow-up at 3 and 12 months.⁶⁷

Box 58.1 Consideration for treatment of LTBI in selected clinical conditions

	TB cases/10 000 person years
HIV infection	35–162
Intravenous drug use	10–76
Silicosis	68
Recent latent TB infection	1.6–12.9
Chest X-ray changes consistent with prior TB	2.0–13.6

Box 58.2 Consideration for treatment of LTBI in conditions with a high relative risk of tuberculosis

	Relative risk
Solid organ transplant (renal)	37
Solid organ transplant (heart)	20–74
Jejunoileal bypass	27–63
Silicosis	30
Chronic renal failure/hemodialysis	10–25.3
Gastrectomy	2.5
Diabetes mellitus	2–41
Anti-tumor necrosis factor- α treatment	4–8
Contact smear-positive TB	5–10

In the USA, preventive therapy with a positive tuberculin reaction²⁶ (>5 mm in persons with HIV infection, close contact of infectious disease and with fibrotic X-ray lesions; >10 mm in other at-risk persons, including infants and children younger than 4 years; and >15 mm in low-risk populations) is recommended for the following groups:

1. Close contacts of persons with newly diagnosed infectious tuberculosis.
2. Recent tuberculin skin test converters (defined as a 10 mm or greater increase within a 2-year period for those <35 years of age, and 15 mm or greater increase for those >35 years).
3. Persons with medical conditions that have been reported to increase the risk of tuberculosis:
 - a. diabetes mellitus
 - b. prolonged therapy with adrenocorticosteroids
 - c. immunosuppressive therapy
 - d. some hematological and reticuloendothelial diseases
 - e. intravenous drug users known to be HIV negative
 - f. end-stage renal disease
 - g. clinical situations associated with substantial rapid weight loss or chronic undernutrition.
4. People under 35 years with a tuberculin test >10 mm, even in the absence of the above risk categories, if:
 - a. foreign born from high-prevalence countries
 - b. from medically under-served low-income populations, including high-risk racial or ethnic minority populations
 - c. resident of a long-term care facility.

In the USA, the use of an IGRA test (QuantiFERON-TB Gold) is now recommended as a one-step test for screening for LTBI, rather than tuberculin testing.¹⁵¹

IN HIV-POSITIVE PERSONS

The identification of individuals at high risk of developing tuberculosis in HIV infection is complicated by loss of response to tuberculin, and to some extent IGRA tests, and also the atypical radiological changes. Such therapy was recommended by the WHO and IUATLD.¹⁵² When this policy has been examined in developing countries, short-term benefits have been shown but there are also logistical difficulties in implementing such a policy.^{153,154} A more recent study in the USA did not support isoniazid prophylaxis in high-risk patients with anergy unless they had been exposed to active tuberculosis.¹⁵⁵

For the above reasons, and because of concerns about the higher rates of drug resistance in HIV-infected persons in the UK, chemoprophylaxis in HIV-positive individuals is recommended only in contacts of sputum smear-positive pulmonary disease^{24,110} and to be considered in others with HIV. Isoniazid treatment¹¹¹ is no longer recommended for people treated for TB disease after completion of chemotherapy.^{42,110} In the USA²⁶ LTBI treatment for a tuberculin test of 5 mm (or a positive IGRA test) is advised in HIV-positive individuals as

it is thought that such patients have a high annual rate of disease.¹⁵⁶ It may also be considered for HIV-infected persons who are tuberculin negative but belong to groups in which the prevalence of tuberculosis infection is high.

FOR MULTIDRUG-RESISTANT TUBERCULOSIS

There are no data on what preventive regimen is feasible in persons in contact with MDR-TB. Any LTBI regimen should include two (and ideally three) drugs to which the organism is known to be susceptible, although the resistance pattern can be so extensive that no preventive regimen is available. If the drug susceptibility pattern is not known then ofloxacin or ciprofloxacin with pyrazinamide might be effective.¹⁵⁷ The CDC suggest this combination, or ethambutol and pyrazinamide.¹⁵⁸

The view in the UK is that, since only a minority of people infected with tuberculosis develop clinical disease, and because there are no data on which to base advice, long-term regular follow-up of individual cases is currently advised.²⁴

OPPORTUNIST (NON-TUBERCULOUS) MYCOBACTERIA

Isolates of opportunist mycobacteria – also called atypical mycobacteria, mycobacteria other than tuberculosis (MOTT), non-tuberculous mycobacteria (NTM) or environmental mycobacteria – are increasing. Although this may be related to an increasing incidence, there has been a very significant rise in the isolation of rapidly growing mycobacteria (RGM), e.g. *M. chelonae*, *M. gordoniæ* and *M. abscessus*, with the increasing use of liquid culture, with its greater sensitivity, but many of these isolates appear to be commensal, rather than associated with clinical disease. NTM are ubiquitous in the environment and the significance of an isolate can be established only by considering the specimen type from which the organism was isolated, the number of isolates, the degree of growth and the species of *Mycobacterium*. In general, in non-sterile sites, multiple isolates are required to establish disease, whereas one positive culture from a sterile site, particularly if supported by histopathology, is usually sufficient.^{159,160}

The management of opportunistic organisms was reviewed by the Joint Tuberculosis Committee of the British Thoracic Society (BTS) in 1999, and guidelines on their management produced,¹⁵⁹ although these are much less based on controlled trials than is the case for tuberculosis. The 5-year follow-up results of controlled trials in *M. avium intracellulare* (MAC), *M. malmoense* and *M. xenopi* with both quinolone- and macrolide-containing regimens have also recently been published.¹⁶¹ Guidelines from the USA are much more recently updated.¹⁶⁰ These, and the earlier BTS advice, modified by reference 161, are summarized in Table 58.6, but for detailed recommendations the original references should be consulted.

Table 58.6 Treatment of opportunist mycobacteria^{159–161}

Organism	Situation	UK advice	USA advice
HIV-negative			
Any	Cervical nodes in children	Excision	Excision
<i>M. kansasi</i>	Adult pulmonary disease	9RE; 15–24RE if recurrent	HR + E 15 mg/kg until culture negative for 1 year
<i>M. avium intracellulare</i> (MAC)	Adult pulmonary disease	24RHCipro/Clari or 24RHE	Clari/R/E 25 mg/kg three times weekly or daily Clari/R/E 15 mg/kg ± other until culture negative for 12 months (see text)
<i>M. malmoense</i>	Adult pulmonary disease	24RHCipro/Clari or 24RHE	Not covered
<i>M. xenopi</i>	Adult pulmonary disease	24RHCipro/Clari or 24RHE	Not covered
<i>M. kansasi</i>	Non-pulmonary disease	9RE initially; add macrolide or streptomycin/prothionamide depending on response	As for pulmonary disease
MAC	Non-pulmonary disease	24REClari	Excision/debridement + drugs as for adult pulmonary disease
<i>M. malmoense</i>	Non-pulmonary disease	24REClari	RHE ± Clari, quinolones Duration unspecified
<i>M. xenopi</i>	Non-pulmonary disease	24REClari	HEClariR or rifabutin ± initial streptomycin
Rapid growing organisms			
<i>M. abscessus</i> and other rapid growers	Disease	Pulmonary: resect if possible under drug cover. Use REClari; consider other drugs Non-pulmonary: wound debridement; Cipro/Clari, plus aminoglycoside or imipenem	Pulmonary: resect if possible under multidrug cover including Clari Non-pulmonary: surgical debridement; Clari-based treatment for 4–6 months Clari/amikacin + initial cefoxitin
<i>M. fortuitum</i>	Disease	As <i>M. abscessus</i>	Complex; see ref. 160
<i>M. chelonae/gordonae</i>	Disease	As <i>M. abscessus</i>	Complex; see ref. 160
<i>M. marinum</i>	Skin	Co-trimoxazole; tetracycline; R/E until resolved	Clari/ethambutol until resolved, then 2 months. Add rifampicin if deep structures involved
HIV-positive			
MAC	Treatment	HAART + 24R(Rifabutin)EClari	Clari/Azithro + E ± rifabutin until resolution of symptoms and reconstitution of cell-mediated immunity
MAC	Prophylaxis	1st Azithro 1200 mg/week 2nd Clari 500 mg every 12 h 3rd Azithro 1200 mg/week + rifabutin 300 mg/day	Azithro 1200 mg/week or Clari 1000 mg/day if CD4 below 50/mL. Rifabutin 300 mg/day effective but less well tolerated
<i>M. kansasi</i>	Treatment	HAART + 24R(Rifabutin)EClari	Not covered
<i>M. malmoense</i>	Treatment	HAART + 24R(Rifabutin)EClari	Not covered
<i>M. xenopi</i>	Treatment	HAART + 24E(Rifabutin)EClari	Not covered

Azithro, azithromycin; Cipro, ciprofloxacin; Clari, clarithromycin; E, ethambutol; H, isoniazid; HAART, highly active antiretroviral therapy; R, rifampicin. The number in front of the letters represents the duration in months.

Generally, in HIV-negative people, these opportunistic organisms cause disease in two main settings:

- In children, usually under the age of 5 years, isolated lymphadenopathy, usually cervical, occurs and should be managed by surgical excision.^{159,160,162}
- In HIV-negative patients with underlying structural lung disease, often chronic obstructive pulmonary

disease, infection with *M. kansasi*, *M. avium* complex, *M. malmoense* or *M. xenopi* can all simulate conventional tuberculosis or bronchiectasis with nodularity. Unlike the management of tuberculosis where the drug susceptibility data must be scrupulously followed, the susceptibility to individual drugs in vitro does not correspond to clinical response and should largely be ignored, being of major

utility only in *M. kansasi*i disease, and for macrolide susceptibility. Laboratory studies also show that there is synergy between drugs, with rifampicin and ethambutol in particular, which are bactericidal in combination, although the organism has been reported as in-vitro resistant to them singly.¹⁶³ Clinical trials on pulmonary *M. kansasi*i have shown that 9 months of treatment with rifampicin and ethambutol is adequate for most people, but that longer treatment may be needed in some cases.¹⁶⁴

For the other mycobacteria which cause pulmonary infection, treatment with rifampicin and ethambutol, sometimes with isoniazid as well, gives cure rates of approximately 80%.¹⁶⁵ Unfortunately, results using either clarithromycin or ciprofloxacin, with rifampicin and ethambutol replacing isoniazid, have not shown much improvement.¹⁶¹ Treatment of extra-pulmonary disease other than *M. marinum* disease in adults is more complex and detailed recommendations should be followed.^{159,160}

In HIV-positive patients, restoring immune function with combinations of antiretroviral treatment is as important as, if not more so than, antimycobacterial treatment.¹⁶⁰ There are important interactions between macrolides, rifamycins and protease inhibitors and/or antiretroviral drugs (see Table 58.5) which may limit treatment. In those who require treatment for pulmonary or disseminated disease, rifampicin, ethambutol and clarithromycin on an indefinite basis are advised.^{159,160} For prophylaxis against *M. avium* complex, the first-choice recommendation is azithromycin 1200 mg weekly, with clarithromycin 500 mg every 12 h as second, and azithromycin 1200 mg once weekly plus rifabutin 300 mg once daily as third choice.¹⁶⁰

Roderick J. Hay

The most prevalent superficial mycoses are caused by different groups of pathogenic fungi, the dermatophytes or ringworm fungi, *Candida* and *Malassezia* species. These infections are very common, usually infecting otherwise healthy individuals, although the clinical pattern of infection and response to treatment will be affected if the patient is immunosuppressed. Dermatophyte infections include clinical disease states such as tinea capitis (scalp), cruris (groin), corporis (body) and pedis (feet). They are caused by filamentous fungi of the genera *Trichophyton*, *Microsporum* and *Epidermophyton* spp. *Malassezia* species are commensal yeasts on normal skin, but under certain conditions can cause human disease such as pityriasis versicolor. *Candida* species are the main cause of mucocutaneous infections, including oral and vaginal candidiasis (or thrush) as well as skin disease, particularly in the region of body folds. In addition there are other less common superficial fungal pathogens.

DERMATOPHYTOSIS

TINEA CAPITIS

Tinea capitis presents with a range of clinical features from alopecia (or hair loss) with little inflammation to the formation of a kerion, which is a pustular and inflammatory mass containing hair shafts and fungi. Tinea capitis is mainly a disease of childhood.¹ This is an infection that is difficult to diagnose on clinical grounds alone and it is important to confirm the diagnosis using mycological sampling. The mycological causes of tinea capitis vary geographically but it is useful to know whether the infection can be spread from child to child (anthropophilic) or whether it originates from an animal source (zoophilic) such as a cat or dog. Common organisms include *Trichophyton tonsurans* (anthropophilic), *T. violaceum* (anthropophilic) and *Microsporum canis* (zoophilic). In the UK, *T. tonsurans* is now more common than *M. canis* but in other countries in Europe the latter dominates. Whatever the cause, it is important to treat other infected individuals; in the case of anthropophilic infections this includes other family members and with zoophilic infections domestic pets such

as cats may be infected. In other parts of the world, *T. violaceum* and *T. soudanense* are more common. Identification of the cause is important as there are differences in response rates between *Trichophyton* and *Microsporum* species that may determine the medication used.²

Generally no topical therapy is effective long term for tinea capitis. For instance, ketoconazole shampoo may be effective clinically for *T. tonsurans* infection during the active treatment phase but there is a very high relapse rate.³ The main alternatives are all oral therapies (Table 59.1). Griseofulvin (500–1000 mg/day with food) is given for 8 weeks or longer but has the disadvantage of being more protracted and having a higher relapse rate in some infections.⁴ Griseofulvin in suspension form, for use in children, is also not available in all countries. Oral terbinafine 250 mg/day for 4 weeks (unless *M. canis* when double doses are needed)⁵ or itraconazole 100 mg/day are appropriate but must be continued for 4 weeks, depending on severity⁶ (Table 59.1 – see modified child dose regimen for terbinafine). Pediatric formulations of these drugs are also not universally available.

In children with tinea capitis caused by *M. canis*, a 6-week course of either itraconazole 100 mg or griseofulvin 500 mg/day exhibited equivalent efficacy of 88%, but itraconazole was better tolerated.⁷ A longer course may be necessary in people with severe disease. Higher doses of itraconazole (200 mg/day or 3 mg/kg solution) may be advantageous, especially as only 40% of patients with *T. tonsurans* infection responded to 4 weeks of itraconazole 100 mg/day.⁸ Corticosteroids, even in cases of kerion, are not recommended. An alternative approach is once-weekly fluconazole 6–8 mg/kg.⁹

TINEA CRURIS

Tinea cruris is more common in men than in women, producing a red, scaly rash with a prominent margin covering the groin, scrotum and thighs. It is caused by various dermatophytes, mainly *Epidermophyton floccosum* and *T. rubrum*. Topical imidazoles such as clotrimazole, miconazole

Table 59.1 Treatment of tinea infections

Condition	Agent	Daily dose	Duration
Tinea capitis	Griseofulvin Itraconazole Terbinafine	10 mg/kg 100 mg 250 mg ^a	2–3 months 2–6 weeks 2–4 weeks
Tinea cruris	Clotrimazole Miconazole Sulconazole Itraconazole Terbinafine	Topical twice daily Topical twice daily Topical twice daily 200 mg 250 mg	2–3 weeks 2–3 weeks 2–3 weeks 1 week 1 week
Tinea corporis	Itraconazole Terbinafine Terbinafine, 1% cream	200 mg 250 mg Topical twice daily	1 week 1 week 1 week
Tinea pedis	Terbinafine, 1% cream Terbinafine film-forming solution Clotrimazole, 1% cream	Topical twice daily One application Topical twice daily	1 week 1 week
Moccasin-type tinea pedis	Itraconazole Terbinafine	200 mg 250 mg	2 weeks 2 weeks

^aModified terbinafine dose in children <20 kg, 62.5 mg/day; 20–40 kg, 125 mg/day; >40 kg, 250 mg/day.

or sulconazole twice daily for at least 2 weeks are usually effective (Table 59.1). Oral itraconazole (200 mg/day)¹⁰ or terbinafine (250 mg/day) for 7 days¹¹ are highly effective and may be preferred. An alternative topical therapy is terbinafine 1% cream applied once daily for 1 week which is effective in >90% of cases.¹²

TINEA CORPORIS

Tinea corporis (ringworm) tends to affect exposed areas of the extremities and may be treated systemically, as for tinea cruris, or with azole or terbinafine creams (Table 59.1). Topical therapy is usually used for infections of limited extent.

TINEA PEDIS

Tinea pedis (athlete's foot) affects about 16% of the population and is often recurrent. Terbinafine cream 1% twice daily for 1 week compares well with 1% clotrimazole cream twice daily for 4 weeks (97% vs 84% response)¹³ (Table 59.1). However, topical azole creams (e.g. bifonazole, miconazole) or powders are effective. A single application of terbinafine, a film-forming solution, applied to the soles is also curative in many cases.¹⁴ Moccasin-type tinea pedis affecting the soles is invariably due to *T. rubrum*: 2–4 weeks' therapy with either terbinafine 250 mg/day or itraconazole 200 mg/day are the best options.

SEBORRHEIC DERMATITIS, PITYRIASIS VERSICOLOR AND MALASSEZIA FOLLICULITIS

There is a range of superficial diseases related to superficial infection with, or sensitization by, *Malassezia* species. These are seborrheic dermatitis (dandruff is a form of the latter

confined to the scalp), cradle cap, pityriasis versicolor and *Malassezia* folliculitis.

Pityriasis versicolor is a superficial skin infection of the upper trunk, mainly caused by *M. globosa*, which results in patchy hypo- or hyperpigmented scaly macules on the trunk. It can be treated with azole creams or ketoconazole shampoo applied daily for up to 7 days. Topical terbinafine cream is also effective. Topical treatments are often difficult to apply as the area affected is often extensive; oral itraconazole 200 mg/day for 7 days is 85% effective.¹⁵ *Malassezia* folliculitis is less common, but causes itchy pustular lesions on the upper chest or back and is best treated with oral itraconazole.

Seborrheic dermatitis is characterized by excess scaling of the scalp, face and anterior chest associated with inflammation; dandruff or scaling of the scalp may be a manifestation of seborrheic dermatitis. Cradle cap in infants is thought to be a similar process. The mechanism by which *Malassezia* contributes to these conditions is not understood, but they are common problems: some authors have stated a lifetime incidence of seborrheic dermatitis of 10% for the normal population with an incidence of 50% in HIV-infected patients. Seborrheic dermatitis frequently accompanies symptomatic HIV infection and may be one of the first signs of infection.

Seborrheic dermatitis is a chronic disease that relapses rapidly after treatment. It may also be difficult to effect improvement despite antifungal therapy and anti-inflammatory agents. Topical corticosteroids have largely been supplanted by the use of topical azole creams with or without a steroid component. Lithium succinate 8% ointment is also effective. Patients with very inflammatory lesions benefit from combined hydrocortisone 1% and azole antifungal preparations. Oral itraconazole 200 mg/day is also effective.¹⁶ By contrast, fluconazole is not very effective, especially in those with AIDS. Maintenance antifungal therapy is not recommended for seborrheic dermatitis, unless it is very severe.

FUNGAL NAIL DISEASE (PARONYCHIA AND ONYCHOMYCOSIS)

Fungi may affect the nail fold (paronychia) or the nail itself (onychomycosis). Paronychia is usually associated with *Candida albicans* and occasionally other *Candida* species. Confirmation by culture is desirable because many cases of paronychia are due to bacteria, especially *Staphylococcus aureus*, and irritant dermatitis also contributes to nail fold inflammation. Onychomycosis is caused by a variety of fungi: the most common is *T. rubrum*, which causes about 80% of cases in the UK; less common dermatophyte causes include *T. interdigitale*, *Epidermophyton floccosum*, *T. erinacei*, *T. soudanense*, *T. tonsurans*, *T. violaceum* and *M. canis*. Non-dermatophyte molds that occasionally cause onychomycosis, usually of the toenails, include *Fusarium* spp., *Aspergillus* spp., *Acremonium* spp., *Scytalidium dimidiatum*, *S. hyalinum*, *Scopulariopsis brevicaulis* and *Onychocola canadensis*. *Scytalidium* species can also infect the toe web spaces, soles and fingernails, mimicking dermatophytosis. Rarely true onychomycosis is caused by *C. albicans*.

CANDIDA PARONYCHIA

Candida paronychia, when mild and localized, will usually respond to imidazole lotions, applied topically for up to 12 weeks. In addition, patients should carefully dry their hands after washing, which is often the primary reason for the development of paronychia. Sometimes where irritant dermatitis is present a topical steroid cream is useful. For patients with extensive *Candida* paronychia or an immunodeficiency state, including chronic mucocutaneous candidosis, itraconazole 200 mg/day for 3–6 weeks is usually adequate, although some patients require longer therapy. Patients who also have onychomycosis require longer therapy. Fluconazole is also active against *Candida* spp., doses of 200 mg/day being effective depending on the severity of disease and the immune status of the patient.¹⁷

ONYCHOMYCOSIS

The treatment of onychomycosis depends on the species of infecting fungus, whether and how many fingernails or toenails are involved, the clinical pattern of nail involvement, and the age and immune status of the patient.¹⁸

DISTAL SUBUNGUAL AND SUPERFICIAL ONYCHOMYCOSIS

In distal fingernail disease affecting less than 30% of the nail plate in non-immunocompromised patients, topical therapy can be used. Options include 28% tioconazole and amorolfine nail paint applied once or twice weekly.¹⁹ Alternative

strategies include bifonazole 1% combined with urea paste 40%, which softens the nail plate for subsequent ablation and has a reported response rate of up to 70%.²⁰

However, the overall cure rate of topical therapy is only about 40% and many months of treatment are required. Failure is more likely if more than 30% of the nail is involved. Removal of the nail after application of 40% urea ointment alone²¹ or surgical ablation is an alternative option for these patients.

EXTENSIVE DISTAL OR PROXIMAL SUBUNGUAL, ENDONYX AND TOTALLY DYSTROPHIC ONYCHOMYCOSIS

For patients with proximal nail involvement or extensive distal nail disease, which may also include the skin around the nails, systemic therapy is appropriate. Both itraconazole 200 mg/day or 400 mg/day for 1 week per month and terbinafine 250 mg/day yield a response in excess of 75% for fingernail involvement with dermatophytes but terbinafine is more effective than intermittent itraconazole for toenail disease.²² Treatment is usually given for 3 months for fingernails²³ and 6–12 months for toenails. Relapse may occur after discontinuation of therapy – 22% in one study.²⁴ Studies with itraconazole have shown lower efficacy rates than terbinafine, which is also more cost-effective,²⁵ but this depends on the infecting fungus. Despite these measures many nail infections are difficult to treat and other measures such as retreating with terbinafine²⁶ or using a combined treatment with itraconazole or terbinafine and amorolfine nail lacquer²⁷ may be successful. The presence of longitudinal streaks in the nail plate is often associated with relapse and removal of these areas using 40% urea ointment may be useful.

In patients with non-dermatophyte onychomycosis of the toenails, itraconazole or terbinafine may be appropriate for those caused by *Aspergillus* spp. However, these are less effective therapies for *Fusarium* or *Acremonium* onychomycosis and the data supporting use in *Scopulariopsis* and *Scytalidium* infections are limited. Response rates in toenails are <80% and disease-free nails 1 year after therapy are seen in only 35–50% of cases.²⁸ Nail plate ablation after urea treatment may be the preferred option.

In leukemic patients with onychomycosis it is important to ascertain whether *Fusarium* is the cause. Removal of the nail may prevent disseminated *Fusarium* infection, which carries a high mortality.²⁹

Onychomycosis, including rapidly developing onychomycosis, caused by dermatophytes is common in people with AIDS. Although the normal treatment regimens for nail infection can be used, often it is necessary to double the dose and prolong treatment times.

Onychomycosis in children is usually due to dermatophyte infection. In very small children fluconazole syrup 2–3 mg/day may be preferable. In older children itraconazole or terbinafine are effective, although responses are often poorer than in adults.

MUCOSAL CANDIDOSIS

Mucosal fungal infections are extremely common. The vast majority are caused by *C. albicans* but occasionally by other yeasts, especially *C. glabrata*, and rarely by filamentous molds such as *Aspergillus* spp.

OROPHARYNGEAL CANDIDOSIS

Before the AIDS epidemic, oropharyngeal candidosis (OPC) was largely seen in patients at the extremes of age, those receiving inhaled steroids or antibiotic therapy, following oral cavity radiotherapy, after cytotoxic chemotherapy and in denture wearers. Chronic oral candidosis occurs in patients with chronic mucocutaneous candidosis (CMC). *C. albicans* is the primary pathogen and rarely *C. glabrata* and *C. krusei* (Table 59.2). The most common pattern of OPC is the pseudomembranous form, but an erythematous type is also found. Occasionally, denture-related candidosis or angular cheilitis is the primary manifestation. In untreated AIDS, the pseudomembranous or erythematous forms predominate.

Topical agents such as nystatin or amphotericin B oral suspension (1 mL every 6 h for 2–3 weeks) are effective in non-immunocompromised patients. Clotrimazole troches (available in the USA) are also effective. Miconazole oral gel in a dose of 10 mL every 6 h is particularly useful for denture-related candidosis or in infants.

Table 59.2 Intrinsically resistant fungi

Species	Antifungal agents
<i>Candida krusei</i>	Fluconazole, ketoconazole
<i>Candida glabrata</i> ^a	Fluconazole, ketoconazole, itraconazole
<i>Candida parapsilosis</i>	Echinocandins
<i>Candida lusitaniae</i> ^a	Amphotericin B
<i>Malassezia</i> spp.	Amphotericin B
<i>Trichosporon</i> spp.	Amphotericin B
<i>Aspergillus</i> spp.	Ketoconazole, fluconazole
Mucorales	Azoles, flucytosine, echinocandins
<i>Scedosporium apiospermum</i> (<i>Pseudallescheria boydii</i>)	Amphotericin B
<i>Scedosporium prolificans</i>	Amphotericin B, azoles, flucytosine
<i>Paecilomyces</i> spp.	Amphotericin B
<i>Fusarium</i> spp.	Azoles, flucytosine
<i>Penicillium</i> spp.	Ketoconazole

^aA substantial proportion or majority of isolates.

In immunocompromised patients, fluconazole 100 mg/day is more effective than topical therapy and is the agent of first choice, with response rates in excess of 90%. Ketoconazole and itraconazole are also effective at doses of 200–400 mg/day but are less well absorbed in conditions of hypochlorhydria that complicate AIDS and bone marrow transplantation. Improved serum levels of both itraconazole and ketoconazole are achieved by acid drinks such as orange juice or cola and food. Itraconazole oral solution overcomes this problem.

VULVOVAGINAL CANDIDOSIS

Vulvovaginal candidosis is common. By the age of 24 years, 60% of 76 women had suffered at least one episode of vulvovaginal candidosis.³⁰ Among these women, 36% had at least one episode a year and 3% had it ‘almost all the time’. Certain conditions increase the incidence and possibly the severity of vulvovaginal candidosis. These include pregnancy, antibiotic use, diabetes mellitus and cystic fibrosis.³⁰ HIV-seropositive women are no more likely to develop vaginal candidiasis than controls,³¹ but in these patients there is often a worse response to initial treatment and a shorter time to relapse. Over 90% of cases are caused by *C. albicans*, about 5% by *C. glabrata* and other species such as *C. tropicalis* can be isolated from the remainder.

Treatment may be local or systemic (Table 59.3). Topical treatment regimens with azoles yield response rates of 80–90%. Many different formulations are available, which vary primarily in cost. Women without predisposing factors, such as pregnancy, will usually prefer single-dose or 3-day treatments. Responses are slower in those with predisposing factors and 5- to 14-day treatment regimens are generally preferable if topical therapy is preferred. Nystatin, one to two pessaries inserted high into the vaginal vault nightly for 14 nights, has a lower response rate (80%) than the azoles and stains clothing, but is useful for azole-resistant organisms such as *C. glabrata*.

Oral therapy is preferred by many women; fluconazole as a single dose of 150 mg or itraconazole two 200 mg doses 8 h apart are effective in over 90% of patients. Itraconazole may be preferable for *C. glabrata* infections.

In pregnancy, local therapy with a clotrimazole 500 mg vaginal tablet is often effective and does not expose the fetus to an antifungal.³² This is desirable in the first trimester, although there is no evidence that azoles are teratogenic in humans at the doses usually used.^{33,34} However 4 days’ therapy is more effective than single-dose therapy and 7 days’ therapy even better.³⁵ Later in pregnancy, systemic therapy with fluconazole or itraconazole are accepted alternatives.³⁶ Treatment of vaginal candidiasis in pregnancy appears to reduce preterm birth.³⁷

Suppressive treatment may be indicated for frequent recurrent infections. Continuous therapy for 3–6 months suppresses symptoms and reduces the subsequent frequency of relapse, and once monthly intermittent therapy with itraconazole 400 mg was partially successful.³⁸ If symptoms recur, local treatment

Table 59.3 Examples of treatment regimens for vulvovaginal candidosis

Antifungal agent	Formulation	Dose	Duration
Local therapy			
Clotrimazole	Vaginal tablet	1–200 mg	3–7 daily doses
Clotrimazole	Vaginal tablet	500 mg	1 dose
Econazole	Vaginal tablet	150 mg	3 daily doses
Miconazole	Pessary	100–200 mg	3–7 daily doses
Miconazole	Pessary	1200 mg	1 dose
Nystatin	Vaginal tablet	100 000 U	14 daily doses
Terconazole	Pessary	300 mg	1 dose
Terconazole	Vaginal tablet	80 mg	3 days
Butoconazole	2% cream	5 g	1–3 daily doses
Clotrimazole	1% cream	5 g	7–14 daily doses
Clotrimazole	10% cream	5 g	1 dose
Econazole	1% cream		Twice daily for 3–7 days
Fenticonazole	2% cream	5 g	7 daily doses
Miconazole	2% cream	5 g	7 daily doses
Terconazole	0.4–2% cream	5 g	3 daily doses
Tioconazole	2% cream	5 g	3 daily doses
Tioconazole	6.5% cream	5 g	1 dose
Systemic therapy			
Fluconazole	Capsule	150 mg	1 dose
Itraconazole	Capsule	200 mg	2 doses, or 3 days

with single-dose clotrimazole 500 mg fortnightly or intermittent single-dose oral treatment with fluconazole 150 mg may be helpful. There is no evidence to date of antifungal resistance resulting from such a regimen, although *C. glabrata* infections are more common in women who have received repeated courses of azole therapy.

OTOMYCOSIS (OTITIS EXTERNA)

Otomycosis is a relatively common problem in non-immunocompromised patients and is commoner in hot humid climates. The causative fungi include *Aspergillus niger* and *C. albicans*. The latter may form a blackish mat in the ear canal but many infections do not have characteristic features.

The vast majority of cases of otomycosis respond to a combination of cleaning of the ear canal and topical antifungal therapy. Clotrimazole solution or cream, applied at least twice daily for a minimum of a week, is probably the best primary therapy. Alternatives include cresyl acetate solution or topical

ketoconazole, econazole or amphotericin B. Care should be taken in the application of any of these compounds if the tympanic membrane is perforated, as hearing loss has been reported.

Occasionally, invasive otomycosis of the bone, in particular of the mastoid, occurs usually in immunosuppressed patients. It is usually caused by *Aspergillus fumigatus*, but occasionally by other organisms. Many, but not all, patients are immunocompromised. These patients require systemic antifungal therapy according to the nature of the organism; surgical debridement is also often necessary.

CHAPTER

60 Systemic fungal infections

Paula S. Seal and Peter G. Pappas

The treatment of fungal disease has evolved significantly with the recent introduction of several new antifungal agents. The number of immunocompromised patients, including solid organ and stem cell transplant recipients and others on chronic immunomodulating therapy, continues to increase as has the population at risk of invasive fungal infection. New clinical trial data and treatment guideline recommendations have become available while emerging fungal pathogens pose a challenge with regard to the most appropriate antifungal regimens. In this chapter, we discuss the approach to treatment of the more common systemic mycoses.

INVASIVE CANDIDIASIS

CANDIDEMIA

Candidemia is the fourth most common cause of nosocomial bloodstream infections in the USA, with an attributable mortality ranging between 15% and 49% in adults.^{1–3} Recent epidemiological studies have demonstrated the increase of non-*albicans* *Candida* spp. as a cause of invasive candidiasis.⁴ Factors associated with mortality in invasive candidiasis include higher APACHE II scores, non-*parapsilosis* isolates, persistently positive blood cultures and significant underlying illness.

All patients with candidemia require systemic antifungal therapy. Specific recommendations are detailed in Table 60.1. The selection of an antifungal agent should be based on the *Candida* species, presumed susceptibility, a history of prior therapy including recent azole exposure, and a clinical suspicion of deep organ involvement, such as central nervous system, endocardial or hepatic/splenic involvement.^{5,6} All patients with candidemia require a dilated fundoscopic examination to evaluate for endophthalmitis. Removal of central venous catheters is strongly recommended in non-neutropenic patients and may decrease the duration of candidemia.⁷

The standard therapy for many patients with candidemia without prior azole exposure is fluconazole (6 mg/kg per

day).^{8–11} In the first multicenter randomized trial comparing amphotericin B deoxycholate (AmB-d) with fluconazole as treatment for candidemia in non-neutropenic patients, no difference in outcome to therapy was found.⁸ Based on these data and other studies, the recommended duration of therapy is 14 days after documented clearance of *Candida* bloodstream infection together with resolution of signs and symptoms of infection.^{8–15} Recent data suggest that echinocandins are an effective first-line therapy for candidemia; most experts agree that patients who are moderately to severely ill should be treated initially with an echinocandin. Echinocandins are also the agents of choice for patients with prior azole exposure, allergy or intolerance to other antifungals, and those at high risk of infection with *C. glabrata* or *C. krusei*.¹⁵ Current recommended therapy is at least 3–5 days of echinocandin therapy followed by fluconazole as stepdown therapy when the patient is clinically stable and candidemia has cleared. Among the more common species, *C. parapsilosis* has decreased susceptibility to the echinocandins, and initial treatment with fluconazole is recommended.⁴

Amphotericin B (AmB) is also effective for candidemia, but its role as initial therapy is restricted to resource-limited environments, echinocandin or azole intolerance, documented resistance to current therapy, or suspicion of a non-*Candida* yeast (e.g. *Cryptococcus*, *Histoplasma*, *Trichosporon*).

The role for the expanded spectrum triazoles (e.g. voriconazole and posaconazole) is very limited. They lack any clear advantage over conventional therapy with fluconazole, echinocandins or AmB. Currently, their role is limited to treatment of fluconazole-resistant *Candida* spp. which are susceptible to one of these agents (e.g. *C. krusei*).

Breakpoints for *Candida* spp. exist for susceptibility testing to fluconazole, itraconazole, voriconazole, flucytosine (5FC) and the echinocandins.^{16,17} General susceptibility patterns of *Candida* species are detailed in Table 60.2. When there is concern about azole resistance, susceptibility testing should be performed. All *C. glabrata* isolates should ideally be tested for azole susceptibility.

Table 60.1 Treatment of invasive candidiasis

Condition	Primary therapy	Alternative therapy	Comments
Candidemia Non-neutropenic	Fluconazole 800 mg (12 mg/kg) loading dose then 400 mg (6 mg/kg) per day; or an echinocandin	LFAmB 3–5 mg/kg per day; or voriconazole 4 mg/kg every 12 h for 2 doses, then 3 mg/kg per day	Duration of therapy is 14 days from negative blood culture and resolution of clinical signs and symptoms An echinocandin is favored for patients with moderate to severe disease and among patients with risk factors for non- <i>albicans</i> <i>Candida</i> spp.
Neutropenic	LFAmB 3–5 mg/kg per day; or an echinocandin	Voriconazole 4 mg/kg every 12 h for 2 doses, then 3 mg/kg per day; or fluconazole 800 mg (12 mg/kg) loading dose, then 400 mg (6 mg/kg) per day	Duration of therapy is 14 days from negative blood culture, resolution of clinical signs and symptoms, and recovery from neutropenia
Endocarditis	LFAmB 3–6 mg/kg or AmB-d 0.6–1.0 mg/kg per day, ± 5FC 100 mg/kg per day; or an echinocandin	Fluconazole 400–800 mg (6–12 mg/kg) per day for stepdown therapy in stable patients, negative blood cultures and susceptible organisms	Surgical intervention is recommended Duration of induction therapy is 6 weeks, followed by lifelong suppressive therapy For echinocandins, higher than standard dosing is recommended: caspofungin 50–150 mg/day; micafungin 100–150 mg/day; anidulafungin 100–200 mg/day
Meningitis	LFAmB 3–6 mg/kg per day ± 5FC 100 mg/kg per day	Fluconazole 400–800 mg (6–12 mg/kg) per day	Duration of therapy is 4–6 weeks pending clinical improvement and resolution of CSF abnormalities; stepdown therapy with fluconazole 400–800 mg (6–12 mg/kg) per day
Chronic disseminated	LFAmB 3–6 mg/kg or fluconazole 400–800 mg (6–12 mg/kg) per day	An echinocandin	Stepdown fluconazole is appropriate following 1–2 weeks' induction with LFAmB or an echinocandin Antifungal therapy is indicated until radiographic resolution of lesions
Osteomyelitis	LFAmB 3–6 mg/kg or AmB-d 0.6–1.0 mg/kg per day; or fluconazole 6–12 mg/kg per day	An echinocandin	Duration of parenteral therapy is 3–6 weeks, followed by stepdown therapy with oral fluconazole for 6–12 months Surgical intervention may be indicated in selected cases
Endophthalmitis	AmB-d 0.7–1.0 mg/kg plus 5FC 100 mg/kg per day; and/or intravitreal AmB-d 5 µg plus 5FC; or fluconazole 400–800 mg (6–12 mg/kg) per day	LFAmB 3–6 mg/kg; or voriconazole 6 mg/kg every 12 h for 2 doses, then 3–4 mg/kg every 12 h	Duration of parenteral therapy is at least 4–6 weeks Vitrectomy may be necessary for sight preservation
Esophagitis	Fluconazole 200–400 mg (3–6 mg/kg) per day; or AmB-d 0.3–0.7 mg/kg per day; or an echinocandin (see comments)	Itraconazole solution 200 mg/day; or posaconazole 400 mg every 12 h; or voriconazole 200 mg every 12 h	Duration of therapy is 14–21 days Oral agents are preferred; intravenous agents are indicated in the setting of intolerance to oral agents For the echinocandins, the following dosing is recommended: caspofungin 50 mg/day; micafungin 150 mg/day; anidulafungin 200 mg/day

AmB, amphotericin B; AmB-d: amphotericin B deoxycholate; CSF, cerebrospinal fluid; 5FC, flucytosine; LFAmB, lipid formulation of amphotericin B.
 Voriconazole standard dosing: loading dose of 400 mg every 12 h (6 mg/kg every 12 h) for 1 day, followed by a maintenance dose of 200 mg every 12 h (4 mg/kg every 12 h).
 Posaconazole standard dosing: 200 mg every 6 h until stabilization of disease followed by maintenance dose of 400 mg bid.
 Itraconazole standard dosing: loading dose of 200 mg every 8 h for 3 days followed by maintenance dose of 200 mg every 12 h.
 Echinocandin loading dose: Caspofungin 70 mg loading dose, Anidulafungin 200 mg loading dose, Micafungin no loading dose.
 Echinocandin standard dosing: Caspofungin 50 mg/day; Micafungin 100 mg/day; Anidulafungin 100 mg/day.

CANDIDA ENDOCARDITIS

Candida primarily causes prosthetic valve endocarditis, although native valve endocarditis may complicate candidemia, often as a consequence of illicit intravenous drug use. Mortality rates for *Candida* endocarditis are as high as 30%.¹⁸ Both valvular replacement and antifungal therapy are

required for the management of *Candida* endocarditis given the risk of embolism, difficulty in sterilizing blood cultures, and high mortality rate with medical therapy alone.¹⁹

Most of the data pertaining to treatment of *Candida* endocarditis are retrospective. Historically, the most common treatment is AmB-d (0.7–1.0 mg/kg per day), with or without flucytosine (25 mg/kg every 6 h), followed by stepdown therapy with an azole, usually fluconazole (6–12 mg/kg per day). Lipid

<i>C. lusitaniae</i>	S	S	S	S	S	S to R	S

I, intermediate susceptibility; R, resistant; S, susceptible; S-DD, susceptible dose-dependent.

^a*C. parapsilosis* isolates resistant to echinocandins are uncommon.

formulation of amphotericin B (LFAmB) (3–6 mg/kg per day) is less nephrotoxic and generally preferred to AmB-d.^{20,21}

Echinocandins at dosages higher than those used to treat candidemia have been used successfully to treat endocarditis. The suggested dose range for caspofungin is 50–150 mg/day, for micafungin 100–150 mg/day and for anidulafungin 100–200 mg/day. Successful treatment in the absence of vascular surgery with AmB-d–caspofungin induction or caspofungin–fluconazole induction, followed by suppressive therapy with either caspofungin or fluconazole, has been demonstrated in several cases.^{21–26}

Prosthetic valve endocarditis requires chronic suppressive therapy with an azole due to the high risk of relapse. Lifelong suppressive therapy with fluconazole 400–800 mg/day is also recommended in patients who are not surgical candidates.^{24,26}

CANDIDA MENINGITIS

Central nervous system (CNS) *Candida* infections are usually complications of candidemia or neurosurgical procedures in adults.^{27–29} *C. albicans* is the most common cause of *Candida* meningitis. Disseminated candidiasis may be associated with cerebral microabscesses in close proximity to the vasculature and is a particularly common complication in neonates.³⁰

In suspected CNS candidiasis in adults, the preferred first-line therapy is LFAmB. For neonates, AmB-d (1 mg/kg per day) is still generally used due to its proven efficacy and good tolerance. Echinocandins have poor CNS penetration and cannot be recommended.

In the absence of prospective trial data, current treatment regimens, based on retrospective data, support combination therapy with LFAmB (3–6 mg/kg per day) and flucytosine (25 mg/kg every 6 h). Combination therapy is also supported by in-vitro synergy and cerebrospinal fluid (CSF) penetration by flucytosine.³⁰ Liposomal AmB is less nephrotoxic and has greater CNS penetration, and may offer a therapeutic advantage in adults, but this is unproven. Upon evidence of significant clinical improvement after initial treatment with AmB, fluconazole (6–12 mg/kg per day) stepdown therapy

is recommended.^{9,11–13,15} For fluconazole-resistant isolates such as *C. krusei*, *C. guilliermondii* or *C. glabrata*, voriconazole (3 mg/kg every 12 h) is an acceptable alternative, provided susceptibility is confirmed.⁷ Duration of antifungal therapy is poorly defined, but most experts suggest at least 4–6 weeks. Significant improvement in the CSF findings and related symptoms should be demonstrated before considering step-down therapy to an azole.^{2–4,31} In patients with infected ventricular shunts, shunt removal is critical to clear infection. Instillation of AmB directly into the shunt has limited efficacy and is generally discouraged.

HEPATOSPLENIC (CHRONIC DISSEMINATED) CANDIDIASIS

Hepatosplenic candidiasis, also known as chronic disseminated candidiasis, is a distinctive clinical entity appearing during recovery from neutropenia. It is manifested by abdominal pain, hepatomegaly, with or without splenomegaly, and elevated alkaline phosphatase. Involvement of liver, spleen and kidneys is common. Biopsy is required for diagnosis which demonstrates granulomata surrounding yeasts and hyphae; cultures of biopsy material are usually negative. Historically, hepatosplenic candidiasis has been treated with AmB-d, LFAmB and fluconazole.^{32–36} More recently, data have emerged supporting the use of echinocandins and voriconazole.^{30,37,38} Duration of therapy is guided by improvement/resolution of lesions on radiographic imaging. Two weeks of parenteral therapy with LFAmB (3–5 mg/kg per day) or an echinocandin, followed by an oral azole (fluconazole 6 mg/kg per day) is a typical approach to therapy. Months of systemic antifungal therapy are usually required to achieve cure. Evidence of radiographic resolution is important to avoid relapse.

CANDIDA OSTEOMYELITIS

Up to 60% of *Candida* osteomyelitis cases are a consequence of candidemia, with intravenous drug use as the most important predisposing factor.³⁹ *Candida* osteomyelitis can occur as late as

14 months after the initial episode of candidemia.⁴⁰ Treatment recommendations for osteoarticular *Candida* infections are based on small series and case reports. Initial antifungal therapy with an AmB formulation or an echinocandin for 2–3 weeks, followed by surgical debridement and subsequent oral stepdown therapy to an azole is ideal. Success has also been documented with medical therapy with AmB for at least 6 weeks. Regardless of the initial regimen chosen, suppressive therapy with fluconazole (6 mg/kg per day) for 6–12 months should follow.⁴¹

OCULAR CANDIDIASIS

Up to 10% of patients with untreated candidemia develop ocular *Candida* infection, manifested as either chorioretinitis or endophthalmitis. The diagnosis is usually based on clinical findings, but can be confirmed by a positive culture or Gram stain from a vitreous aspirate. In most cases, ophthalmological consideration of partial vitrectomy and intravitreal AmB-d (5 µg) is recommended.³⁰ Conventional therapy is intravenous AmB in combination with flucytosine and/or intravitreal AmB-d. Systemic AmB has poor ocular penetration, combination therapy is usually recommended.^{42–44} Fluconazole (6–12 mg/kg per day) has excellent intravitreal penetration, and can be used as initial treatment in selected cases and for salvage therapy.^{43,45} In cases of fluconazole or AmB-d treatment failure, limited data support the use of treatment with LFAmB (3–6 mg/kg per day) or voriconazole.^{46,47} Voriconazole has excellent vitreal penetration at dosages of 3–4 mg every 12 h; it may also be given topically.⁴⁸ Echinocandins have poor ocular penetration and are generally not recommended for *Candida* endophthalmitis. Duration of therapy is usually 4–6 weeks of systemic therapy until clinical infection has resolved.³⁰

CANDIDA ESOPHAGITIS

Esophageal candidiasis (EC) usually coexists with oropharyngeal disease, although in 30% of cases there are no oral lesions visible. It is an AIDS-defining illness and is common among patients receiving myeloablative chemotherapy. Rare reports of esophageal candidiasis in immunocompetent individuals and after omeprazole therapy suggest that hypochlorhydria favors development of disease.

The majority of cases of oropharyngeal candidiasis are due to *C. albicans*; however, cases of *C. glabrata* and *C. krusei* are reported.^{49–51} All cases of suspected or proven EC should be treated with systemic antifungals. In patients with suspected esophageal disease, empirical therapy with fluconazole 200–400 mg/day is a reasonable initial approach. Itraconazole solution (200 mg/day), posaconazole suspension (400 mg every 12 h) or voriconazole (200 mg every 12 h) can be used to treat fluconazole-refractory disease. Duration of therapy is 14–21 days. Intolerance to oral therapy or inability to swallow warrants treatment with intravenous fluconazole (400 mg/day), AmB-d (0.3–0.7 mg/kg per day) or an echinocandin.

ASPERGILLOYSIS

Aspergillus species are important invasive fungal pathogens, causing considerable morbidity and mortality in immunocompromised hosts. They also cause chronic, saprophytic and allergic conditions in immunocompetent patients. *Aspergillus* species grow well on standard media; identification to species level is usually recommended. Pathology specimens reveal the characteristic angular dichotomously branching septate hyphae by direct microscopy or culture.⁵² Diagnosis is based on a combination of culture, histopathology, radiographical imaging and serological studies. The use of serum enzyme immunoassay for galactomannan has remarkably enhanced the early diagnosis of invasive aspergillosis; its use in CSF and bronchoalveolar lavage (BAL) fluid remains investigational, as does the use of serial galactomannan for therapeutic monitoring.^{53,54}

INVASIVE ASPERGILLOYSIS

Invasive aspergillosis typically affects patients who are significantly immunocompromised. Untreated mortality approaches 100%.⁵⁵ Those at risk of invasive aspergillosis include patients with advanced HIV infection, prolonged neutropenia, allogeneic hematopoietic stem cell transplantation (HSCT) and inherited immunodeficiency.⁵² Outcome depends in part on the potential for immune recovery, stage of disease when treatment is initiated and the rate of disease progression. Prompt initiation of antifungal therapy is important in highly immunocompromised patients. Thus, empirical therapy is appropriate for suspected disease in these patients. In contrast, in less immunocompromised patients, disease progression is often slower, allowing the diagnosis to be confirmed before treatment is given. Specific recommendations regarding therapy are detailed in Table 60.3.

In the USA, voriconazole and AmB-d are the only compounds licensed for the primary treatment of invasive aspergillosis, while LFAmB, itraconazole (200 mg tablets every 12 h) and caspofungin (50 mg/day) are approved for salvage therapy. Primary therapy with parenteral or oral voriconazole (4 mg/kg every 12 h) is recommended for the treatment of most forms of invasive aspergillosis. In the largest prospective, randomized trial for invasive pulmonary aspergillosis, voriconazole was superior to AmB-d (1.0–1.5 mg/kg per day) and other licensed antifungal therapy with significantly improved survival (53% vs 32%) and successful response at 12 weeks and at the end of the study period.⁵⁶ Parenteral voriconazole is recommended for seriously ill patients and those unable to tolerate oral medications. In the event of drug intolerance or disease progression, LFAmB is an acceptable alternative, and is preferable to AmB-d.^{57–60} Optimal dosing of LFAmB for invasive aspergillosis is unclear. Many experts prescribe an initial dose of 5–6 mg/kg per day, although a recent randomized trial comparing two initial doses of LFAmB (3 mg/kg

Table 60.3 Treatment for aspergillosis

Condition	Primary therapy	Alternative therapy	Comments
Invasive aspergillosis	Voriconazole ^a	LFAMB 5–6 mg/kg per day or caspofungin 70 mg loading dose, 50 mg/day maintenance dose or posaconazole ^b or itraconazole ^c	Duration of therapy not defined Recommend treatment until resolution of symptoms and radiographic changes Initial monotherapy with voriconazole is preferred Alternative therapy with combination therapy or change in class is recommended in setting of treatment failure
Chronic necrotizing pulmonary aspergillosis	Voriconazole ^a or itraconazole ^c	LFAMB 5–6 mg/kg/day or caspofungin 70 mg loading dose, 50 mg/day maintenance dose or posaconazole ^b	Oral azole therapy is preferred Chronic azole suppressive therapy is required for months
Aspergilloma	Antifungal therapy is of minimal benefit. Surgical evaluation is recommended	Itraconazole ^c or voriconazole ^a	Oral ketoconazole and parenteral AmB are ineffective

^aVoriconazole standard dosing: loading dose of 400 mg every 12 h (6 mg/kg every 12 h) for 1 day, followed by a maintenance dose of 200 mg every 12 h (4 mg/kg every 12 h).
^bPosaconazole standard dosing: 200 mg every 6 h until stabilization of disease followed by maintenance dose of 400 mg bid.
^cItraconazole standard dosing: loading dose of 200 mg every 8 h for 3 days followed by maintenance dose of 200 mg every 12 h.

per day vs 10 mg/kg per day) showed similar efficacy (50% vs 46% success, respectively).⁶¹

Primary combination therapy remains investigational but may be useful in the context of salvage therapy. For salvage therapy, a change in therapeutic class is recommended using LFAMB or an echinocandin. Azole use as combination therapy should take into account prior therapy, host factors and pharmacokinetic considerations. Optional agents include LFAMB, posaconazole (200 mg every 6 h, followed by 400 mg every 12 h with stable disease), itraconazole (200 mg tablets every 12 h) and caspofungin (50 mg/day).⁵² In one salvage study, caspofungin therapy was 40% successful, with less than 5% of patients experiencing drug-related nephrotoxicity or hepatotoxicity.⁶² Oral itraconazole has had similar results (39%), but is a less attractive alternative and is rarely used in this setting.^{63,64} Posaconazole is approved as salvage therapy in Europe for patients refractory to AmB or itraconazole. In an open-labeled salvage trial, 42% of posaconazole recipients vs 26% of control patients were successfully treated.⁶⁵

The management of breakthrough invasive aspergillosis during azole prophylaxis or suppressive therapy has not been defined by clinical trial data, but changing drug class from the azoles is suggested. Medical management should always include reversal of the underlying condition, when feasible. Surgical resection of lesions contiguous with the great vessels or pericardium, those associated with hemoptysis, or lesions eroding into the pleural space or ribs is recommended.⁵²

Resistance to itraconazole and the expanded-spectrum azoles is infrequent among *Aspergillus* spp. With the exception of *A. terreus*, few *Aspergillus* isolates demonstrate in-vitro resistance to AmB. Based on clinical experience and in-vitro data, primary treatment of *A. terreus* infection should involve the use of an expanded spectrum triazole.⁶⁶

Persistent neutropenia is often associated with a fatal outcome in invasive aspergillosis. In these patients granulocyte-colony stimulating factor or granulocyte macrophage-colony stimulating factor may be used to reverse immunosuppression, although the benefit is unproven. Case reports also suggest a potential role for the use of interferon- γ as adjunctive therapy for invasive aspergillosis in immunocompromised non-neutropenic patients, particularly those with chronic granulomatous disease.

Treatment of invasive aspergillosis should continue while the patient is immunocompromised and until there has been resolution of disease. In the neutropenic patient, treatment should continue until the neutrophil count recovers and there has been radiographic disease regression. In solid organ transplant recipients, therapy should be continued until there is a complete or near-complete clinical response.

CHRONIC NECROTIZING ASPERGILLOSIS

Chronic necrotizing pulmonary aspergillosis (CNPA) is a complex condition sharing features of invasive aspergillosis and pulmonary aspergillomata. CNPA is more common among patients with underlying lung disease or low-grade immunosuppression. It usually is not life threatening with appropriate treatment. All patients with CNPA have radiological evidence of one or more cavitary lesions in the lung, usually in the upper lobe. The cavities may contain aspergillomata. Serology is often positive for *Aspergillus* galactomannan and inflammatory markers are elevated. CNPA requires systemic antifungal therapy.^{67,68}

Itraconazole (200 mg capsules every 12 h) and voriconazole (4 mg/kg intravenously every 12 h, or 200 mg orally every 12 h) appear to be the agents of choice for CNPA.^{69,70}

Other options include intracavitary AmB and voriconazole.^{71,72} Oral therapy of CNPA is generally preferred. Chronic suppressive therapy with an azole is essential to prevent relapse.

Surgery should be avoided if possible, as complications are common, including fungal empyema and significant intra- or postoperative bleeding. Embolization of involved vasculature may be preferable to surgery for hemoptysis.

ASPERGILLOMA

The vast majority of pulmonary fungus balls are due to *Aspergillus* spp., with rare cases due to *Scedosporium apiospermum* or the zygomycetes. A pulmonary aspergilloma is composed of *Aspergillus* hyphae, fibrin and mucus, consolidated within a pre-existing pulmonary cavity or ectatic bronchus.⁷³ Radiographically these can appear solid or as water density within a cavity but clearly demarcated from the wall of the cavity. Adjacent pleural thickening is common. Aspergillomata most commonly occur in patients with underlying lung disease such as cavitary tuberculosis or histoplasmosis, sarcoidosis, emphysema or fibrotic lung disease.

Approximately 10% of aspergillomata resolve spontaneously. Medical therapy is of limited benefit for the treatment of aspergillomata. Itraconazole (200 mg every 12 h) is of marginal symptomatic and little radiological benefit.⁷⁴

Hemoptysis is the main indication for surgical intervention.⁷⁵ In non-surgical candidate patients with recurrent hemoptysis, bronchial artery embolization may be used as a temporizing measure until medical therapy or surgical resection can occur. Endobronchial or intracavitary instillation of the aspergilloma with AmB has been used with some success.⁵² There are few published data for voriconazole, but many experts agree that this is a reasonable option for many patients with acute or intermittent hemoptysis due to aspergillomata.

MUCORMYCOSIS (ZYGOMYCOSIS)

Most human causes of zygomycosis belong to the genera *Rhizopus*, *Mucor*, *Rhizomucor*, *Cunninghamella* and *Absidia*. These organisms are found in soil and dust and infection is usually acquired by inhalation of the spores. Zygomycetes have a predilection to cause invasive sinusitis, cutaneous, pulmonary or disseminated infection in immunocompromised hosts such as diabetics and allogeneic stem cell transplant recipients. The clinical diagnosis can be difficult to distinguish from invasive aspergillosis. In a recent review of 929 cases of zygomycosis, rhinocerebral zygomycosis was more closely associated with diabetes, whereas pulmonary

infection was more closely associated with malignancy.⁷⁶ Diagnosis is suggested histologically based on the presence of non-septate, broad-based hyphal structures with 90° branching.⁷⁷ Routinely obtained cultures of infected tissue are often negative.⁷⁸

The drug of choice for zygomycosis is AmB. AmB-d (1.0–1.5 mg/kg per day) has been the cornerstone of therapy for decades. LFAmB is efficacious in doses of 5–10 mg/kg per day. Posaconazole, a newer triazole administered as an oral suspension, is an alternative drug for zygomycosis, but is not approved for primary therapy.^{79,80} Posaconazole (400 mg every 12 h) has demonstrated success as salvage therapy after failure of AmB, with treatment success rates of 60% at 12 weeks of therapy.^{80,81} Combination antifungal therapy with LFAmB and posaconazole or caspofungin has proven effective in several reports.⁸² A recent retrospective analysis of rhino-orbital-cerebral mucormycosis in non-neutropenic patients demonstrated greater success with combination therapy of AmB plus caspofungin (50 mg/day) versus AmB monotherapy.⁸³ Antifungal therapy versus combination antifungal therapy plus surgical intervention has led to survival rates of 61–69% versus 70%, respectively.⁷⁶

Deferasirox, a non-desferrioxamine iron-chelating agent with in-vitro activity against many zygomycetes, is being examined as a potential adjunctive agent in combination with more traditional antifungal agents. Prompt correction of the underlying disorder is necessary for optimal management of zygomycosis, i.e. control of hyperglycemia, neutropenia or modulation of immunosuppressive therapy.

ENDEMIC MYCOSES AND CRYPTOCOCCUS

CRYPTOCOCCOSIS

Human cryptococcal infections due to *C. neoformans* and *C. gattii* have increased in prevalence in immunocompromised hosts, with mortality rates of 10–25% in non-HIV patients.⁸⁴ *C. neoformans* is found ubiquitously in the soil and is frequently associated with birds, particularly pigeons and chickens. *C. gattii* is often associated with river red gum and forest red gum trees. Inhalation is the principal portal of entry. Although the organism is widely distributed, infection is uncommon in normal hosts. Immunosuppressed patients are at greatest risk of complicated infections. Diagnosis is made on the basis of culture, or microscopically by India-ink preparation. Histopathological findings demonstrate budding yeasts staining positive for capsular material (mucicarmine stain). Measurement of cryptococcal antigen (CrAg) in serum and CSF has become a standard for non-culture-based diagnosis among the deep mycoses, and its presence is considered indicative of invasive disease.

CRYPTOCOCCAL PNEUMONIA

The presentation of pulmonary cryptococcosis is dependent on the host's immune status, and ranges from asymptomatic infection to life-threatening acute respiratory distress syndrome (ARDS).⁸⁵ All immunocompromised and/or symptomatic patients with pulmonary disease require systemic therapy. However, the optimal antifungal therapy and its duration have yet to be clearly delineated. Recommendations regarding therapy are detailed in Table 60.4.

Asymptomatic immunocompetent patients with culture-proven disease, or those with mild-to-moderate pulmonary disease, should be treated with fluconazole (400 mg/day) for 3–6 months.^{86–88} In a retrospective analysis of non-CNS cryptococcal disease in HIV-negative patients, fluconazole was found to have similar efficacy compared to AmB-d (0.5–1.0 mg/kg per day). Itraconazole (200 mg every 12 h) for 6–12 months is an acceptable alternative.⁸⁹ AmB can be used with progressive pulmonary involvement or azole intolerance.⁸⁵ Immunocompromised patients with moderate-to-severe pulmonary disease should undergo a 2-week course of induction with AmB (0.5–1.0 mg/kg per day) or LFAmB (3–6 mg/kg per day) plus flucytosine (25 mg/kg every 6 h) followed by consolidation with oral fluconazole (400–800 mg/day) for a minimum of 10 weeks. Between 6 and 12 months of suppressive therapy with fluconazole (200 mg/day) is recommended. Alternative therapy with AmB-d plus flucytosine in combination for a minimum of 6–10 weeks is less efficacious.^{85,87} Lumbar puncture should be considered in all patients with

cryptococcal pulmonary disease, regardless of symptoms or underlying disease. Only asymptomatic, non-immunocompromised patients with negative or low-titer serum CrAg can be safely excluded from undergoing lumbar puncture.

CNS CRYPTOCOCCAL DISEASE IN NON-HIV PATIENTS

Meningitis is the most common manifestation of cryptococcal CNS disease. CNS cryptococcosis are much less common and are more frequently associated with *C. gattii* infections.

Recommended therapy for immunocompetent patients is combination therapy for at least 4 weeks of AmB-d (0.7–1.0 mg/kg per day) plus flucytosine (25 mg/kg every 6 h).^{86,90} An alternative regimen based on supporting data in HIV-infected patients is induction with AmB-d (0.7–1.0 mg/kg per day) plus flucytosine (25 mg/kg every 6 h) for 2 weeks, followed by consolidation with oral fluconazole (400–800 mg/day) for at least 10 weeks. The addition of flucytosine and fluconazole to consolidation therapy are each independently associated with CSF sterilization.^{88,91,92} Monitoring of CSF pressure and sterilization of CSF after 2 weeks is recommended.

Current treatment guidelines for normal and non-HIV immunosuppressed patients are extrapolated from the experiences of CNS cryptococcosis in HIV patients. Recommended treatment is induction with combination AmB-d (0.7–1.0 mg/kg per day) plus flucytosine (25 mg/kg every 6 h) for 2 weeks, followed by consolidation with oral fluconazole

Table 60.4 Treatment of cryptococcosis

Condition	Primary therapy	Alternative therapy	Comments
Pneumonia Non-immunocompromised	Fluconazole 400 mg (6 mg/kg per day)	Itraconazole 400 mg/day; or LFAmB 3–6 mg/kg or AmB-d 0.5–1.0 mg/kg per day ± 5FC 100 mg/kg for 6 weeks	Duration of therapy is 6 months. LFAmB is indicated for moderate to severe disease or azole intolerance
Immunocompromised	LFAmB 3–6 mg/kg or AmB 0.5–1.0 mg/kg per day, ± 5FC 100 mg/kg induction; fluconazole 400–800 mg/day consolidation		Duration of parenteral therapy is 2 weeks. Consolidation with oral fluconazole 400 mg/day for 10 weeks is recommended, followed by suppressive fluconazole 200 mg/day for 6–12 months
Meningoencephalitis, non-immunocompromised	LFAmB 3–6 mg/kg or AmB-d 0.7–1.0 mg/kg per day, ± 5FC 100 mg/kg per day for 4–6 weeks	LFAmB 3–6 mg/kg or AmB 0.7–1.0 mg/kg per day, ± 5FC 100 mg/kg per day for 2 weeks, then fluconazole 400 mg/day for 8 weeks	All patients should receive suppressive fluconazole 200–400 mg/day for 6 months following induction/consolidation
Transplant recipient	LFAmB 3–6 mg/kg plus 5FC 100 mg/kg per day for 2 weeks, then fluconazole 400–800 mg/day for 8 weeks	LFAmB 3–6 mg/kg per day for 4–6 weeks, then fluconazole 400–800 mg/day for 8 weeks	Chronic suppressive therapy with fluconazole 200 mg/day for 6–12 months is recommended
HIV-positive	LFAmB 3–6 mg/kg or AmB 0.7–1.0 mg/kg ± 5FC 100 mg/kg per day for 2 weeks, then fluconazole 400 mg/day for 8 weeks	LFAmB 3–6 mg/kg per day for 4–6 weeks, then fluconazole 400 mg/day for 8 weeks; itraconazole 200 mg every 12 h is an alternative oral azole	Maintenance therapy with fluconazole 200 mg/day is recommended in AIDS patients; itraconazole 400 mg/day is an alternative suppressive regimen

AmB, amphotericin B; AmB-d, amphotericin B deoxycholate; 5FC, flucytosine; LFAmB, lipid formulation amphotericin B.

(400–800 mg/day) for a minimum of 10 weeks; suppression with fluconazole (200 mg/day) for 6–12 months is recommended.^{85,88,91,92} This regimen is preferred to the combination regimen of AmB-d/flucytosine for 6 weeks.^{86,91} Rarely, salvage therapy involves intrathecal and/or intraventricular administration of AmB. AmB-d can be replaced with LFAmB, 3–6 mg/kg per day, during induction.⁹³ Itraconazole (200 mg every 12 h) may be substituted for fluconazole if necessary, but may be associated with a higher relapse rate than fluconazole.⁹¹

Aggressive management of increased intracranial pressure is critical to a successful outcome in most patients with CNS cryptococcosis. Frequent lumbar punctures, sometimes daily, may be required for days or weeks until the opening pressure is consistently less than 250 mm/H₂O. The decision to place a drainage device (lumbar drain, ventriculostomy, ventriculoperitoneal shunt) is based on clinical considerations and patient preference.

CRYPTOCOCCOSIS IN HIV-INFECTED PATIENTS

All HIV-positive patients with suspected cryptococcal infection warrant evaluation with a serum CrAg and fungal blood cultures. Those with a CD4 count <200 cells/mm³ and concurrent pneumonia also warrant sputum culture. Cryptococcal pneumonia should be treated regardless of symptoms to prevent dissemination of cryptococcal disease.⁸⁵

Evaluation for cryptococcal meningitis in HIV-infected patients includes brain imaging and CSF CrAg titers, as well as CSF fungal culture with documentation of the opening pressure. In cryptococcal meningitis cases, 99% of serum CrAg will be positive.^{85,91,92} Randomized trial data demonstrate faster CSF sterilization and decreased mortality rates with combination therapy of AmB-d (0.7–1.0 mg/kg per day) or LFAmB (3–6 mg/kg per day) plus flucytosine (100–150 mg/kg divided into four doses daily) compared to monotherapy with AmB.^{91,94} Induction for a 2-week minimum is followed by consolidation with oral fluconazole (400 mg/day).^{89,91,92,94,95} Other treatment options include fluconazole (400–800 mg/day) and flucytosine (100–150 mg/kg divided into four doses daily) for 6 weeks.⁹⁶ If salvage therapy is required, intrathecal or intraventricular AmB may be used.

Upon treatment for cryptococcal meningitis, patients with AIDS require maintenance therapy with antiretroviral therapy (ARV) and fluconazole (200 mg/day) to prevent relapse. Fluconazole is recommended for maintenance therapy of AIDS-associated cryptococcal meningitis as it is superior to AmB-d in this setting (relapse rates of 2% vs 17%, respectively).⁹⁷

Fluconazole also demonstrated superiority to itraconazole for maintenance therapy (relapse rates of 4% and 24%, respectively).⁹⁸ Itraconazole (200 mg every 12 h) may be used as an alternative to fluconazole therapy when necessary in the treatment of both pulmonary and CNS cryptococcal infection. Chronic suppressive antifungal therapy can be

discontinued once there is clinical control of disease, CSF cultures are negative, and the CD4 count is consistently >150 cells/mm³.

HISTOPLASMOSIS

Histoplasmosis due to *Histoplasma capsulatum* occurs in most regions of the world, but is most common in Midwestern and South Central USA. It is also highly endemic in parts of Central and South America. The organism is found in soil enriched by bat and bird droppings. Inhalation is the primary portal of entry. Disease manifestations are dependent on the host immune status and the intensity of the exposure.⁹⁹ Diagnosis is based on a combination of culture, histopathology and serological studies, of which culture is the gold standard. Histology reveals granulomata with small intracellular oval yeast forms with eccentric nuclei. Intracellular budding yeast cells are best visualized with a methenamine silver stain. Antigen assays performed on urine and blood specimens have a sensitivity of 90% and 70%, respectively. Cross-reactivity can occur in urine *Histoplasma* antigen assays with blastomycosis, coccidioidomycosis, paracoccidioidomycosis and, less commonly, penicilliosis.¹⁰⁰

ACUTE PULMONARY HISTOPLASMOSIS

Presentation of acute exposure can range from asymptomatic infection to severe pulmonary pneumonitis with respiratory distress. Complications, although uncommon, include mediastinal lymphadenopathy, chronic cavitary histoplasmosis and fibrosing mediastinitis.¹⁰¹ Other sequelae include persistent cough and focal inflammatory manifestations. Table 60.5 details treatment recommendations.

Acute pulmonary histoplasmosis usually resolves spontaneously within 1 month and does not require therapy. Persistent symptoms for more than 1 month may be indicative of complicated disease, signifying a need for therapy. Such patients should be treated with itraconazole (200 mg once or twice daily) for 6–12 weeks.¹⁰²

Moderate-to-severe acute pulmonary histoplasmosis is treated with LFAmB (3–5 mg/kg per day) for 2 weeks, followed by stepdown therapy with itraconazole (200 mg every 12 h) for a total of 12 weeks.¹⁰⁰ AmB-d (0.7–1.0 mg/kg per day) can be substituted for LFAmB. Methylprednisolone (0.5–1 mg/kg per day) is recommended for concurrent hypoxemia and respiratory distress.¹⁰³ Duration of therapy has not been clearly defined, but treatment should continue until resolution of infiltrates on chest radiograph.⁹⁹

COMPLICATIONS FROM ACUTE PULMONARY HISTOPLASMOSIS

Complications of pulmonary histoplasmosis include histoplasomas, mediastinal granulomas, mediastinal fibrosis, and

Table 60.5 Treatment of histoplasmosis

Condition	Primary therapy	Alternative therapy	Comments
Acute pulmonary			
Mild	Symptoms <4 weeks do not warrant therapy Symptoms >4 weeks: itraconazole 200 mg every 12 h		Duration of therapy is 6–12 weeks
Moderate to severe	LFAmB 3–5 mg/kg per day; itraconazole 200 mg every 12 h	AmB-d 0.7–1.0 mg/kg per day	Duration of parenteral therapy is 2 weeks; itraconazole stepdown therapy for a 12-week duration Concomitant methylprednisolone is recommended for 2 weeks in the setting of hypoxemia
Chronic cavitary pneumonia	Itraconazole 200 mg every 12 h	AmB 0.7–1.0 mg/kg per day for induction (1–2 weeks), then itraconazole 200 mg every 12 h	Duration of therapy is 12–24 months
Disseminated	LFAmB 3-mg/kg per day	Itraconazole 200 mg every 12 h	Therapy for at least 12 months. For milder disease, initial itraconazole is acceptable. For more severe disseminated histoplasmosis, AmB is preferred for induction, followed by stepdown therapy to itraconazole Duration of parenteral of therapy is 2–6 weeks
Meningoencephalitis	LFAmB 5–6 mg/kg per day; or itraconazole 200 mg every 12 h		Duration of parenteral of therapy is 4–6 weeks; itraconazole stepdown therapy is for a minimum of 12 months

AmB, amphotericin B; AmB-d, amphotericin B deoxycholate; LFAmB, lipid formulation amphotericin B.

mediastinal lymphadenitis, pericarditis and erythema nodosum. Most complications do not warrant antifungal therapy, only management of the complication itself. Associated inflammatory reactions should be treated with anti-inflammatory medications, including, but not limited to, steroids.^{99,104}

CHRONIC PULMONARY HISTOPLASMOSIS

Chronic pulmonary histoplasmosis usually occurs in the setting of underlying baseline lung disease, often presenting radiographically as chronic cavitary lesions with surrounding inflammation.^{101,102,105} Itraconazole (200 mg every 12 h) is recommended as first-line therapy for 12–24 months to avoid relapse. Duration of therapy is based on resolution of lesions on radiographic imaging, which should be performed every 4–6 months. As antigen tests are often negative in chronic cavitary histoplasmosis, serial antigen testing is not recommended.⁹⁹

DISSEMINATED HISTOPLASMOSIS (DH)

Hematogenous spread of acute infection, occurring within the first few weeks of infection, is a consequence of defective cell-mediated immunity. Disseminated histoplasmosis can present with symptoms of pancytopenia, skin lesions, mucosal ulcers, hepatosplenomegaly and gastrointestinal disease. Symptoms are usually present for at least 3 weeks and are associated with radiographic and laboratory findings.⁹⁹ Antigen levels should be monitored during and 12 months after therapy to observe for relapse.

DH IN HIV-NEGATIVE PATIENTS

Progressive disseminated histoplasmosis should be treated with either itraconazole (200 mg every 12 h) or LFAmB (3–5 mg/kg per day). Response rates of 80–100% have been documented for the treatment of mild-to-moderate disease with oral itraconazole, with relapse rates of 10–15%. Recommended duration of therapy is for at least 12 months.^{102,106} Moderate to severe disease should be treated with LFAmB (3–5 mg/kg per day) or amphotericin B lipid complex (ABLC) (5 mg/kg per day) for 2 weeks, followed by stepdown therapy with itraconazole (200 mg every 12 h) for at least 12 months. Immunosuppressed patients should receive itraconazole (200 mg/day) suppressive therapy until reversal of the immunological disorder. Duration of therapy is based on resolution of symptoms, radiographic and laboratory abnormalities.⁹⁹

DH IN PATIENTS WITH AIDS

Higher success rates and lower mortality have been demonstrated with LFAmB (3–5 mg/kg per day) versus AmB-d (0.7–1.0 mg/kg per day) for 1–2 weeks as induction therapy for DH in patients with AIDS (2% vs 13%, respectively). Following induction with LFAmB, stepdown therapy with oral itraconazole (200 mg every 12 h) is recommended for 12 months.¹⁰⁷ Long-term response rates are higher in ARV recipients compared with non-recipients (100% vs 47%).^{108,109}

Before stopping chronic suppressive antifungal therapy, immune function (CD4 count >150 cells/mm³) improvement

associated with ARV therapy should be documented; blood cultures and urine *Histoplasma* antigen should be negative.¹¹⁰ If the CD4 counts drop below 150 cells/mm³, then suppressive (Itraconazole 200 mg/day) therapy should be restarted.⁹⁹

DH IN NEONATES

Neonatal DH is a severe complication and is often accompanied by meningitis. It reflects an immature and underdeveloped cellular immune system. Untreated disease is rapidly fatal. AmB-d (1 mg/kg per day) is recommended for a 4-week induction course. LFAmB (3–5 mg/kg per day) may be substituted as necessary. Alternative therapy includes shorter duration of AmB-d completed with a course of azole therapy. These recommendations apply for infants with concurrent CNS involvement. Itraconazole (10 mg/kg per day) is favored over ketoconazole for stepdown therapy, although duration of antifungal therapy in neonates is unclear; most experts advise at least 12 months' therapy.

CNS HISTOPLASMOSIS

CNS histoplasmosis occurs in 5–10% of cases of disseminated disease, with neurological symptoms occurring in 25%, and is the most challenging complication to treat. Of the LFAmBs, liposomal AmB achieves the greatest concentration in brain tissue.¹¹¹ Recent experience has demonstrated greater efficacy with higher doses of LFAmB (5 mg/kg per day) for 4–6 weeks, followed by suppressive therapy with itraconazole stepdown therapy.¹¹² Compared to fluconazole (200–400 mg/day), itraconazole has greater efficacy in the treatment of CNS histoplasmosis in animal studies. Stepdown itraconazole therapy (200 mg every 12 h) is recommended for at least 1 year and until there is no clinical/laboratory evidence of active CNS infection and urine *Histoplasma* antigen titers are consistently negative.¹¹³

COCCIDIOIDOMYCOSIS

Coccidioides immitis (endemic to California) and *C. posadasii* (found in all other endemic areas) cause symptomatic infection usually within 1–3 weeks after inhalation of aerosolized arthroconidia. *Coccidioides* species, endemic in the southwestern United States and parts of Central and South America, cause acute and reactivation infections in persons living in an endemic area, in travelers, and especially among immunosuppressed persons.^{114,115}

Acute symptoms, when present, include an influenza-like illness or acute/subacute pneumonia. Most cases are self-limited, resolving spontaneously. Pulmonary sequelae such as pulmonary nodules or cavitary pneumonia arise in 5–10% of cases. There is a strong propensity for extrapulmonary involvement among persons of African or Filipino descent,

pregnant women and immunosuppressed patients (30–50% of cases).^{116–118} Diagnosis is confirmed by sputum culture or positive anticoccidioidal antibodies in serum via complement fixation.^{119–121}

PRIMARY COCCIDIOMYCOSIS (VALLEY FEVER)

Most healthy patients with acute coccidioidomycosis do not require therapy. All immunosuppressed patients, including diabetics, those with poor pulmonary reserve, or women with newly diagnosed disease in the third trimester of pregnancy/postpartum period should receive treatment.¹²¹

Oral azole therapy with ketoconazole (400 mg/day), fluconazole (400–800 mg/day) or itraconazole (200 mg every 8–12 h) for 3–6 months is recommended for acute coccidioidal pneumonia. Patients should be monitored clinically, radiographically and serologically every 3 months for at least 1 year.

Miliary infiltrates or bilateral reticulonodular disease is more common in immunocompromised hosts and those exposed to a large inoculum of spores. In the setting of hypoxia, AmB-d (0.5–1.5 mg/kg per day) or LFAmB (3.0–5.0 mg/kg per day) is indicated until improvement in symptoms and stable radiographic imaging. Subsequent stepdown therapy with ketoconazole (400 mg/day), fluconazole (400–800 mg/day) or itraconazole (200 mg every 8–12 h) can be given for at least 12 months. Fungemia and extrapulmonary involvement should be excluded.¹²²

CHRONIC PULMONARY COCCIDIOMYCOSIS

Chronic coccidioidomycosis occurs in fewer than 10% of cases and is restricted to the lung in 50–70% of cases. Manifestations include asymptomatic nodules, small thin-walled and large thick-walled cavities, progressive destruction and consolidation. Close monitoring for progressive enlargement or pleural involvement is recommended in asymptomatic cases. A positive sputum culture does not always justify therapy, depending on the radiographic status. Surgical evaluation of lesions present for more than 2 years is recommended to minimize the risk of future complications.

Chronic infections often result in persistent cough with serological evidence of coccidioidomycosis. Chronic pulmonary coccidioidomycosis should be treated with ketoconazole (400 mg/day), fluconazole (400–800 mg/day) or itraconazole (200 mg every 8–12 h). Minimal duration of therapy is 12 months, with close monitoring every 3 months. Recurrence of symptoms may occur with cessation of azole therapy. Those patients with a negative coccidioidin skin test during therapy and a peak complement fixation titer of ≥ 256 have very high relapse potential, regardless of the therapy.¹²³ In the presence of clinical and/or radiographic disease progression,

it is recommended to change azoles or commence AmB-d (0.5–1.5 mg/kg per day). In cases of recurrent pulmonary coccidioidomycosis, surgical resection may be beneficial.¹²²

DISSEMINATED COCCIDIODOMYCOSIS

Disseminated coccidioidomycosis, involving lymphoreticular, cutaneous, CNS and osteoarticular sites, often responds better to antifungal therapy than pulmonary infection. Initial therapy with oral itraconazole (200 mg every 12h) or fluconazole (400 mg/day) is recommended. If necessary, dosing of itraconazole and fluconazole can be increased to 200 mg every 6 h and 2000 mg/day, respectively. Duration of therapy has not been clearly defined but treatment for months to years has a 90% response rate.¹²⁴ Itraconazole has greater efficacy in the treatment of skeletal lesions than fluconazole.¹²⁵ Alternative therapy with AmB-d (0.5–1.5 mg/kg per day) or LFAmB (3–5 mg/kg per day) is recommended for vertebral lesions or rapidly progressive disease. Although combination AmB-d and azole therapy is widely used to treat severe, progressive disease, there are no data that demonstrate superiority over single-agent therapy. Surgical debridement of abscesses or stabilization of spinal instability may be necessary if the response to antifungal therapy alone is poor.^{122,126–129}

COCCIDIODIAL MENINGITIS

Coccidioidal meningitis is a progressive lymphocytic meningitis with a 100% mortality when untreated. The clinical course may be indolent over months, or more rapid and fatal within weeks. Fluconazole is the preferred treatment of coccidioidal meningitis, but itraconazole can be used successfully. For fluconazole, initial daily doses of 800–1000 mg, followed by 400 mg/day is recommended. For itraconazole, 400–600 mg/day is recommended, followed by 400 mg/day. For most patients, lifelong suppression with fluconazole (200 mg/day) or itraconazole (200 mg every 12 h) is required. Chronic suppression with fluconazole is successful in approximately 80% of patients at 3 years.¹²⁹

Recent experience with posaconazole is encouraging. Although not approved for this indication, the response of non-CNS coccidioidomycosis is impressive and deserves more detailed investigation. There is far less experience with voriconazole for coccidioidomycosis.

Recommendations for salvage therapy are based upon independent case reports. Intrathecal AmB-d is rarely administered for CNS coccidioidomycosis, being reserved for azole and intravenous AmB refractory disease. AmB (0.1–1.5 mg per dose) is prepared in 5 mL of 5% dextrose and is administered over 3–5 min. The patient should remain in the head-down position for 2 h after administration. The AmB-d dose can be escalated by 0.05 mg/day to a maximum of 1.5 mg.^{122,130} Doses are usually administered 1–3 times weekly. Intrathecal hydrocortisone, 25 mg, can be given to ameliorate adverse

effects. The response to therapy is based on the CSF findings and antibody titers.

COCCIDIODOMYCOSIS IN IMMUNOCOMPROMISED PATIENTS

Solid organ transplantation recipients in endemic areas have up to a 9% risk of coccidioidomycosis within 1 year after transplantation.^{122,131} Fluconazole and ketoconazole doses of 100–200 mg and 200–400 mg/day have been used for primary and secondary prophylaxis, respectively. The risk of dissemination and associated complications following active disease warrants lifelong therapy in these patients.^{132,133}

All HIV-positive patients with active coccidioidomycosis and CD4 counts <250 cell/mm³ require antifungal treatment. Recommendations are based on demonstrated success using AmB-d (0.5–1.5 mg/kg per day) followed by stepdown therapy with fluconazole (400–800 mg/day) or itraconazole (200 mg every 8–12 h). Alternatively, combination AmB-d plus an azole may be used. Therapy is recommended until infection is controlled and a CD4 count of >250 cell/mm³ is achieved in response to ARV.^{134,135}

BLASTOMYCOSIS

Infection with the dimorphic fungus *Blastomyces dermatitidis* ranges from asymptomatic infection to pulmonary disease and disseminated disease. Blastomycosis occurs in Midwestern and South Central USA, central and eastern Canadian provinces, and parts of Africa. Primary infection results from inhalation of the conidia. Most infections are asymptomatic. Among clinically apparent infections, 60% are limited to the lungs and 40% involve extrapulmonary sites, particularly skin/subcutaneous tissues, osteoarticular, genitourinary and/or CNS sites.¹³⁶ Risk factors for infection include activities along streams, excavation of soil enriched with decaying vegetation/wood, hunting and fishing, and outdoor occupation.¹³⁷

Diagnosis is made by culture, histopathology, or by urine or blood antigen detection assays. Pulmonary cases are culture positive from respiratory samples in 86–100% of cases. Typical broad-based budding yeasts can be readily visualized in histological specimens.^{138,139} The *Blastomyces* antigen assay cross-reacts with other fungi, particularly *H. capsulatum*.¹⁴⁰

PULMONARY BLASTOMYCOSIS

Pulmonary blastomycosis infection varies from asymptomatic to chronic pulmonary disease. Symptomatic disease manifests as an acute community-acquired pneumonia which may spontaneously resolve, or progress to chronic pulmonary blastomycosis. Radiographic imaging reveals alveolar infiltrates, fibronodular interstitial infiltrates, one or more mass lesions and, rarely, diffuse bilateral pulmonary infiltrates.¹⁴¹

All symptomatic cases should be treated. Mild-to-moderate disease is effectively treated in 95% of cases with oral itraconazole (200–400 mg per day).¹⁰² Alternative regimens include ketoconazole (400–800 mg/day) and fluconazole (400–800 mg/day), but these are generally less effective.^{142–144} Moderate-to-severe pulmonary disease treated with AmB is cured in 70–90% of patients.¹⁴⁵ Current recommendations for severe disease include initial therapy with LFAmB (3–5 mg/kg per day) or AmB-d (0.7–1 mg/kg per day), followed by stepdown itraconazole therapy (200 mg every 12 h). AmB should be used for 1–2 weeks or until clinical symptoms improve. Total duration of treatment is generally 6–12 months, depending on clinical and radiographic improvement.¹³⁴

EXTRAPULMONARY BLASTOMYCOSES

Treatment for extrapulmonary blastomycosis is based upon organ system involvement. Itraconazole is successful in 90% of non-CNS cases.¹⁰² Mild-to-moderate extrapulmonary disease can be treated with oral itraconazole (200 mg every 12 h). Duration of therapy is at least 6–12 months, depending on clinical improvement of skin or other lesions. Osteoarticular blastomycosis requires at least 12 months of therapy given the higher rate of relapse.¹⁴⁶ Fluconazole (400–800 mg/day) is an alternative agent but is less efficacious.¹⁴³ In the setting of progressive or refractory disease, LFAmB (3–5 mg/kg per day) should be administered.

Moderate-to-severe non-CNS disease is treated with LFAmB (3–5 mg/kg per day) or AmB-d (0.7–1 mg/kg per day) for 1–2 weeks and until clinical improvement is noted. Stepdown therapy with itraconazole (200 mg every 12 h) is recommended for at least 12 months.

CNS BLASTOMYCOSES

CNS involvement is most common among immunocompromised patients, with rates up to 40% in patients with AIDS.¹⁴⁷ Manifestations of CNS blastomycosis include meningitis, epidural, brain or parenchymal abscesses, and mass lesions. LFAmB (5 mg/kg per day) for 4–6 weeks is recommended for induction therapy.¹⁴⁸ Maintenance therapy with an azole is recommended following clinical improvement with fluconazole (800 mg/day), itraconazole (200 mg every 8–12 h) or voriconazole (200–400 mg every 12 h) for at least 12 months.¹³⁶ Experience with voriconazole is promising, and may be the azole of choice for CNS blastomycosis.^{149–153}

IMMUNOSUPPRESSED PATIENTS

Immunosuppressed patients are predisposed to severe disease with increased mortality.^{148,154} Treatment recommendations, based upon small case series and case reports, support LFAmB (3–5 mg/kg per day) for at least 1–2 weeks. Stepdown

therapy with itraconazole (200 mg every 12 h) for at least 12 months is favored. Given the risk of relapsing disease in immunosuppressed patients, lifelong suppressive therapy with itraconazole (200 mg/day) is recommended. Based on experience of treating histoplasmosis in patients with AIDS, suppressive itraconazole therapy may be discontinued after 1 year in those with CD4 counts consistently >150 cells/mm³.

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis, caused by *Paracoccidioides brasiliensis*, is endemic to parts of South America. Primary infection, acquired via inhalation of the conidia, results in pulmonary disease. Although often asymptomatic, reactivation of latent infection may occur decades following exposure. Dissemination involving the mucus membranes, lungs, skin, lymph nodes, adrenal glands and the CNS is common, as is chronic pulmonary disease, which may mimic malignancy or tuberculosis (coexists in 30% of patients).¹⁵⁵ Untreated infection can be fatal. A wet mount of sputum showing the ‘pilot wheel’ image of mother cell and multiple daughter cells or blastoconidia is diagnostic. Methenamine silver stain demonstrates yeast cells with granuloma formation. Culture requires 20–30 days for growth. Serological testing is limited to a few endemic areas.

Mild-to-moderate disease is treated with itraconazole (200 mg/day) for at least 6–12 months, with a response of approximately 90%.^{156,157} Relapse associated with alcoholism, AIDS and subtherapeutic itraconazole levels occurs in 15% of cases.¹⁵⁸ Alternative therapy with ketoconazole (200–400 mg/day) for 12 months yields response rates of 90%.¹⁵⁹ Sulfadiazine (100–150 mg/kg per day) and fluconazole (200–40 mg/day) are other alternatives. A recent comparative study of voriconazole and itraconazole in chronic paracoccidioidomycosis demonstrated success in 89% versus 94% of patients, respectively.¹⁶⁰ Voriconazole is not recommended as first-line therapy. Refractory moderate-to-severe disease and intolerance to other agents should be managed with AmB-d (1.0 mg/kg per day) or LFAmB (3–5 mg/kg per day).

PENICILLIOSIS

Infection due to *Penicillium marneffei* is endemic in South East Asia and largely affects HIV-infected patients with a CD4 count of <100 cells/mm³.^{161–165} Untreated, the mortality rate is high.^{166,167} Diagnosis is made by culture or histopathology and visualization of the organism. Disseminated disease is most common and typically involves lungs, heart, liver, intestine, lymph nodes and bone marrow. The disease resembles histoplasmosis clinically.

P. marneffei is highly susceptible to itraconazole, ketoconazole and flucytosine, and intermediately susceptible to AmB and fluconazole. Mild-to-moderate disease is treated with oral

itraconazole (400 mg/day) for 8 weeks,¹⁶⁸ and moderate-to-severe disease with AmB-d (0.6 mg/kg per day) for 2 weeks, followed by stepdown therapy with oral itraconazole (400 mg/day) for an additional 10 weeks.¹⁶⁹ Long-term itraconazole (200 mg/day) is recommended to prevent recurrence among patients with persistently low CD4 counts (<200 cells/mm³).

SPOROTRICHOSIS

Sporotrichosis is caused by the dimorphic fungus *Sporothrix schenckii*, found globally in decaying soil, vegetation and moss. Transmission usually occurs by cutaneous inoculation via trauma or zoonotic spread, resulting in lymphocutaneous disease. Inhalation of the conidia rarely causes pulmonary or disseminated disease in immunosuppressed hosts.

LYMPHOCUTANEOUS SPOROTRICHOSIS

Most cases of lymphocutaneous infection are localized with proximal spread to the lymphatic circulation. Treatment response rates for lymphocutaneous/cutaneous disease are 90–100% with itraconazole (200 mg/day) and 60–70% with fluconazole (200–400 mg/day).^{170–172} Therapy should be continued for at least 4 weeks beyond resolution of skin lesions. Terbinafine 500 mg or 1000 mg/day has been used successfully, with cure rates of 53% and 87%, respectively.¹⁷³ Treatment with potassium iodide saturated solution, 15–20 drops per day for 3–6 months, leads to cure in 80–100% of cases. Adverse effects are common, and include abdominal pain, nausea and rash.^{174–177}

OSTEOARTICULAR SPOROTRICHOSIS

Osteoarticular sporotrichosis usually occurs in immunosuppressed patients and those with alcoholism.^{178,179} Infection is chronic, resulting from either direct inoculation or hematogenous spread. Articular infection, tenosynovitis and bursitis are all manifestations of this form of disease.¹⁸⁰ Itraconazole (200 mg every 12 h) is recommended for at least 12 months. Unresponsive infection should be treated with AmB-d (0.7–1.0 mg/kg per day). Surgical intervention in combination with medical therapy is not routinely recommended.¹⁸¹

PULMONARY SPOROTRICHOSIS

Pulmonary sporotrichosis may present as chronic fibronodular cavitary disease and is more common in men with underlying lung disease.¹⁸² Mild-to-moderate disease can be treated with oral itraconazole (200 mg every 12 h) for a total of 12 months.¹⁸³ Clinical experience supports the use of LFAmB-d (3–5 mg/kg per day) in severe disease. AmB-d (0.7–1.0 mg/kg per day) may be used as an alternative. Parenteral therapy is warranted until clinical improvement, followed by itraconazole

(200 mg every 12 h) for at least 12 months. Surgical evaluation is recommended for localized disease.

DISSEMINATED SPOROTRICHOSIS

Current management of disseminated sporotrichosis is based on anecdotal experience. Traditionally, treatment of disseminated sporotrichosis requires AmB-d (0.7–1.0 mg/kg per day) or LFAmB (3–5 mg/kg per day) until a clinical response is noted. Subsequent therapy with itraconazole (200 mg every 12 h) for at least 12 months is recommended. Immunosuppressed patients warrant chronic suppressive therapy with itraconazole (200 mg/day) until resolution of the underlying condition.^{183,184}

MENINGEAL SPOROTRICHOSIS

Meningeal sporotrichosis is a rare complication of disseminated infection. Anecdotal experience supports the use of AmB-d for the treatment of meningeal infection. However, LFAmB (5 mg/kg per day) for 4–6 weeks is the preferred agent. Following completion of LFAmB therapy, itraconazole (200 mg every 12 h) for at least 12 months is recommended.¹⁸³ Clinical experience does not support the use of combination therapy.¹⁸⁵

OTHER MOLD INFECTIONS

FUSARIOSES

Fusarium species are found globally in soil, plant debris and aquatic biofilms. Infection ranges from superficial to disseminated disease. The principal routes of transmission are through inhalation of the conidia and direct penetration of skin from breakdown in the normal skin barrier. Most human infections are due to *Fusarium solani* (50%), followed by *F oxysporum* (20%) and *F verticillioides* (10%) and *F moniliforme* (10%).¹⁸⁶ In immunocompetent hosts, infection is more commonly manifested as keratitis and onychomycosis. Disseminated disease usually occurs in the setting of severe neutropenia complicating hematological malignancy, leukemia and stem cell transplantation.¹⁸⁷ Disseminated disease is manifest by positive blood cultures with concurrent skin lesions.¹⁸⁸

Localized infection requires surgical debridement and antifungal therapy. Intravenous AmB, voriconazole (200 mg every 12 h) or posaconazole (400 mg every 12 h with meals) is appropriate for localized infection.¹⁸⁹ Keratitis is treated with topical natamycin 5% (1 drop 6–8 times/day).¹⁹⁰

Treatment of invasive and disseminated infections is usually ineffective in the immunocompromised. AmB (1 mg/kg per day) or LFAmB (>4 mg/kg per day) is preferred for treating invasive fusariosis.^{191,192} Recent data support the use of voriconazole (200 mg every 12 h) and posaconazole

(400 mg every 12 h with meals), in combination with AmB, as alternative treatment or as salvage therapy (63% vs 48%, for voriconazole and posaconazole, respectively).¹⁹³

In addition to medical management, surgical debridement of necrotic tissue may be beneficial. Central venous catheters should be removed in cases of isolated fungemia.

SCEDOSPORIOSIS

Two *Scedosporium* species, *S. apiospermum* (*Pseudallescheria boydii*) and *S. prolificans*, are rare causes of opportunistic infections in humans. *S. apiospermum* causes a wide spectrum of infection from superficial skin disease and mycetomas to CNS and disseminated disease in immunocompromised patients.¹⁹⁴ *S. prolificans* infections in immunocompetent hosts include localized skin, soft tissue, joint and bone disease, usually occurring after trauma; in neutropenic patients, pulmonary disease, fungemia and widely disseminated disease are common.^{195,196} In immunocompromised hosts, these organisms are associated with a 58–100% mortality rate.¹⁹⁷ Concern for breakthrough *Scedosporium* spp. infection has recently increased as a result of antifungal prophylaxis with little or no activity against *Scedosporium* spp. *Scedosporium* spp. have erratic susceptibilities to AmB; *S. apiospermum* has documented resistance to AmB in vitro and in vivo.¹⁹⁸

The expanded spectrum triazoles demonstrate in-vitro activity against *S. apiospermum*. The greatest clinical experience is with voriconazole (4 mg/kg every 12 h), which compares favorably to AmB-d.¹⁹⁹ *S. apiospermum* also demonstrates in-vitro susceptibility to posaconazole, miconazole, ketoconazole and itraconazole.⁶⁰ Cerebral abscesses due to *S. apiospermum* are treated with voriconazole (4 mg/kg every 12 h) or itraconazole (200 mg every 12 h) in conjunction with surgical intervention.²⁰⁰ Treatment should be continued for months.

S. prolificans is resistant to most antifungal agents. Voriconazole exhibits limited in-vitro activity against *S. prolificans* but has little to no in-vivo activity.^{201–203} Voriconazole (4 mg/kg every 12 h) and itraconazole (200 mg every 12 h) have been used in combination with terbinafine (500 mg/day) or an echinocandin with some success, and currently offer the best therapeutic option.^{204–208}

PHAEOHYPHOMYCOSSES

EUMYCETOMA (MADUROMYCOSIS)

Eumycetomas are chronic, granulomatous infections resulting in progressive infection of the subcutaneous tissue of the distal extremities, most commonly the legs and feet. Infections are due to soil fungi (*Eumycetoma* spp.) and higher bacteria (*Actinomycetoma* spp.). Transmission occurs via skin inoculation to produce subcutaneous nodules and draining sinus tracts, in which grains can be visualized. Untreated, eumycetoma can result in chronic disability and osteomyelitis.²⁰⁹

Eumycetomas are endemic in Latin America, Africa and the Indian subcontinent. Multiple fungi cause mycetomas that vary by locality. The more common causative organisms include *Madurella mycetomatis* (Africa and India), *Madurella grisea* (the Americas), *S. apiospermum* (Europe and the USA), and *Fusarium* spp. and *Acremonium* spp., found globally.²¹⁰ The causative organism must be identified to guide antimicrobial or antifungal therapy.

Eumycetomas, less responsive to therapy than actinomycetomas, often require surgical debulking. Clinical experience supports the use of itraconazole and ketoconazole (400 mg/day), for 18–24 months.^{210–212} Fluconazole has proved less successful. The newer triazoles are efficacious but cost-prohibitive in resource-limited settings. Posaconazole (80% success) is dosed at 400 mg every 12 h for 24 months.²¹³ AmB, flucytosine and griseofulvin are not recommended.²¹⁴ Despite medical and surgical intervention, relapse rates as high as 90% have been documented. Fortunately, many eumycetomas remain relatively stable for long periods of time without therapy.

CHROMOBLASTOMYCOSIS

Chromoblastomycosis is a chronic infection of the skin and subcutaneous tissue of non-immunocompromised individuals caused by several dematiaceous fungi, including *Fonsecaea pedrosoi*, *Fonsecaea compacta*, *Phialophora verrucosa*, *Cladosporium* (or *Cladophialophora*) *carriionii*, *Rhinocladiella aquaspersa* and *Botryomycetes caespitosus*. The disease occurs worldwide, but is more common in tropical and subtropical areas.

Although smaller lesions can be surgically excised, larger lesions require antifungal therapy. Resistance to standard antifungal therapy (fluconazole, flucytosine and AmB) is common and affects therapeutic response. Reasonable results have been observed with oral itraconazole (200 mg/day) with or without flucytosine (25 mg/kg every 6 h).²¹⁵ Posaconazole (400 mg every 12 h with meals) has demonstrated success in the treatment of disease refractory to fluconazole, flucytosine and AmB. Terbinafine (200–500 mg/day) demonstrates good clinical activity, with cure rates approaching 80%.²¹⁶ Thiabendazole (2 g/day), with or without flucytosine, is also effective.²¹⁷ Treatment is prolonged, up to 2 years in some cases. Response rates vary by causative organism and extent of disease. Conventional therapy involves cryotherapy and topical heat in conjunction with antifungal therapy. Cryotherapy with liquid-nitrogen-soaked cotton balls, swabs or spray has demonstrated success with negative cultures at 4 months. Historically, local heat (42–46°C) applied directly to the lesion for 2–12 months has been efficacious.^{217,218}

PNEUMOCYSTOSIS

Pneumocystis pneumonia (PCP), caused by *Pneumocystis jirovecii*, occurs in immunocompromised patients. Primary infection is usually an unrecognized event in childhood.

Pneumonia occurs with either reactivation of latent disease or newly acquired infection.

Clinical manifestations of progressive dyspnea, fever, dry cough and progressive chest discomfort are most common. Radiographic imaging in early disease may be normal. As disease progresses, diffuse, bilateral, symmetrical interstitial infiltrates are consistent with PCP.²¹⁹

Diagnosis is confirmed by identification of the organism in tissue, bronchoalveolar lavage fluid or induced sputum by histopathology.^{220–222} Nucleic acid tests have lower specificity than immunological stains and limited availability.^{223,224} First-line therapy for mild-to-moderate disease is oral trimethoprim-sulfamethoxazole (TMP-SMX; 15–20 mg/kg per day trimethoprim and 75–100 mg/kg per day sulfamethoxazole divided in 2–3 doses) for 21 days.^{225,226} With TMP-SMX intolerance, alternative regimens include:

- dapsone 100 mg/day plus TMP 20 mg/kg orally or intravenously in 2–3 doses
- clindamycin 600 mg every 6 h combined with primaquine 15 mg/day
- atovaquone 750 mg every 12 h.

Prior to receiving dapsone, patients should be tested for glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Moderate-to-severe disease necessitates adjunctive corticosteroids: prednisolone 40–60 mg/day for 5 days, followed by a 14-day taper.^{227–230} If parental administration is required, methylprednisolone can be given at 75% of the prednisone dose. The recommended first-line treatment of moderate-to-severe PCP is TMP-SMX (see above dosing) for 21 days.²³¹ If an alternative regimen is required, intravenous pentamidine (4 mg/kg per day) or clindamycin plus primaquine, in order of preference, may be used for 21 days.^{232,233} Response to therapy is multifactorial: severity of illness, degree of immunosuppression, prior history of PCP, medications used for therapy and timing of therapy. PCP prophylaxis is required in HIV patients until the CD4 count is consistently >200 cells/mm³.

Twenty to 85% of patients can develop intolerance to the high dose of TMP-SMX. Side effects to TMP-SMX consist of skin rash, including Stevens-Johnson syndrome, nausea, vomiting, fever, leukopenia, thrombocytopenia, renal insufficiency with hyperkalemia, and hepatitis.^{234–238}

In the absence of a consensus regarding the appropriate time to initiate ARV in patients with severe PCP, current clinical practice includes delaying the initiation of ARV until after the completion of anti-PCP therapy, or holding ARV initiation until at least 2 weeks into therapy for PCP. Recent data suggest that initiating ARV therapy during initial PCP treatment may be beneficial.^{239,240}

CHAPTER

61 Zoonoses

Lucy Lamb and Robert Davidson

BRUCELLOSIS

Worldwide about 500 000 human cases of brucellosis occur annually with a patchy global distribution.¹ The disease is endemic in the Mediterranean basin, the Arabian Gulf, the Indian subcontinent and parts of Mexico, Central and South America. Brucellosis is a systemic disease that can involve any organ or system of the body. The responsible species are: *Brucella melitensis* (sheep, goats and camels); *B. abortus* (cattle, buffalo, yaks, camels); *B. suis* (pigs, wild hares, caribou, wild rodents and reindeer); *B. ovis* (sheep) and *B. canis* (dogs). *B. melitensis* remains the main cause of human brucellosis worldwide.² Disease from marine species have emerged (*B. pinnipediae* and *B. cetaceae*). Infected animals shed large numbers of bacilli in milk, urine and products of conception. Humans are infected by direct contact with infected animals or by ingestion of unpasteurized milk or milk products. The infective dose of *Brucella*, especially of *B. melitensis* is very low (10 organisms). The incubation period is usually 7 days to 3 months, although longer intervals have been reported.

In humans the disease manifests as an acute (<2 months) or subacute (2–12 months) febrile illness which may persist and progress to become chronic (>1 year). *Brucella* has been considered a potential biological weapon as it has a propensity for airborne transmission and induction of chronic debilitating disease with vague clinical characteristics. Nowadays its inclusion is of historical significance because of the emergence of new, more virulent weapons.³

ANTIBIOTIC THERAPY – DRUG COMBINATIONS

Treatment has been designed to shorten the duration of symptoms, prevent relapse and avert complications such as arthritis, sacroiliitis, spondylitis, encephalitis, endocarditis, epididymo-orchitis and abortion. Monotherapies have a high rate of relapse so a combination of two drugs is usually used.

The recommendations for specific drug combinations in published sources are very inconsistent. The regimen of choice recommended by the World Health Organization (WHO) Expert Committee is doxycycline 200 mg/day plus rifampicin (rifampin) 600–900 mg/day for 6 weeks; however, these guidelines were published in 1986 and are subject to debate.⁴

There are significant differences in effectiveness between currently recommended treatment regimens. A recent Systematic Review in the British Medical Journal summarizes the evidence-based treatment options.^{1,5} The therapy of brucellosis is complicated by the location of the organism within an acid compartment in reticuloendothelial cells, where optimal concentrations and effects of antibiotics are difficult to achieve. Therefore regimens should include at least one agent with good intracellular penetration.

The main outcomes of trials indicate the following:

- Monotherapy is not recommended because of its high failure rates.
- The combination of tetracycline–streptomycin is significantly superior to tetracycline–rifampicin, mainly due to a reduced rate of relapse. The tetracycline recommended is doxycycline 200 mg/day. Doxycycline is central to treatment regimens as the minimum inhibitory concentrations (MICs) of tetracycline for *Brucella* are generally <1 mg/L. Streptomycin works synergistically with doxycycline and is recommended at a dose of 1 g/day for the first 14 days of treatment. Adverse events in general and discontinuation because of these events were similar in the two treatment groups.
- Comparing the aminoglycosides, there is a trend to support the use of gentamicin rather than streptomycin. Thus gentamicin could replace streptomycin for dual treatment regimens. This has the added advantage of allowing therapeutic drug monitoring, which is routinely available for gentamicin.
- A regimen consisting of a quinolone plus rifampicin or streptomycin is less effective than the above, although the adverse events are less in this group.

- The optimal treatment regimen includes triple combination therapy with tetracycline–aminoglycoside–rifampicin and this has been found to be significantly more effective than most dual regimens. The tetracycline–rifampicin combination is administered for 6–8 weeks and the aminoglycoside for 2 weeks. If this is not successful, then a regimen containing a tetracycline–aminoglycoside combination is recommended.
- It is recommended that patients are treated for ≥6 weeks to prevent relapse, with a tetracycline and an aminoglycoside being administered for the first 7–14 days.

CHILDREN WITH BRUCELLOSIS

The treatment of childhood brucellosis will vary according the child's age. Optimal treatment of brucellosis remains based on combinations of doxycycline with either rifampicin or streptomycin. Doxycycline is not recommended for children younger than 9 years. Instead, a regimen consisting of gentamicin 5 mg/kg (5 days) or streptomycin 20 mg/kg (14 days) and co-trimoxazole 8 mg/kg (6 weeks), or co-trimoxazole plus rifampicin 20 mg/kg (6 weeks), are shown to be effective with low relapses. Relapses could be treated with a triple drug regimen, such as co-trimoxazole–aminoglycoside–rifampicin. There is no evidence on the use of triple drug regimens in children at present but adult studies have shown that this is an area for possible further research.⁶

TREATMENT OF BRUCELLOSIS DURING PREGNANCY AND LACTATION

Brucellosis can cause fetal death at any stage of pregnancy, whether maternal infection is mild or severe. The natural history of brucellosis in pregnant women may be altered by the early institution of antimicrobial therapy, particularly prior to vaginal bleeding. An important consideration when treating brucellosis in pregnant women is the possibility of fetal toxicity of the drugs. Although the data are limited, it is known that the incidence of abortion observed in patients with active brucellosis exceeds that in patients with other micro-organisms. Treatment with either co-trimoxazole (although monotherapy is not recommended because of the high incidence of relapse) or co-trimoxazole plus rifampicin had a strong protective effect against abortion. The length of treatment is 6 weeks, similar to non-pregnant individuals.⁷

SPINAL BRUCELLOSIS

Brucellosis affects many organ systems, with septic arthritis and osteomyelitis being common, especially in the elderly. It is a destructive disease, often confused with tuberculosis, so a thorough history (particularly focusing on risk factors like prior unpasteurized milk consumption) and examination are essential. Early diagnosis and treatment are vital for patient

prognosis. The evidence supports the classic treatment regimen of doxycycline 100 mg every 12 h for at least 12 weeks, with streptomycin 1 g/day for the first 2 weeks. Alternative therapies using fluoroquinolones and co-trimoxazole are only considered when adverse reactions are reported.⁸

Another study showed that triple therapy using a combination of streptomycin 1 g/day intramuscularly for 15 days, doxycycline 100 mg every 12 h and rifampicin 15 mg/kg per day for 45 days had good response rates and low relapse rates.⁹

NEUROBRUCELLOSIS

Central nervous system involvement is a serious complication of brucellosis.¹⁰ The recommended treatment regimen should include doxycycline (which crosses the blood–brain barrier better than generic tetracycline), plus rifampicin plus ceftriaxone. High concentrations in the cerebrospinal fluid (CSF) offers significant efficacy against the pathogen.¹¹ Although the therapy should be individualized, the duration of therapy should be a minimum of 6 months with suitable antibiotics.¹² Treatment should be continued until the CSF analysis has returned to normal. Steroids may prevent early clinical deterioration following the commencement of antibiotics.¹³

BRUCELLA ENDOCARDITIS

This devastating condition has a higher mortality rate than endocarditis caused by other pathogens due to its rapid valvular destruction and the late diagnosis of cases. The aortic valve is most commonly involved. Optimal therapy is a combination of antibiotics and surgery, although medical therapy with close observation can be attempted in hemodynamically stable patients. The recommended antibiotic regimen is a combination of doxycycline 200 mg/day, rifampicin 900 mg/day and gentamicin (for the first 21 days). The addition of a third-generation cephalosporin instead of an aminoglycoside is an alternative.¹⁴ Treatment should be continued for a year or more.^{15–17}

BRUCELLOSIS IN PATIENTS INFECTED WITH HIV

Twelve patients with brucellosis and HIV co-infection have been reported from Spain; all were cured by the combination of doxycycline and streptomycin.¹⁸ A case reported from India responded well to a regimen consisting of 6 weeks of tetracycline 250 mg every 6 h for 6 weeks and 3 weeks of streptomycin 1 g/day.¹⁹

PREVENTION OF LABORATORY-ACQUIRED BRUCELLOSIS

Brucellosis is one of the most common laboratory-acquired infections, as it has a potential for aerosolization. It is recommended that the organism should be handled

according to Level 3 Biosafety Precautions. Aerosol-generating procedures should be avoided or minimized. Prophylaxis to laboratory workers exposed to *Brucella* is recommended: doxycycline 100 mg every 12 h plus rifampicin 450–600 mg/day. An alternative, e.g. in pregnancy, is co-trimoxazole plus rifampicin.²⁰ The duration of prophylaxis should be a minimum of 3 weeks, and usually continued for 6 weeks. Laboratory staff are followed up with serological testing for 3 months after exposure.²¹

ANTHRAX

Bacillus anthracis is a large, Gram-positive, non-motile, aerobic, spore-forming rod. The principal virulence factors are encoded on two plasmids: one is involved in synthesis of a capsule that inhibits phagocytosis of the vegetative forms; the other is involved in the production of the exotoxins that are important for its virulence. The exotoxins consist of the edema toxin and the lethal toxin which are divided into A (enzymatically active) protein and B (binding) protein necessary for entry into the host cell.²²

Between 20 000 and 100 000 cases of anthrax are estimated to occur worldwide annually. Anthrax can exist in the soil as long-lived spores and cause infection in humans, and farm and wild animals. In 1979, it was recognized that anthrax could be used as a biological weapon after 66 people died from human exposure (by inhalation) to the accidental discharge of anthrax spores at a military biological facility in Sverdlovsk, Russia. Further evidence includes the deliberate use in the USA in the 1990s.²³

Human anthrax has three major clinical forms: cutaneous, inhalation and gastrointestinal. Cutaneous anthrax is a result of introduction of the spore through the skin from animal hair or hides, inhalation anthrax (woolsorter's disease) through the respiratory tract, and gastrointestinal anthrax by ingestion. Anthrax meningitis may occur as a result of a bacteremia after inhalational anthrax; it is rare and has mortality close to 100%. If untreated, anthrax in all forms can lead to septicemia and death. Early treatment of cutaneous anthrax is usually curative.

POSTEXPOSURE PROPHYLAXIS

Postexposure prophylaxis is recommended to individuals by the public health authorities when there is an evident risk of exposure to anthrax. A long period of prophylaxis is required because of the latency period that may occur prior to the germination of spores. Recently there has been concern about antibiotic resistance, particularly to penicillin, doxycycline, chloramphenicol, macrolides and rifampicin. Ciprofloxacin is the drug of choice (500 mg every 12 h) (Table 61.1).

Table 61.1 Recommendations for anthrax postexposure prophylaxis

Type of therapy	Adults (including pregnant women)	Children
Recommended initial therapy	Ciprofloxacin 500 mg every 12 h ^a	Ciprofloxacin 10–15 mg/kg every 12 h ^a
Alternative initial therapy	Doxycycline 100 mg every 12 h	Doxycycline 100 mg every 12 h if >8 years and >45 kg
Optimal therapy (if strain susceptible)	Amoxicillin 500 mg every 8 h or doxycycline 100 mg every 12 h	Amoxicillin 500 mg every 8 h if >20 kg; 40 mg/kg divided into 3 doses if <20 kg

^aAlthough fluoroquinolones are not recommended for use during pregnancy and in young children, the possibility of antibiotic resistance warrants their use in exposed pregnant women and children. This also applies to doxycycline in extreme circumstances. The total duration of treatment should be 60 days.

ANTHRAX VACCINE

An anthrax vaccine has been licensed for use in humans. Limited clinical data suggest that after completing a primary immunization course, protection against cutaneous and inhalation anthrax is afforded.²⁴ The vaccine is administered at 0, 2 and 4 weeks and again at 6, 12 and 18 months. Studies in rhesus monkeys have demonstrated complete protection against aerosol challenge at 8 weeks and 88% protection at 100 weeks. Annual boosters are required to maintain immunity. The vaccine has been given to the American Armed Forces since 1988 because of the concern of anthrax as a biological weapon. Contraindications to its use include sensitivity to vaccine components and a history of anthrax. No serious adverse side effects have been reported.

TREATMENT OF ANTHRAX

Penicillin is the drug of choice in sensitive strains, but alternative agents have been used because of reports of resistance (Table 61.2).

Surgical debridement of the black, necrotic eschar is contraindicated. Systemic steroids have been used for the extensive edema, but their efficacy is unproven.

ANIMAL BITES

Animal bites continue to pose major public health challenges.²⁵ Dogs represent the species most frequently responsible for bite-related injuries, followed by cats (~80% and <20%, respectively). Wildlife, farm animals, rodents and other pets are responsible for the remainder. Most wounds are contaminated with multiple strains of aerobic and anaerobic bacteria. The common bacteria involved are *Pasteurella multocida*, *Staphylococcus aureus*, *Staphylococcus intermedius*, alpha-hemolytic

Table 61.2 Recommendations for treatment of inhalational and cutaneous anthrax

Type of therapy	Inhalational anthrax		Cutaneous anthrax	
	Adults	Children	Adults	Children
Initial therapy	Ciprofloxacin 400 mg iv every 12 h	Ciprofloxacin 20–30 mg/kg iv, divided into 2 doses	Mild: ciprofloxacin 500 mg p.o. every 12 h Severe: intravenous	Ciprofloxacin 20–30 mg/kg iv, divided into 2 doses
Optimal therapy if susceptible	Benzylpenicillin 2.4 g iv every 4 h Doxycycline 100 mg iv every 12 h	Benzylpenicillin 150 mg/kg per day in 4 divided doses for children <12 years; for children >12 years, use adult doses	Doxycycline 100 mg p.o. every 12 h Severe: ciprofloxacin 400 mg i.v. every 12 h Amoxicillin 500 mg p.o. every 8 h	As per inhalational doses Amoxicillin 500 mg every 8 h if >20 kg; 40 mg/kg divided into 3 doses if <20 kg

Note: Treatment should continue for 60 days in the context of bioterrorism and for 7–10 days for natural exposure.

streptococci, *Capnocytophaga canimorsus* (formerly called dysgonic fermenter 2, DF2) and other members of the oral flora of animals. Anaerobic bacteria including *Fusobacterium*, *Bacteroides*, *Porphyromonas* and *Prevotella* spp. are present in approximately one-third of bite wounds and are associated with the formation of abscesses and with relatively serious infections. *Past. multocida* is found in infections from cat bites. The bacteriology of bite wounds inflicted by exotic animals reflects the animals' oral flora.^{26,27} Infection rates differ significantly between cat and dog bites (30–50% vs 2–4%). Risk factors for infection include patient age >50 years, puncture wounds, full-thickness wounds and wounds requiring debridement.

Animal bite wounds can be classified into three groups on the basis of the injury received: avulsions, lacerations or punctures. Avulsions and lacerations tend to be associated with dog bites whilst puncture wounds occur with cat bites. Ferrets are becoming more popular as pets and tend to bite children particularly on the face.

MANAGEMENT AND PROPHYLAXIS OF INFECTED ANIMAL BITES

The initial evaluation should include a thorough assessment of the wound and the patient's medical history and status, determination of the time that has elapsed before treatment was initiated, and identification of the animal responsible and the circumstances under which the bite occurred. The wound should be cleansed and debrided, and tetanus, rabies and antimicrobial prophylaxis should be considered. There is a debate regarding primary versus delayed repair. Most studies favor the use of primary surgical closure because of the improved cosmetic outcome. However, with certain wounds which present late or have an increased risk for complications, then primary closure is not recommended.

Prophylactic administration of antimicrobials should be considered in:

- moderate or severe injuries
- possible bone or joint penetration

- facial, genital and hand wounds
- those patients with underlying illnesses: liver disease, limb edema or prosthetic joints.

Amoxicillin-clavulanic acid has good activity against the likely organisms, and is the best choice both for prophylaxis of infection-prone bites and for empirical treatment of infected bites before the results of cultures become available. Other combinations include a second-generation cephalosporin that has anaerobic activity such as cefuroxime, a combination of penicillin with a first-generation cephalosporin such as cefradine or, for penicillin-allergic individuals, clindamycin plus a fluoroquinolone. For patients with a head injury who might have evidence of a skull fracture, then a combination of antimicrobials with good CSF penetration, such as vancomycin, ceftriaxone and metronidazole, is recommended.

There are an increasing number of methicillin-resistant *Staph. aureus* (MRSA) infections from animal bites. A newly released article in the *Lancet Infectious Disease* journal has suggested that additional steps should be taken in managing these patients.²⁸

- Consider radiological imaging in case of fracture or bone penetration.
- Consider prophylactic antibiotics to cover MRSA (trimethoprim-sulfamethoxazole, doxycycline, minocycline and clindamycin).
- Consider admission if the patient is immunocompromised or septic.

RAT-BITE FEVER

The term 'rat-bite fever' refers to two similar diseases caused by different Gram-negative facultative anaerobes: streptobacillary rat-bite fever, caused by infection with *Streptobacillus moniliformis* (a pleomorphic fastidious Gram-negative bacillus) is more common in North America, and spirochetal rat-bite fever, caused by *Spirillum minus* also known as sodoku (a short, thick, Gram-negative spirochete with darting motility) is more common in Asia.²⁹ Both organisms are common inhabitants of the pharynx of wild, pet and laboratory rats

in all parts of the world. Humans usually acquire the disease through the bite of a rat, though a history of a bite is sometimes absent in *S. moniliformis* infections, which may be acquired by oral ingestion. An example was illustrated by a milk-associated outbreak in Haverhill in 1926.³⁰ Cases of *S. moniliformis* rat-bite fever have been associated with the bites of mice, squirrels and gerbils, and exposure to animals that prey on these rodents. The reported incidence of rat-bite fever caused by *S. moniliformis* from laboratory rat bites is low. The efficacy of prophylaxis against rat-bite fever has yet to be assessed in practice.

STREPTOBACILLUS MONILIFORMIS INFECTION

The clinical syndrome is characterized by fever, rigors and migratory polyarthralgias. After exposure, the incubation period is usually <7 days, and ranges from 3 days to more than 3 weeks. If a bite occurs it usually heals quickly with minimal residual inflammation. Other reported clinical features include headache, nausea, vomiting, myalgia, minimal regional lymphadenopathy, anemia, endocarditis, myocarditis, meningitis, pneumonia, focal abscesses and a rash (75% of patients). Most cases resolve spontaneously, but if untreated has a mortality of 10% (ranging from 7% to 13%). It is therefore important to initiate antibiotic treatment early. Diagnosis is made from blood cultures; however, as the organism is fastidious, the growth time may be prolonged. Other methods used for diagnosis include fatty acid profiles, high-resolution polyacrylamide gel electrophoresis and polymerase chain reaction (PCR) assays.

Penicillin is the treatment of choice for proven or highly suspected cases of rat-bite fever. Only one penicillin-resistant strain has been reported, over 50 years ago.³¹ Tests of *S. moniliformis* antibiotic susceptibility usually demonstrate sensitivity to penicillins, cephalosporins, carbapenems, aztreonam, clindamycin, erythromycin, nitrofurantoin, bacitracin, tetracycline, teicoplanin and vancomycin. Adults with uncomplicated *S. moniliformis* should receive 400 000–600 000 IU/day (240–360 mg) of intravenous penicillin G for at least 7 days and the dose should be doubled if no response is seen in 2 days. Children should receive 20 000–50 000 IU/kg per day (12–30 mg/kg per day) of intravenous penicillin for 5–7 days, followed by oral penicillin V, 25–50 mg/kg per day (maximum 3 g/day) divided into four doses. For penicillin-allergic patients both streptomycin and tetracycline appear to be effective; erythromycin has been associated with treatment failures. Cephalosporins have also been shown to be effective.

Complications such as septic arthritis, meningitis and pneumonia require more intensive treatment with intravenous penicillin. Endocarditis due to *S. moniliformis* is rare and generally occurs on previously damaged valves. It will probably respond to standard regimens used to treat endocarditis caused by other penicillin-sensitive organisms.

SPIRILLUM MINUS INFECTION (SODOKU)

Sodoku differs from streptobacillary rat-bite fever both clinically and geographically; it is more common in Asia. After a longer incubation period (14–18 days), the bite site becomes indurated and may ulcerate, and is associated with regional lymphadenopathy. Fevers regularly relapse and may be separated by afebrile periods lasting 3–7 days. Fifty percent of patients develop a violaceous red–brown macular rash which has occasional plaques and urticarial lesions. Joint manifestations are rare. Sodoku is highly sensitive to penicillin but a Jarisch–Herxheimer reaction may occur following the initiation of treatment.

TULAREMIA

Francisella tularensis is an extremely virulent aerobic, Gram-negative coccoid, facultative intracellular bacterium, which does not form spores but can survive in water, soil, hay and animal carcasses for up to 6 months. There are two types:

- Type A is found mostly in North America and is transmitted from the rabbit tick to humans. It is highly virulent, causing disease in humans with an inoculum of <25 bacteria.
- Type B is widespread throughout the Northern Hemisphere and is the only subspecies in Europe. It is associated with rodents and hares; humans contract the disease by inhalation, direct contact, insect bites or ingestion. Type B is generally non-lethal in humans but may cause a prolonged complicated disease.³²

Tularemia is considered to be a category A bioterrorist threat by the US Centers for Disease Control and Prevention (CDC) as it is easy to acquire, weaponize and is transmissible by aerosol, although there have been no confirmed cases of its use in this situation. After exposure, ulceroglandular, oculoglandular and glandular disease are common manifestations, accompanied by fever, chills, myalgias and cough. Other forms may occur such as pulmonary disease and a typhoidal form. Rare complications include meningitis, pericarditis and endocarditis. The main difference between type A and type B is the ability of the former to replicate faster and cause necrosis. Diagnosis relies on clinical suspicion, serological testing, blood cultures and now PCR.

TREATMENT OF TULAREMIA

Aminoglycosides are the mainstay of treatment and whilst streptomycin has been used historically, gentamicin is also active against tularemia. Relapses have been seen with doxycycline. There are encouraging reports of quinolones showing activity against the bacteria. There is no currently licensed vaccine. Streptomycin is the antibiotic of choice, at a dose of 7.5–15 mg/kg intramuscularly every 12 h for 7–14 days, the

higher doses being used for more severe illness. Gentamicin is an acceptable alternative to streptomycin; the recommended dose is 3–5 mg/kg per day in divided doses.

PLAQUE

Yersinia pestis is a Gram-negative, non-spore-forming bacillus. It is transmitted by the oriental rat flea, *Xenopsylla cheopis*. There are three main forms: bubonic, septicemic and pneumonic plague. Pneumonic plague is rare, highly transmissible between humans and has a high mortality rate. Its presence should alert authorities to the deliberate release of *Y. pestis*.³³ Diagnosis is made by culture of the organism from blood, sputum or aspiration of the buboes with special staining. Some laboratories can perform specific IgM testing and PCR.

TREATMENT OF PLAGUE

Early treatment is essential to prevent fatal pneumonic plague. Patients must be nursed in isolation with negative pressure (48 h for bubonic and 4 days for pneumonic). The CDC guidelines recommend streptomycin (15 mg/kg intravenously every 12 h) for 10 days or gentamicin with doxycycline or ciprofloxacin.³⁴ In a recent study in New Mexico it was found that gentamicin alone (5 mg/kg intravenously every 24 h) or in combination with a tetracycline (intravenous doxycycline 200 mg/day or 100 mg every 12 h) was as efficacious as streptomycin for treating human plague.³⁵ This study was supported by a clinical trial in Tanzania which showed gentamicin 2.5 mg/kg intramuscularly every 12 h for 7 days and doxycycline 100 mg every 12 h for 7 days (2.2 mg/kg in children) to be effective treatments for adult and pediatric plague.³⁶ Penicillins and cephalosporins are considered to be ineffective against plague, although in-vitro and animal studies have shown ceftriaxone to have variable activity.

Trimethoprim-sulfamethoxazole is recommended for plague when tetracyclines are contraindicated. Chloramphenicol is used in cases of plague meningitis as it penetrates the blood-brain barrier.

PROPHYLAXIS OF PLAGUE

Any person within 2 meters of a confirmed case of plague should receive postexposure prophylaxis with ciprofloxacin 500 mg every 12 h or doxycycline 100 mg every 12 h for 7 days.

BARTONELLA-ASSOCIATED INFECTIONS

The genus *Bartonella* comprises 19 distinct species, at least eight of which are responsible for human disease; some examples are shown below.^{37,38}

- *Bartonella bacilliformis* causes bartonellosis (Carrion's disease).
- *Bartonella henselae* causes cat-scratch disease, peliosis hepatitis and bacillary angiomatosis.
- *Bartonella quintana* causes trench fever, endocarditis, bacillary angiomatosis and chronic or recurrent bacteraemia.
- *Bartonella vinsonii* is isolated from blood of small rodents.
- *Bartonella elizabethae* (*Rattus* rats have been shown to be a reservoir) causes endocarditis.
- *Bartonella clarridgeiae* (isolated from blood of 5% of pet cats and 17% of stray cats) may be responsible for some cases of cat-scratch disease.
- *Bartonella grahamii* causes cases of retinitis.
- *Bartonella washoensis* causes myocarditis.

Bartonellae are small, fastidious, intracellular Gram-negative bacilli that are aerobic and oxidase negative. The diagnosis of these diseases is complicated as there is no optimal procedure for the isolation of the organism.

RECOMMENDATIONS FOR TREATMENT

BARTONELLOSIS (CARRION'S DISEASE)

Oroya fever

B. bacilliformis is a Gram-negative intraerythrocytic organism transmitted by the *Lutzomyia* sandfly and is limited to the Andean river valleys of Peru and Ecuador. The bacteria cause Oroya fever (acute Carrion's disease) which is a life-threatening septicemia with acute hemolysis which can be complicated by superinfections, particularly with *Salmonella* species. Recommended treatment is with oral or intravenous chloramphenicol 500 mg every 6 h for 14 days plus oral amoxicillin or ciprofloxacin 500 mg every 12 h for 10 days (adults). Treatment for children is with oral or intravenous chloramphenicol 50–75 mg/kg per day in four doses for 14 days plus amoxicillin. Penicillin G, chloramphenicol, tetracycline and erythromycin have also been used for treatment.

Verruga peruana

Verruga peruana (chronic Carrion's disease) is an infection characterized by benign cutaneous vascular lesions accompanied by osteoarticular pain. Chloramphenicol is ineffective treatment for this eruptive stage of infection. Recommended treatment is with rifampicin 10 mg/kg per day orally (safe in children and pregnancy) for 14 days or streptomycin 15–20 mg/kg per day intramuscularly for 10 days. There are failures with rifampicin and resistance has also been shown to develop when used alone. More recently, ciprofloxacin (500 mg orally every 12 h for 7–10 days) and azithromycin have been used with success.³⁹

BARTONELLA HENSELAE

B. henselae (formerly *Rochalimaea henselae*) is a small Gram-negative rod, which causes several syndromes that sometimes overlap. *B. henselae* causes cat-scratch disease but, like *B. quintana* (see below), also causes a wide range of clinical diseases including bacillary angiomatosis, peliosis hepatitis, lymphadenitis, bacteremia and aseptic meningitis. Cats are the main reservoir of *B. henselae* and the bacterium is transmitted to cats by the cat flea (*Ctenocephalides felis*). The immune status of the host determines the disease expression. Antibiotics have been shown to improve the disease occurring in the immunocompromised host.

Uncomplicated cat-scratch disease

The current recommendation for patients with mild-to-moderate disease is no antibiotic treatment (the risk of adverse drug reactions and the generation of resistant flora outweigh the benefits). Adenopathy which occurs in cat-scratch disease should be investigated to rule out other infections (fungal, mycobacterial or malignancy) by fine needle aspiration, which may also alleviate symptoms. Patients should be reassured that the adenopathy is benign and will heal in 2–4 months. Those with bulky adenopathy may be treated with azithromycin (500 mg orally day 1 and 250 mg days 2–5) or doxycycline (100 mg every 12 h) and rifampicin (300 mg every 12 h) and/or aspiration.

Complicated cat-scratch disease

The combination of doxycycline (100 mg every 12 h) with rifampicin 300 mg orally every 12 h has been successful for treating retinitis and is preferred if there is neurological involvement. The optimal duration has not been determined but a prolonged course of 4–6 weeks is recommended. There is also evidence that *B. henselae* infections and cat ownership are linked to some cases of HIV-associated dementia.⁴⁰

Bacillary peliosis hepatitis

This occurs in immunocompromised patients and is caused by *B. henselae* but not *B. quintana*. Peliosis hepatitis is a vascular proliferation of sinusoidal hepatic capillaries resulting in blood-filled spaces in the liver; it is associated with HIV infection. Treatment is recommended with erythromycin 500 mg every 6 h for 4 months or doxycycline 100 mg every 12 h for 4 months.

BARTONELLA QUINTANA

B. quintana (formerly *Rochalimaea quintana*) is transmitted by the human body louse and humans are the only known reservoir. It causes trench fever, a disease extensively reported during the World Wars, prior to the antibiotic era. During this period there were no fatal cases and clinical manifestations

lasted for 4–6 weeks before recovery. Nowadays it is recommended that patients who have trench fever or chronic bacteremia with *B. quintana* should be treated with doxycycline 200 mg/day orally for 4 weeks plus gentamicin 3 mg/kg intravenously for 2 weeks. Treatment of the chronic phase is necessary for the prevention of endocarditis.

BACILLARY ANGIOMATOSIS

Both *B. henselae* and *B. quintana* can cause bacillary angiomatosis in immunocompromised hosts such as patients with HIV infection. This is a vascular proliferative disease involving the skin and other organs. The drug of choice for treatment is erythromycin (500 mg orally every 6 h for 3 months, or intravenously if severe). Patients intolerant of erythromycin can receive doxycycline 100 mg every 12 h for 3 months.

LEPTOSPIROSIS

Leptospirosis is an emerging global health problem with a wide geographical distribution occurring in tropical, subtropical and temperate zones. Pathogenic leptospires belong to the species *Leptospira interrogans*, with serovar *canicola* being the most frequent in the USA and Europe and serovar *icterohaemorrhagiae* causing the severe form (Weil's disease). Leptospirosis is primarily a disease of wild and domestic animals which may asymptotically pass large numbers of leptospires in their urine. Humans are infected mainly due to occupational or recreational contact with contaminated surface water, commonly during the summer. Rats are the most common source of human infection in developing countries, and dogs and livestock in industrialized countries. *Leptospira* may enter the body through cut or abraded skin, mucus membranes and conjunctivae. The acute generalized illness may mimic other tropical diseases (e.g. dengue fever, malaria and typhus) and common symptoms include fever, chills, myalgia, nausea, diarrhea and conjunctivitis. Manifestations of severe disease include jaundice, renal failure, hemorrhage and shock.⁴¹

PROPHYLAXIS OF LEPTOSPIROSIS

Chemoprophylaxis with doxycycline in soldiers visiting endemic areas was found to significantly reduce the number of cases of leptospirosis.⁴² In a randomized controlled trial, doxycycline prophylaxis did not reduce leptospiral rates but had a significant protective effect in reducing morbidity and mortality during outbreaks.⁴³ Chemoprophylaxis with doxycycline, either 200 mg weekly or a short course for 3 days, is recommended for outbreak control or travelers, although the data are limited. Penicillin G has been shown to be of little use. Empirical treatment with doxycycline has the additional benefit of covering other infections such as rickettsioses.

TREATMENT OF LEPTOSPIROSIS

The recommended treatment of leptospirosis is benzylpenicillin (1.2–2.4 g intravenously every 6 h for 7 days), with alternatives being doxycycline 100 mg every 12 h for 7 days, ceftriaxone 1 g/day for 7 days or cefotaxime. The mortality rate, duration of fever and progression of dysfunction of vital organs were similar among doxycycline, cefotaxime and penicillin for patients with both suspected and confirmed leptospirosis.⁴⁴ Ceftriaxone has efficacy against severe leptospirosis and is potentially preferable to penicillin (i.e. easier for healthcare personnel to administer, cost-effective and broader antimicrobial activity).^{45,46}

LYME DISEASE

Lyme disease is a multisystem disorder caused by spirochetes of *Borrelia burgdorferi*, which are transmitted by the bite of the tick species *Ixodes scapularis* and *I. pacificus*. Lyme disease is the most common tick-borne infection in North America and Europe.⁴⁷ Clinical manifestations involve the skin, joints, nervous system and heart. Early Lyme disease is characterized by erythema migrans which appears 1–2 weeks after infection and may persist for 8 weeks.⁴⁸ Approximately 50% of patients with proven Lyme disease do not recall having erythema migrans. Once *B. burgdorferi* disseminates throughout the body, a variety of systemic symptoms can occur, including secondary skin lesions, fever, headache and myalgia. Late complications include arthritis, neurological abnormalities and myocardial conduction defects.

The diagnosis is based on tick exposure, clinical features and serological tests or culture/PCR from joint aspirates or biopsy of lesions. Serological tests support but are not essential for the diagnosis of erythema migrans. The CDC recommends screening with an enzyme-linked immunosorbent assay (sensitive but not specific) for confirmation, followed by a Western immunoblot test (more specific).⁴⁹ After an infection, antibodies will persist for months or years, so serological testing does not reliably confirm past infection.

PROPHYLAXIS OF LYME BORRELIOSIS

The best method for preventing infection is to avoid exposure to vector ticks. Antimicrobial prophylaxis with doxycycline (200 mg single dose) and/or serological testing is recommended for the following situations:

- An attached tick is reliably identified as adult or nymph.
- The patient has come from an endemic area.
- Prophylaxis can be started within 72 h of removal of the tick.
- The local infection rate with *B. burgdorferi* is >20%.
- Doxycycline treatment is not contraindicated (pregnancy and children <8 years).

TREATMENT OF LYME DISEASE

EARLY DISEASE

Erythema migrans

In the absence of neurological disease or atrioventricular block the recommended treatment is with doxycycline 100 mg every 12 h for 14–21 days, amoxicillin 500 mg every 8 h or cefuroxime 500 mg every 12 h for 14–21 days. Macrolides are less effective and only recommended to patients intolerant of the first three antibiotics. Dosages include azithromycin 500 mg/day for 7–10 days, clarithromycin 500 mg every 12 h for 14–21 days or erythromycin 500 mg every 6 h for 14–21 days (weight-adjusted doses in children).

Lyme meningitis and other early neurological Lyme disease

Ceftriaxone 2 g/day for 14 days is recommended for adults, with weight-adjusted doses in children. In patients intolerant of β-lactams, doxycycline 200–400 mg/day in two divided doses for 10–28 days may be adequate. Alternatives for children are penicillin G (200 000–400 000 IU/kg per day), ceftriaxone (50–75 mg/kg per day) or cefotaxime (150–200 mg/kg per day in 3–4 divided doses). Although antibiotics do not hasten the resolution of facial nerve palsy, they are recommended to prevent further sequelae. A lumbar puncture is recommended for patients with a clinical suspicion of CNS involvement.

Lyme carditis

Patients may be treated with oral or parenteral antibiotics such as doxycycline or ceftriaxone, respectively, for 14 days. This should be done in hospital for patients with conduction block.

LATE DISEASE

Lyme arthritis

Lyme arthritis can usually be treated successfully with oral antibiotics like doxycycline, amoxicillin and cefuroxime (as per recommended doses for erythema migrans) for 28 days if there is no neurological disease. For persistent arthritis or joint swelling, a further course of ceftriaxone 2 g intravenously for 2–4 weeks is recommended. If there is no resolution and PCR is negative, then symptomatic treatment is advised (i.e. non-steroidal anti-inflammatory drugs or steroid injections).

Late neurological disease

Treatment with ceftriaxone (2 g intravenously) for 2–4 weeks.

Acrodermatitis chronica atrophicans

Treatment is as for erythema migrans.

Post Lyme disease syndromes

Most cases of Lyme disease are cured with antibiotics. There is a small sample of cases in which symptoms persist after treatment. These symptoms include muscle aches, joint pains, sleep disturbance and fatigue. The cause is unknown. There is no convincing evidence for the existence of symptomatic chronic *B. burgdorferi* infection among patients after a previously recommended course of treatment.⁵⁰

RELAPSING FEVER

Relapsing fever, caused by spirochetes belonging to the genus *Borrelia*, was once the cause of worldwide epidemic disease. This infection was mainly due to infection with *Borrelia recurrentis* which is the louse-borne form of the disease. There has been a reduction in this infection through improved living standards and the introduction of insecticides (reducing the louse vector).⁵¹ There is a tick-borne form of the disease which persists in endemic foci around the world, particularly in African nations. In Africa relapsing fever results from four main agents: *Borrelia crocidurae* in the west, *Borrelia hispanica* in the north, *Borrelia duttonii* (tick borne) and *Borrelia recurrentis* (louse borne) persisting in the east. All four agents cause relapsing fever; however, there are subtle clinical differences between species with the mortality rates being higher in the species found in the east.

TREATMENT OF RELAPSING FEVER

The recommended treatment for patients with tick-borne relapsing fever is doxycycline 100 mg every 12 h for 7–10 days or tetracycline 500 mg every 6 h for 7–10 days. When tetracyclines are contraindicated then a macrolide antibiotic may be given. Penicillins are effective when given intravenously.⁵² Treatment with any effective antibiotic typically induces the Jarisch–Herxheimer reaction within 2 h of initiating therapy and coincides with the clearing of spirochtemia. It is not prevented by prior treatment with prednisolone, but may be diminished with meptazinol.⁵³ Louse-borne relapsing fever responds to a single oral dose of tetracycline 500 mg, doxycycline 100 mg or erythromycin 500 mg.^{54,55} The fever lasts longer in patients treated with penicillin, and there are more frequent failures and relapses.

RICKETTSIOSSES

Rickettsioses are acute febrile, zoonotic diseases caused by rickettsiae, which are small, fastidious, obligate intracellular coccobacilli that invade endothelial cells and induce the formation of vasculitis.⁵⁶ Various arthropods (lice, fleas, ticks and mites) act as vectors and some mammals constitute the principal reservoirs. There are eighteen rickettsioses

now recognized. With the exception of *Rickettsia prowazekii* (epidemic typhus), all are zoonoses, and with the exception of *Coxiella burnetii* (Q fever), all are unable to survive outside a mammalian host or vector.

The main types are described below:

- **Murine typhus** is caused by *R. typhi*, with rats and other rodents acting as reservoirs and *Xenopsylla cheopis* (oriental rat flea) as the principal vector. Most cases are mild and present with non-specific features including fever, constitutional symptoms and a maculopapular rash.
- **Mediterranean spotted fever** and its variants are caused by *R. conorii* and transmitted by dog ticks in urban and suburban areas. The disease is present in Europe, Africa and Asia. Clinical features include fever, constitutional symptoms and a generalized maculopapular rash; there may be an eschar from the tick bite. Most cases are mild and the overall fatality rate is 2%.
- **African tick bite fever** is a rickettsiosis commonly encountered in travel medicine. Caused by *R. africae*, it is endemic in some parts of rural sub-Saharan Africa and the eastern Caribbean. Cattle ticks of the *Amblyomma* genus act as both reservoirs and vectors. Clinically patients present with a headache, neck myalgia, eschars and lymphadenitis; 30% may have a vesicular rash and mouth blisters. Most cases are self-limited with patients infected during wild game safaris and bush walks. No fatalities have been reported.
- **Scrub typhus** is a common infectious disease of rural south and southeastern Asia and the western Pacific, where there are ~1 million cases/year. It tends to occur in personnel working on the land or rice fields and there have been a large number of reports in military personnel. The disease is caused by *Orientia tsutsugamushi* transmitted by the bites of mites (chiggers). Patients present with fever, lymphadenitis and an eschar (50%). Most cases are mild; however, if untreated, complications ensue. It has a fatality rate of 1–35%.
- **Epidemic typhus** caused by *R. prowazekii* is transmitted in louse-infested environments such as refugee camps and prisons.
- **Rocky Mountain spotted fever** is caused by *R. rickettsii* and is transmitted by *Amblyomma* and *Dermacentor* ticks. The disease is endemic in South East and Midwestern USA and South America, and affects mainly hikers who get exposed to tick-infested habitats.

Other rickettsioses include North Asia tick typhus (*R. sibirica*), Queensland tick typhus (*R. australis*) and *R. aeschlimannii*.

DIAGNOSIS

The main laboratory options available include culture, PCR and serological tests but patients tend to be diagnosed clinically. In practice, serology is used the most but mainly to provide a retrospective diagnosis.

TREATMENT OF RICKETTSIOSSES

As laboratory diagnosis is difficult patients are started on presumptive therapy whenever a case of rickettsiosis is suspected. The standard regimen consists of doxycycline 200 mg/day for 3–14 days. Chloramphenicol and macrolides are good alternatives to doxycycline. The fluoroquinolones tend to fail clinically despite exhibiting good in-vitro activity.

PREVENTION

The best preventive measure is to avoid typical risk settings when traveling in areas of endemicity; if this is not possible, then measures aimed at reducing the risk of arthropod bites should be taken (i.e. using repellents and self-checking methods). Weekly 200 mg doxycycline has been used to prevent scrub typhus in military personnel deployed in endemic areas and could be recommended to travelers.⁵⁷ Currently there are no vaccines available.

Q FEVER

Q fever is a worldwide zoonosis caused by *Coxiella burnetii*, an obligate, intracellular, Gram-negative organism which is seen throughout the world.⁵⁸ The organism can infect a variety of hosts including humans, ruminants, pets, birds, reptiles and ticks. It is known to be category B bioterrorism agent, as it can survive in the environment for weeks, it can be aerosolized and is highly infectious.⁵⁹ Human infection is usually acquired by inhalation of small numbers of airborne organisms when in proximity to infected domestic animals, hides, manure, dust, milk and, especially, placentas. Infection may also be acquired via ingestion or direct skin penetration. It has been shown that in endemic areas patients do not necessarily need to be directly exposed to ruminants to get an infection. The incidence of Q fever is higher in certain countries such as France (500 cases/million persons) and Australia (38 cases/million persons), whereas in the USA the incidence is much lower (0.28 cases/million persons). There have been reports of Q fever infection acquired by US military personnel deployed overseas in Iraq and Afghanistan. The incubation period for Q fever is 2–6 weeks.⁶⁰

CLINICAL MANIFESTATIONS

Q fever has a variable presentation and infection can lead to asymptomatic seroconversion, acute disease or chronic disease. Various host factors – including male sex, immunosuppression and age – influence the extent of the clinical disease:

- *Acute disease:* 50–60% of patients are asymptomatic. Early disease leads to a flu-like illness, with a significant number of patients having pneumonia or hepatitis.

- *Chronic disease:* Patients with certain conditions (pregnancy, immunosuppression, heart valve lesions) are more susceptible to developing chronic disease, of which endocarditis is the most common form and carries a high mortality rate. Rare manifestations include osteomyelitis, granulomatous hepatitis, chronic pulmonary infections and chronic fatigue syndrome.

DIAGNOSIS

Diagnosis relies on serological testing with antibody detection by immunofluorescence and PCR (useful in early disease). Isolation of the organism should only be done when the appropriate laboratory facilities are in place. Diagnosis relies on phase variation of *C. burnetii* with phase 1 antibodies elevated in chronic disease and phase 2 in acute.

TREATMENT OF Q FEVER

- *Acute disease:* Doxycycline 100 mg every 12 h for 14 days is recommended unless the patient is pregnant, younger than 8 years or allergic (an alternative is co-trimoxazole). The utility of the macrolides is unclear and the fluoroquinolones may be useful in the treatment of CNS disease (although there is a lack of supporting data).
- *Chronic disease:* In-vitro studies have shown that a combination regimen of doxycycline (100 mg every 12 h) and hydroxychloroquine (200 mg every 8 h) for 18 months should be considered for the treatment of Q fever endocarditis. Surgery is an important component of treatment. Alternative regimens used include fluoroquinolones or rifampicin instead of hydroxychloroquine. Osteoarticular Q fever is rare and should be treated for a prolonged time period.
- *Vaccine:* In Australia there is a licensed whole cell vaccine which might be beneficial in people such as veterinarians, abattoir workers and laboratory personnel (efficacy >95%).

EHRLICHIOSIS

'Ehrlichiosis' is a generic name for infections caused by obligate intracellular bacteria in the family Anaplasmataceae, chiefly *Ehrlichia* and *Anaplasma*.⁶¹ Human infections are caused by at least three distinct species discovered during the period 1980–1990: *Ehrlichia chaffeensis* (human monocytic ehrlichiosis, HME), the canine pathogen *Ehrlichia ewingii* (similar to *E. chaffeensis* but propagates in neutrophils) and *Anaplasma phagocytophilum* (human granulocytic anaplasmosis, HGA).

Most infections are transmitted in May to August by a tick bite. Patients present with fever, headache, myalgia, leukopenia and/or thrombocytopenia and increased transaminase levels. Rashes are more common in HME and CNS infections in HGA. Fatalities are more common in the immunosuppressed.

DIAGNOSIS

An empirical diagnosis must be made early as the disease can be rapidly progressive and fatal. Diagnosis is confirmed by peripheral blood smears (more useful for HGA), molecular diagnosis by PCR, in-vitro cultivation (possible for *E. chaffeensis* or *A. phagocytophilum*) and serology by a four-fold rise or fall in antibody titer (however, there are high false-positive rates).

TREATMENT OF EHRLICHIOSIS

Although there have been no clinical trials conducted, empirical data support the use of tetracyclines to treat all forms of ehrlichiosis (doxycycline for 5–14 days) which should be initiated promptly. An alternative is rifampicin, which has shown some clinical success. There are few data to support the β-lactams, macrolides, quinolones and aminoglycosides. In the case of young children (<8 years) it is recommended that they start with doxycycline for 3 days and then continue with amoxicillin for 14 days.

VIRAL ZOONOSES

No specific treatment is established for most viral zoonoses. The exceptions are hantavirus (hemorrhagic fever with renal syndrome, hantavirus pulmonary syndrome) and Lassa fever.

LASSA FEVER

Lassa fever is a viral hemorrhagic fever transmitted by multimammate rats (*Mastomys natalensis*) and is found predominantly in West Africa.⁶²

CLINICAL MANAGEMENT

All suspected cases should be admitted to isolation facilities. Ribavirin (ribavirin) and general support are needed. Ribavirin is a guanosine analog which has broad-spectrum antiviral activity and should be given within 6 days of the start of the illness. Ribavirin should be given intravenously in a loading dose of 30 mg/kg, followed by 15 mg/kg every 6 h for 4 days, then 7.5 mg/kg every 8 h for 6 days. The only important adverse effect of ribavirin in humans is mild, usually reversible, anemia. It is contraindicated in pregnant women.

PROPHYLAXIS OF LASA FEVER

For needlestick or other high-risk contact, oral ribavirin 5 mg/kg every 8 h for 2–3 weeks would be a logical step, although it is of unproven efficacy.

Ribavirin is also useful in other hemorrhagic fevers such as Argentine hemorrhagic fever and also in hantavirus infections.^{63,64} However, the use of ribavirin for hantavirus pulmonary syndrome has so far not demonstrated an appreciable drug effect. There is a requirement for further trials to assess the efficacy and safety of this drug.⁶⁵

CHAPTER

62 Malaria

Nicholas J. White

Malaria is the most important parasitic disease of humans. It is estimated to affect approximately 200 million people. The annual death toll from *Plasmodium falciparum* infections is approximately one million. Pregnant women, infants and those over 60 years old are at greatest risk. Most of the deaths are in African children, and most occur away from facilities where optimum antimalarial treatment can be given. Unlike many other infections, the mortality rate rose in recent decades and this was attributed directly to increasing antimalarial drug resistance.¹ Fortunately there has been a huge international investment in malaria control and this trend has now reversed as effective drugs have been rolled out. Much antimalarial treatment is still administered for the empirical self-treatment of febrile illnesses in the tropics. The amounts of the drugs used are enormous, and ineffective self-treatment is widespread. As malaria is one of the most common causes of fever in tropical countries it must be excluded in any febrile patient living in, or returning from, the tropics. Ideally, antimalarial drugs should be given only for the treatment of microscopically confirmed malaria infections or for the prevention of malaria in pregnant women or travelers. The rapid development of resistance to most of the available antimalarial drugs by the potentially lethal parasite *P. falciparum* has compromised considerably recommendations for both prevention and treatment.² The most important recent development in antimalarial chemotherapy has been the introduction of the artemisinin derivatives. There has been a global switch from ineffective monotherapies to artemisinin-based combination therapies (ACTs) for the treatment of uncomplicated falciparum malaria, and artesunate is replacing quinine for the treatment of severe malaria. It is now accepted that, in order to delay the emergence of resistance, just as in the treatment of tuberculosis, leprosy and HIV/AIDS, combinations of drugs with different modes of action should be used. Where possible, fixed-dose artemisinin derivative combinations (FDCs) are replacing the separate medicines.³ As resistance has now been reported to all available antimalarial drugs, treatment recommendations must be under constant review.

ANTIMALARIAL DRUG RESISTANCE AND THE CHOICE OF DRUGS

Although it had been suspected for three centuries, the first cases of quinine resistance were documented only 90 years ago. Fortunately, quinine resistance progressed very slowly and quinine still remains useful today.

Within a few years of the introduction of the dihydrofolate reductase inhibitors pyrimethamine and proguanil as antimalarial treatments in the late 1940s and early 1950s, high-level

resistance was noted in both *P. falciparum* and *Plasmodium vivax*.⁴ Resistance could also be selected readily in the laboratory. Nevertheless, these drugs remained useful in prophylaxis, but for treatment, use of proguanil was discontinued, and pyrimethamine was later prescribed in a fixed combination with long-acting sulfonamides – most commonly sulfadoxine (SP).

Chloroquine took over rapidly as the treatment of choice for all malaria, and was also used widely in prophylaxis. Chloroquine resistance in *P. falciparum* was first recorded in the late 1950s, and by the early 1970s had become a significant problem in South America and South East Asia. During the 1980s, chloroquine resistance spread remorselessly across southern Asia and in the 1990s marched across the entire length and breadth of the African continent. Few tropical countries are now unaffected, and chloroquine is no longer recommended for falciparum malaria. High-level chloroquine resistance in *P. vivax* was reported first on the island of New Guinea, and more recently in other parts of Oceania, Asia and South and Central America.^{4,5}

Amodiaquine shares cross-resistance patterns with chloroquine, but is significantly more effective than chloroquine against resistant parasites and has replaced chloroquine in some areas. It is combined with artesunate and is now available as an FDC ACT.

Resistance to combinations of pyrimethamine and long-acting sulfonamides (SP) developed rapidly after their introduction for routine treatment in South East Asia and South America, and has spread across Africa, where they replaced chloroquine as first-line treatment. The SP combination is now used only in combination with artesunate⁵ but it is still used alone in intermittent preventive treatment (IPT). The combination of chlorproguanil (or proguanil) and dapsone is more effective than SP against antifol-resistant parasites and provides less selection pressure to the emergence of resistance.⁶ However, development of a fixed-dose formulation has stopped recently because of the risks of anemia related to dapsone hemolysis.

Mefloquine is generally effective against multiresistant strains of *P. falciparum*. Resistance emerged in South East Asia during the 1990s, where mefloquine was used but the artesunate-mefloquine ACT remains highly effective almost everywhere.^{7,8}

Although halofantrine is intrinsically more active than mefloquine, susceptibility to the two drugs is linked, and serious concerns over cardiotoxicity and its high cost have limited its use.⁹ Fortunately, resistance to quinine has remained low grade in South America and South East Asia (although susceptibility has declined slowly) and has not been a problem in Africa. However, because of consistent minor adverse effects, adherence is very poor with the 7-day courses of quinine necessary for cure, and treatment failure rates up to 50% have been reported. Quinine is usually combined with either tetracycline (or doxycycline) or in some areas clindamycin to prevent recrudescences of falciparum malaria. Even in areas with a high prevalence of resistance, the quinine–tetracycline combination, given for 7 days, still retains cure rates of >85%.¹⁰

Atovaquone–proguanil has been introduced recently. It is highly effective against all malaria parasites and is used mainly as chemoprophylaxis. High-level resistance to atovaquone was reported in early clinical trials and remains a concern if this drug is deployed widely. However, the very high costs of manufacture and consequent high price have limited its use.

The artemisinin compounds are antimalarial peroxides derived from qinghao or *Artemisia annua* (sweet wormwood). Discovered in China, they are the most rapidly effective and have the broadest stage-specificity of action of all antimalarial drugs.¹¹ They are well tolerated, retain excellent efficacy against multi-resistant parasites and are rapidly effective in severe malaria. As they also prevent gametocyte development, and therefore reduce transmission, this can decrease the incidence of malaria in low transmission settings. Resistance has been reported recently but is confined to Western Cambodia.^{12,13} In uncomplicated malaria these drugs are used in combination with other antimalarial drugs (ACTs). Combined with existing drugs they accelerate the initial therapeutic response, improve efficacy, reduce gametocyte carriage and, in the case of mefloquine, improve tolerance. Artesunate–mefloquine has proved highly effective in South East Asia, despite pre-existing mefloquine resistance.⁸ The fixed combination of artemether and lumefantrine is a highly effective and well-tolerated alternative to artesunate–mefloquine. It is now the most widely used ACT in the world. Dihydroartemisinin–piperaquine is another fixed combination from China with excellent activity against multidrug-resistant parasites.¹⁴

RESISTANCE

Resistance to antimalarial drugs arises through the selection of rare naturally arising mutants with reduced drug susceptibility. Unlike some bacteria, plasmodia do not have transferable resistance mechanisms, but they are eukaryotes, and they can acquire or lose polygenic resistance mechanisms during meiosis. Resistance arises readily to drugs such as the antifols or atovaquone because single-point mutations confer resistance (as opposed to a requirement for several unlinked mutations, i.e. epistasis) and per-parasite mutation frequencies for viable mutations are relatively high (>1 in 10¹³ mitotic divisions).¹⁵ Pyrimethamine and the active metabolites of the antimalarial biguanides (cycloguanil from proguanil, and chlorcycloguanil

from chlorproguanil) interfere with folic acid synthesis in the parasite by inhibiting the bifunctional enzyme dihydrofolate reductase-thymidylate synthase (DHFR). Sulfonamides act at the previous step in the synthetic pathway by inhibiting dihydropteroate synthase (DHPS), and there is marked synergy between the two classes of compounds (see Ch. 2). Resistance in *P.falciparum* and *P.vivax* is associated with point mutations in the DHFR gene that lead to reduced affinity (100–1000 times less) of the enzyme complex for the drug. For *P.falciparum* the first mutation is usually at position 108 of *PfDHFR* (serine to asparagine). For *P.falciparum* this has little clinical effect initially, but mutations then arise at positions 51 and 59, which confer increasing resistance to pyrimethamine.¹⁶ Infections with ‘triple’ mutants are relatively resistant but some therapeutic response is usually seen, particularly if there is background immunity. The acquisition of a fourth mutation at position 164 (isoleucine to leucine) renders the available antifolate antimalarials completely ineffective. This mutation is prevalent in parts of South East Asia and South America, and has recently emerged in East Africa.¹⁷ Mutations conferring moderate levels of pyrimethamine resistance do not necessarily confer cycloguanil resistance, and vice versa. For example, mutations at position 16 (alanine to valine) plus serine to threonine at position 108 confer high-level resistance to cycloguanil but not pyrimethamine. In general, the biguanides (cycloguanil, chlorcycloguanil) are more active than pyrimethamine against the resistant mutants (and they are more effective clinically too), but they are ineffective against parasites with the DHFR 164 mutation. *P.vivax* shares similar antifol resistance mechanisms through serial acquisition of mutations in *PvDHFR*.

The marked synergy with sulfonamides and sulfones is very important for the antimalarial activity of sulfa–pyrimethamine or sulfone–biguanide combinations. Sulfonamide and sulfone resistance also develops by progressive acquisition of mutations in the gene encoding the target enzyme DHPS (which is a bifunctional protein with the enzyme dihydropteridine pyrophosphokinase). Specifically altered amino acid residues have been found at positions 436, 437, 540, 581 and 613 in the DHPS domain. The 581 and 631 mutations do not occur in isolation, but always on top of an initial mutation (usually alanine to glycine at 437).¹⁸

The mode of action and mechanisms of resistance of the quinoline antimalarials remains controversial. These drugs are weak bases, and they concentrate in the acid food vacuole of the parasite, but this in itself does not explain their antimalarial activity. Chloroquine binds to ferriprotochlorophyrin IX, a product of hemoglobin degradation, and thereby chemically inhibits heme dimerization (see Ch. 2). Chloroquine also inhibits competitively glutathione-mediated heme degradation, another parasite detoxification pathway. Chloroquine resistance is associated with reduced concentrations of drug in the acid food vacuole. Both reduced influx and increased efflux have been implicated. Resistant parasites pump chloroquine out 40–50 times faster than drug-sensitive parasites. This efflux mechanism is similar to that found in multidrug-resistant (MDR) mammalian tumor cells. One of the efflux mechanisms is through an ATP-requiring

transmembrane pump, P-glycoprotein. These MDR genes (*pfmdr1*) are found in increased numbers in most quinine and mefloquine-resistant *P. falciparum* parasites, and point mutations (notably asparagine to tyrosine at position 86) are associated with chloroquine resistance. However, the key first step in aminoquinoline resistance is the development of point mutations in PfCRT (a food vacuolar membrane protein with a probable transporter function).^{19,20} The principal correlate of chloroquine resistance is a point mutation, resulting in a change in coding from lysine to threonine, at position 76 of PfCRT. From an epidemiological standpoint multiple unlinked mutations are probably required for the development of high-level chloroquine resistance, and it is likely that other contributors to quinoline resistance remain to be discovered. The role of these mechanisms in resistance to the other aryl aminoalcohol antimalarials (amodiaquine, halofantrine, lumefantrine, piperaquine and pyronaridine) also remains to be elucidated.

The chloroquine efflux mechanism in resistant parasites can often be inhibited by a number of structurally unrelated drugs such as calcium-channel blockers, tricyclic antidepressants, phenothiazines, cyproheptadine and antihistamines, whereas mefloquine resistance is reversed by penfluridol, which does not reduce chloroquine efflux. Clinical trials of reversers have yielded conflicting results. Whether general use of resistance reversers will be a safe and feasible therapeutic option remains to be seen. In general, antimalarial drug resistance to mefloquine, quinine, lumefantrine and halofantrine is linked but, as suggested by their different susceptibility to reversing agents, chloroquine resistance and mefloquine resistance are not linked closely. Indeed, within a particular geographical area there is a reciprocal relationship; mefloquine resistance is correlated inversely with chloroquine resistance. Part of this is explained by the greater propensity of wild type compared with mutant *pfmdr1* to amplify this gene (which reduces mefloquine susceptibility).²¹

Atovaquone interferes with parasite mitochondrial electron transport and depolarization within the parasite mitochondria, thereby blocking cellular respiration. High levels of resistance result from single point mutations in the gene encoding cytochrome b. This gene is encoded on a small extrachromosomal plastid-like DNA-containing organelle that may have an intrinsically high mutation rate. Viable resistance mutations arise frequently in vivo (about 1 in 10^{12} asexual divisions).

The artemisinin drugs are thought to kill malaria parasites by generating carbon-centered free radicals, which alkylate critical proteins. Parasiticidal activity is dependent on the integrity of the peroxide bridge. Although in general multiresistant parasites are more artemisinin resistant, the degree of resistance is slight and very unlikely to be of clinical relevance. Reduced susceptibility to artemisinins can be induced experimentally, and resistance manifest in vivo by slow parasite clearance has been reported recently from Western Cambodia.¹³

Several factors encourage the development of antimalarial drug resistance:

- The intrinsic frequency with which the genetic changes occur.
- The degree of resistance conferred by the genetic change (pharmacodynamics).
- The proportion of all transmissible infections that are exposed to the drug.
- The drug concentration profile (pharmacokinetics).
- The pattern of drug use.
- The immunity profile of the community.¹⁵

Resistant parasites will be selected when parasites are exposed to subtherapeutic drug concentrations. Thus non-immune patients infected with large numbers of parasites who receive inadequate treatment (because of poor drug quality, reduced adherence, vomiting of an oral treatment, etc.) are a potent source of resistance. This emphasizes the importance of correct prescribing and good adherence to prescribed drug regimens in slowing the emergence of resistance. Resistance develops more slowly in high-transmission areas because the patients' background immunity may eliminate the resistant mutants and stop them being transmitted. The spread of resistant mutant parasites is facilitated by the use of drugs with long elimination phases, which provide a 'selective filter', allowing infection by the resistant parasites while the residual antimalarial activity prevents infection by sensitive parasites. Slowly eliminated drugs such as mefloquine (terminal half-life 3 weeks) or chloroquine (terminal half-life 2 months) persist in blood for months after drug administration and provide such a selective filter.

PREVENTION OF RESISTANCE USING COMBINATIONS OF ANTIMALARIAL DRUGS

The emergence of resistance can be prevented by the use of combinations of drugs with different mechanisms of action, and therefore different drug targets and unlinked resistance mechanisms.^{15,22} The same rationale underlies the current treatment of tuberculosis, leprosy, HIV infections and many cancers. If two drugs with different mechanisms of action are used, then the per-parasite probability of developing resistance to both drugs is the product of their individual per-parasite probabilities. For example, if the per-parasite probability of developing resistance to drug A and drug B are both 1 in 10^{12} , then a simultaneously resistant mutant will arise spontaneously every 1 in 10^{24} parasites. As there are approximately 10^{17} malaria parasites in the entire world, and a cumulative total of less than 10^{20} in 1 year, such a simultaneously resistant parasite would arise spontaneously roughly once every 10 000 years – if the drugs always confronted the parasites in combination. Thus the lower the de-novo per-parasite probability of developing resistance, the greater the delay in the emergence of resistance. This powerful approach has several limitations. If not everyone receives the combination, and some patients receive only one of the components, or there is already high-level resistance to one of the components, then resistance can arise (emphasizing the importance of achieving high coverage when these drugs are deployed). Combinations are also more expensive. However, the increased cost is outweighed by the longer-term benefits.

CLINICAL ASSESSMENT OF RESISTANCE

Low-grade resistance (late parasitological failure; R1 resistance) is usually manifest by recrudescences, which tend to occur several weeks after primary treatment. Most recrudescences of malaria occur within 6 weeks of initial treatment. For quinine and other rapidly eliminated drugs the median time to recrudescence as resistance begins is approximately 3 weeks; however, for drugs that have long terminal half-lives, such as mefloquine, the recrudescences can occur up to 10 weeks, and possibly longer, after the primary treatment. Although the treatment is unable to eradicate the parasites in such cases, the multiplication rate is suppressed while therapeutic blood concentrations are still present in the blood. The more susceptible the parasites, the lower the blood concentrations required to suppress parasite multiplication. As resistance worsens, the median time to recrudescence becomes shorter and an increasing number of patients are seen in whom parasitemia fails to clear by 7 days following treatment (early treatment failure; R2 resistance). Eventually the situation deteriorates further and some patients do not respond at all to antimalarial treatment (R3 resistance). Obviously, alternative treatment should be employed before this stage. In the individual patient long parasite clearance times (>4 days) are a common predictor of subsequent recrudescence.

UNCOMPLICATED MALARIA

MANAGEMENT

Infections with *P. vivax*, *P. malariae* or *P. ovale* are very rarely fatal, but *P. falciparum* malaria may progress rapidly to severe disease and death, particularly in the non-immune patient or young children in endemic areas. If the clinician is in any doubt about the severity of the infection, the patient should remain in hospital under observation. Otherwise, uncomplicated malaria can be treated on an outpatient basis. If there is any uncertainty over speciation of the parasites they should be considered as *P. falciparum*, and if there is any doubt over drug susceptibility the infection should be considered as resistant.⁵ A thorough history and examination should pay particular attention to the likely origin of the infection and any previous antimalarial treatment. Except in areas without facilities for diagnosis, antimalarial treatment should be given only for slide- or dipstick-confirmed malaria. In general, administration of the first dose should be observed. Symptomatic measures are important. The incidence of vomiting, particularly in children, is proportional to fever. Young children with high fevers should be cooled, given paracetamol (acetaminophen) (15 mg/kg), and allowed to settle before receiving the first oral dose of antimalarial treatment. The patient should be observed for 1 h after drug administration; if vomiting occurs within this period the drugs should be re-administered (see below). Ideally, patients should be seen daily for a clinical

examination and a blood smear until they are asymptomatic and parasite negative. They should be advised to return to the same hospital or clinic if fever recurs within 6 weeks.

SPECIFIC ANTIMALARIAL TREATMENT

P. VIVAX, *P. OVALE* AND *P. MALARIAE*

P. vivax is the most common cause of malaria in the Indian subcontinent, Central America, North Africa and the Middle East. There is unequivocal evidence of chloroquine resistance in *P. vivax* from parts of Asia, the Americas and Oceania, but in most vivax-affected areas, infections with this parasite, and the other two that cause the benign human malarias, remain sensitive to chloroquine. Treatment is rapidly effective and usually well tolerated. The main adverse effect is troublesome pruritus in dark-skinned patients, which occurs in approximately 50% of cases. The quinoline antimalarials may all exacerbate the orthostatic hypotension that commonly complicates malaria, and symptomatic postural hypotension is common.²³ Rarely (less than 1 in 1000), chloroquine treatment is associated with transient neuropsychiatric abnormalities. All the currently available ACTs except artesunate–sulfadoxine–pyrimethamine reliably and rapidly treat vivax malaria.

The total dose of chloroquine is 25 mg base/kg, divided classically as 10, 10 and 5 mg/kg given on days 0, 1 and 2, respectively. This schedule may be compressed into a 36 h treatment regimen, giving 10, 5, 5 and 5 mg/kg at 12-hour intervals²⁴ (Table 62.1). Both *P. vivax* and *P. ovale* infections produce persistent dormant hepatic forms of the parasite (hypnozoites), which are resistant to chloroquine. These become activated between 3 weeks and 1 year after the primary infection, and cause the relapses so characteristic of these infections. (A *relapse* is a recurrent infection caused by the development of persistent hypnozoites: the primary blood-stage infection has cleared. A *recrudescence* is a blood-stage infection that is not eradicated, but may decline below the level of microscopic detection, and then increases later causing patent parasitemia and clinical illness.) The hypnozoites are sensitive only to the 8-aminoquinoline antimalarials. The eradication of both the blood stage and the persistent liver stages of *P. vivax* and *P. ovale* malaria is called a ‘radical cure’. For this, primaquine has in the past been given in an adult daily dose of 15 mg base (0.25 mg/kg) for 14 days, with strains of *P. vivax* from Oceania and some parts of South East Asia being treated with a daily dose of 22.5–30 mg base (0.375–0.5 mg/kg) for 14 days. Shorter courses are less effective. It is now recommended by the World Health Organization (WHO) that *P. vivax* everywhere should be treated with a higher dose: 0.5 mg base/kg for 14 days.⁵ Primaquine has weak asexual-stage activity against *P. vivax* and this may mask low-level chloroquine resistance if the two drugs are given together. Thus chloroquine plus primaquine constitutes a ‘combination treatment’. In patients with a ‘mild variant’ of glucose-6-phosphate dehydrogenase

Table 62.1 Antimalarial drugs: recommended doses for treatment

	Uncomplicated malaria: dose^a	Usual adult dose^a	Severe malaria^b
Chloroquine	10 mg base/kg followed by 10 mg/kg at 24 h and 5 mg/kg at 48 h or 5 mg/kg at 12, 24 and 36 h. Total dose 25 mg base/kg. For <i>P. vivax</i> or <i>P. ovale</i> add primaquine 0.5 mg base/kg daily for 14 days ^c for radical cure	4 × 150 mg tablets followed by 4 then 2 or 2, 2	No longer recommended
Sulfadoxine–pyrimethamine (SP)	25/1.25 mg/kg single oral dose	3 tablets	Not recommended
Mefloquine	25 mg/kg; give 15 mg base/kg followed by 10 mg/kg dose 8–24 h later. Alternatively, give 8–8.3 mg/kg daily for 3 days	3 × 250 mg tablets + 2 × 250 mg tablets	
Artesunate	In combination with a slowly eliminated drug 4 mg/kg daily for 3 days. ^{d,e} If used alone or with a tetracycline or clindamycin, 4 mg/kg followed by 2 mg/kg daily: total 7 days	4 × 50 mg daily for 3 days in combination 4 × 50 mg followed by 2 × 50 mg daily for 6 days	2.4 mg/kg i.v. or i.m. immediately then at 12, 24 h and then daily ^b
Artemether	Same oral dose regimens as for artesunate ^e	5 × 40 mg daily for 3 days in combination	3.2 mg/kg i.m. immediately followed by 1.6 mg/kg daily ^b
Dihydroartemisinin	Same oral dose regimens as for artesunate ^e	5 × 40 mg followed by 3 × 40 mg daily for 6 days	
Dihydroartemisinin–piperaquine	Adult dose: 120/720 mg daily for 3 days	3 tablets once daily for 3 days	
Artemether–lumefantrine	Adult dose: 80/480 mg every 12 h for 3 days with food or milk	4 tablets every 12 h for 3 days	
Quinine	10 mg salt/kg every 8 h for 7 days. Often combined with tetracycline ^f (4 mg/kg) every 6 h, doxycycline (3.5 mg/kg) daily or clindamycin (10 mg/kg) every 12 h, all for 7 days	2 × 300 mg every 8 h	20 mg salt/kg by intravenous infusion over 4 h ^g followed by 10 mg/kg infused over 2–8 h every 8 h ^b
Quinidine	Recommended only if alternatives unavailable. Dose as for quinine		10 mg base/kg infused at constant rate over 1 h followed by 0.02 mg/kg per minute, with electrocardiographic monitoring ^b
Atovaquone–proguanil	1000/400 mg once daily for 3 days with food or milk	4 tablets every 6 h for 3 days	

^aConfusingly, many antimalarials are provided in different salts, so treatment recommendations are given in weights of base equivalent. It is important that these are not confused.

^bOral treatment should be substituted as soon as the patient can take tablets by mouth.

^cIf possible, check for glucose-6-phosphate (G6PD) deficiency. In patients with mild G6PD deficiency, give 0.75 mg/kg once weekly for 6 weeks. Do not use in pregnant women, newborns or in severe G6PD deficiency.

^dFor hyperparasitemic patients (>4% parasitemia in a non-immune) give artesunate for 5 days; 4 mg/kg daily for two additional days.

^eACTs currently recommended by WHO are artesunate–mefloquine, artesunate–amodiaquine, artesunate–SP, artemether–lumefantrine and dihydroartemisinin–piperaquine.

^fDoxycycline 3.5 mg/kg daily is an alternative to tetracycline. Tetracycline or doxycycline should not be given to pregnant women or children <8 years old.

^gAlternatively for the initial loading dose, 7 mg salt/kg can be infused over 30 min followed by 10 mg salt/kg over 4 h.

(G6PD) deficiency a single weekly dose of primaquine (0.75 mg/kg) can be given daily for 6 weeks.

Primaquine is an oxidant drug and causes hemolysis in patients with hereditary defects in the pentose-phosphate shunt, most commonly G6PD deficiency. In patients with severe variants of G6PD deficiency, primaquine is contraindicated; however, for patients with mild variants, primaquine should be given in a weekly dose of 45 mg base (0.75 mg/kg) for 6 weeks. Despite its use for over 50 years, the safety profile of primaquine needs further characterization. Primaquine should not be used in pregnancy or given to newborns. Pyrimethamine and the pyrimethamine–sulfonamide combinations are relatively ineffective against *P. vivax* in many areas

because of acquired resistance. All the other antimalarial drugs are active, and so for mixed infections requiring treatment for *P. falciparum* it is not necessary to add chloroquine. However, primaquine should be given as well to prevent relapses.

UNCOMPLICATED *P. FALCIPARUM* MALARIA

Antimalarial treatments are increasingly using combinations of antimalarial drugs. Several of the ACTs (artesunate–mefloquine, artemether–lumefantrine, dihydroartemisinin–piperaquine) can be relied upon everywhere in the

world. Resistance limits where artesunate–amodiaquine and artesunate–SP can be used. Atovaquone–proguanil is not deployed widely but is reliably effective for imported malaria. ACTs are now recommended first-line treatments in endemic areas everywhere. In a very few specific areas such as Central America where *P.falciparum* remains definitely sensitive, chloroquine can still be used in a total treatment dose of 25 mg base/kg (adult dose 1500 mg). There is no significant difference between the phosphate, sulfate or hydrochloride salts. If there is any doubt about antimalarial sensitivity in the area where malaria was acquired, *P.falciparum* infections should be considered resistant.

UNCOMPLICATED CHLOROQUINE-RESISTANT FALCIPARUM MALARIA

Amodiaquine is more effective than chloroquine against resistant strains of *P.falciparum*. It is also well tolerated. When used in prophylaxis, amodiaquine was associated with a 1 in 2000 incidence of agranulocytosis. The true incidence of this in therapeutic use is not known but is probably much lower, although the incidence is high in HIV-infected children.²⁵ Artesunate–amodiaquine is a treatment option where there is low-level aminoquinoline resistance. An alternative is artesunate–SP containing a single dose of sulfadoxine–pyrimethamine (20/1 mg/kg; corresponding to three tablets in an adult). This is a well-tolerated and effective treatment of sensitive strains. The principal adverse effects result from sulfonamide allergy. When used in prophylaxis the incidence of serious adverse effects is approximately 1 in 7000; fatal adverse effects occur in 1 in 18000.²⁶ In single-dose treatment the incidence of serious adverse effects appears to be significantly lower. Pyrimethamine-induced blood dyscrasias, usually seen in patients with underlying folate deficiency, are most unusual. Artesunate–SP is effective where there is either no antifol resistance or low-grade antifol resistance. There are no significant interactions among these drugs.

MULTIDRUG-RESISTANT *P.FALCIPARUM* MALARIA

ARTESUNATE-MEFLOQUINE

Mefloquine (hydrochloride) has the advantage of a long terminal elimination half-life of 2–3 weeks and in the past has been given in a single dose of 15 mg base/kg (adult dose three tablets of 250 mg) to semi-immune patients. This is no longer recommended.⁵ A higher dose of 25 mg base/kg (five tablets for an adult) is generally more effective and less likely to lead to resistance. Peak whole blood concentrations above 1000 ng/mL are effective. Absorption is augmented, but adverse effects are not increased, if the treatment dose is split (i.e. a 25 mg base/kg dose is given as 15 mg/kg initially, followed by 10 mg/kg 8–24 h later,

or as 8–8.3 mg/kg per day for 3 days). Combining mefloquine with artesunate (4 mg/kg per day for 3 days) improves efficacy and reduces immediate adverse effects. As with many antimalarial drugs, children tolerate mefloquine better than adults.²⁷ The principal adverse effect of mefloquine is immediate vomiting. This is less likely if the dosage is split. Patients must be observed for 1 h after the drug has been given. If vomiting occurs within 30 min the full dose of artesunate–mefloquine should be repeated. For vomiting 30–60 min later, half the dose should be given. Vomiting after 1 h does not require retreatment. Later adverse effects are all more common in adults and comprise nausea, dysphoria, dizziness or ‘muzziness’, poor concentration, sleeplessness, nightmares and postural hypotension. Mefloquine does not have significant cardiac effects. Adverse effects following mefloquine treatment are reported more frequently in women than in men. Serious, but reversible, neuropsychiatric reactions occur in approximately 1 in 1300 Asians patients receiving high-dose mefloquine treatment, but as many as 1 in 200 European and African patients. This rises to 1 in 20 if mefloquine is given following acute treatment of cerebral malaria, and it should not be used in this context.²⁸

ARTEMETHER-LUMEFANTRINE

The combination of artemether and lumefantrine is as effective as artesunate–mefloquine and has some advantages and disadvantages:

1. It is better tolerated (indeed it does not appear to have any significant adverse effects) and, in particular, produces less vomiting and has no central nervous toxicity.²⁹
2. The lumefantrine component is more rapidly eliminated than mefloquine (half-life c. 4 days compared with 14 days for mefloquine in malaria), which would be expected to reduce the selection of resistant parasites. On the other hand, this suppresses reinfections or relapses (post-treatment prophylaxis; PTP) for a shorter period.
3. Artemether–lumefantrine needs to be given twice daily for 3 days instead of once daily, and absorption of lumefantrine is very variable (like atovaquone and halofantrine, it is highly fat dependent³).

DIHYDROARTEMISININ-PIPERAQUINE

Dihydroartemisinin–piperaquine is another fixed-dose artemisinin combination from China. It has proved very well tolerated and highly effective against multiresistant falciparum malaria in adults and children across the world.¹⁴ Piperaquine is a bisquinoine compound with similar pharmacokinetic properties to chloroquine. It suppresses reinfection and relapse for longer than lumefantrine. Dihydroartemisinin–piperaquine is given once daily for 3 days.

ATOVAQUONE-PROGUANIL

Atovaquone-proguanil is very well tolerated and highly effective against all the human malaria parasites. Interestingly, the synergistic activity of proguanil with atovaquone is derived from the parent compound through an uncharacterized mechanism of action and not dihydrofolate reductase inhibition by the triazine metabolite cycloguanil. This is important because atovaquone-proguanil retains excellent activity against highly antifolate-resistant parasites, and also in East Asia where 20% of the population have a genetic polymorphism resulting in reduced CYP₄₅₀ 2C19 activity – the enzyme responsible for conversion of proguanil to cycloguanil. As the main drawback to atovaquone-proguanil is its cost, this compound has been used very little in malaria endemic areas. It is given in a 3-day course, and can be combined with artesunate to form an ACT. There is no pediatric formulation.

HALOFANTRINE

Halofantrine is intrinsically more active than mefloquine and is better tolerated.²⁷ It suffers the disadvantages of requiring multiple dose administration as it has very erratic oral bioavailability. Halofantrine absorption is augmented considerably by co-administration with fats or fatty food. The other adverse effect reported with high-dose treatment is diarrhea. Halofantrine does not have significant adverse central nervous system effects. Use of halofantrine has been associated with sudden death. Halofantrine, like quinidine, induces a predictable prolongation of the electrocardiograph QT interval (delayed ventricular repolarization).⁹ This can be pro-arrhythmic. Atrioventricular conduction abnormalities (first- and, rarely, second-degree block) have also been seen. These cardiac effects are augmented by previous treatment with mefloquine. Halofantrine should not be given to patients who have received mefloquine in the previous month or to patients either with known prolongation of the QT interval or who are receiving other drugs known to prolong the QT interval. This potentially lethal toxicity has markedly limited its use – indeed, as effective alternatives are usually available, there seems no reason to use it.

QUININE

Quinine sulfate, the time-honored remedy, at a dose of 10 mg salt/kg (adult dose 600 mg) every 8 h is effective in a 7-day course. Shorter courses (3–5 days) are much less effective. Quinine is usually combined with tetracycline, doxycycline or, particularly in children or pregnant women, with clindamycin in order to improve cure rates. Quinine is not well tolerated. The characteristic syndrome of ‘cinchonism’, comprising nausea, vomiting, dizziness, dysphoria and high-tone

deafness, is a predictable accompaniment of quinine treatment. In addition, the drug is extremely bitter and many children find it unacceptable. However, serious adverse effects, principally blindness, deafness or cardiac dysrhythmias, are unusual. Hypoglycemia is more common in severe malaria, although it may also develop in uncomplicated malaria treated by quinine, particularly in young children or pregnant women. Hypoglycemia results from stimulation of the pancreatic β-cells and consequent hyperinsulinemia.

ARTEMISININ DERIVATIVES

The artemisinin derivatives comprise the parent compound artemisinin, dihydroartemisinin (which is 5–10 times more potent) and the dihydroartemisinin derivatives artemether, artemotil (arteether) and artesunate. In vivo artesunate and artemether are converted back to dihydroartemisinin. The most widely used derivative is artesunate. These drugs are all well absorbed by mouth and rapidly eliminated (dihydroartemisinin half-life ~1 h). They are all very well tolerated with no consistent adverse effects.²⁹ Serious allergic reactions (usually preceded by urticaria) have been reported in approximately 1 in 3000 patients. The parasitidal and clinical responses are more rapid than with other antimalarials. They also reduce gamete carriage and therefore the transmission potential of the infection.³⁰ The artemisinin derivatives are usually combined with a more slowly eliminated drug in ACTs, in which case they are given over 3 days. In patients who have uncomplicated hyperparasitemia (i.e. a non-immune with more than 4% parasitemia but no vital organ dysfunction) the dose should be extended over 5 days (4 mg/kg per day for an additional 2 days after the 3-day ACT course is completed). When given with rapidly eliminated drugs (e.g. doxycycline or clindamycin) then artemisinin or its derivatives should be given for 7 days in a dose of 4 mg/kg initially then 2 mg/kg per day.

Travelers returning to the countries with no available artemisinin derivatives who have multiresistant *P. falciparum* malaria should be treated with quinine plus tetracycline or doxycycline.

MONITORING THE RESPONSE TO TREATMENT

If possible patients should be seen at least daily until parasite and fever clearance, although this is not possible in most endemic areas. If there is clinical deterioration or repeated vomiting, then parenteral treatment should be substituted. If there is an early failure of treatment suggesting drug resistance, then a different treatment must be substituted. If there is a return of parasitemia after 1 week, it may not be possible to distinguish recrudescence from reinfection in an endemic area (this requires a comparison of parasite genotypes).³¹

The choice of subsequent retreatment will then depend on the prevailing level of resistance. Most drugs can be repeated within 1 month, but for mefloquine this should be avoided as there is an increased risk of neuropsychiatric reactions with retreatment. Either a 7-day course of artesunate (or quinine) and doxycycline (clindamycin in children), or a 3-day, six-dose course of artemether-lumefantrine should be prescribed.

SEVERE P. FALCIPARUM MALARIA

MANAGEMENT

Severe malaria is a multisystem disease requiring intensive care management. Unfortunately, optimum treatment is usually not available in most of the areas of the world where severe malaria occurs. Severe malaria has been defined as the presence of one or more of the following: unrousable coma (cerebral malaria), severe anemia (haematocrit <15% plus parasitemia >100,000/ μ L), renal failure (serum creatinine >265 μ mol/L), pulmonary edema, hypoglycemia (glucose <2.2 mmol/L), shock, bleeding, repeated seizures, metabolic acidosis or haemoglobinuria. The clinician should not feel restricted by this definition.³² A simpler bedside assessment based on any impairment of consciousness or inability to sit unaided (prostration), acidotic breathing (respiratory distress), anuria, hypoglycemia, severe anemia, shock or a high parasitemia (>4% in a non-immune, >20% in any patient) identifies those patients in need of intensive care. Any patient in whom there is doubt as to the severity of the infection should be managed as described below.

A rapid clinical appraisal should be made. This includes assessment of the level of consciousness or central nervous system dysfunction, exclusion of covert seizure activity (clinical evidence of seizures can be subtle), measurement of vital signs (particularly respiratory pattern and rate), questioning of the patient or relatives concerning earlier antimalarial treatment, duration of impaired consciousness, convulsions and urine output. A malaria parasite count (thick and thin blood films), blood glucose, plasma bicarbonate or blood lactate, and hematocrit should be measured immediately. The patient should be rehydrated with saline and, if there is any doubt about the jugular venous pressure, a central venous line should be inserted and central pressure monitored. If hypoglycemia is suspected or confirmed, 0.3 g/kg (25 g) of glucose should be given by slow intravenous injection. The role of prophylactic intramuscular phenobarbital (phenobarbitone) in childhood cerebral malaria is now uncertain after a large study from Kenya showed significant protection against convulsions following 20 mg/kg of intramuscular phenobarbital, but an increased mortality.³³ This was associated with repeated diazepam administration (for uncontrolled seizures) and was attributable to respiratory arrest. No respiratory support was available. Some authorities still give a lower dose (7 mg/kg) of phenobarbital. Patients with respiratory abnormalities should be ventilated early, with care to avoid

even temporary hypercapnia. Prompt anticonvulsant therapy (intravenous lorazepam, midazolam or diazepam) should be given if there are seizures. A lumbar puncture should be performed to exclude coincident meningitis. Hemofiltration should be started early in patients with acute renal failure, and blood (preferably fresh) should be transfused if the hematocrit falls below 20%. Antimalarial drugs should be given on a milligram-per-kilogram basis (in adults and children). The patient should be weighed (or weight estimated) and parenteral treatment given intravenously if possible. Artesunate can be given by slow intravenous injection but quinine or quindine must be given by slow, rate-controlled intravenous infusion. Rises in parasitemia in the first 12 h after antimalarial treatment has started should *not* be attributed to drug resistance, and rapid declines in parasitemia shortly after drug administration do not indicate a very sensitive infection. These changes result from natural fluctuations in parasitemia related to synchronous schizogony and sequestration, respectively. If, by 48 h after starting treatment, parasitemia has not fallen by more than 75% (R3 resistance), then the treatment should be changed; however, this high-level resistance is extremely unusual. Therapeutic responses are assessed in terms of clinical measures: times to recovery of consciousness, and in adults the times to reach Glasgow coma scores of 8, 11 and 15; the time until fever falls below 37.5°C and remains below this for 24 h; and times to sit, eat and walk, together with laboratory measures, which include the rate of fall in plasma lactate or normalization of plasma bicarbonate, and the times to reduce parasitemia by 50%, 90% and 100%. If the parasitemia has not cleared by 7 days, treatment should be continued, provided of course the counts are not rising. Adult patients receiving quinine, artesunate or artemether should receive either a full 3-day course of an ACT (not with mefloquine if the patient had cerebral malaria) or a 7-day course of doxycycline, and children clindamycin, which starts when the patient can take oral medicine.

SPECIFIC ANTIMALARIAL THERAPY

Intravenous artesunate is now established as the treatment of choice for adults with severe malaria. In trials conducted in South East Asia, artesunate reduced the mortality of severe malaria by 35% compared with quinine (Fig. 62.1). As severe malaria has certain differences between adults and children in high transmission areas, there is still uncertainty whether artesunate, artemether or quinine is the preferred treatment in African children with severe malaria.

ARTEMISININ, ARTEMETHER, ARTEETHER AND ARTESUNATE

Artemisinin and its derivatives have given consistently faster parasite and fever clearance times, and have proved rapidly effective in severe malaria.¹¹ Large randomized trials

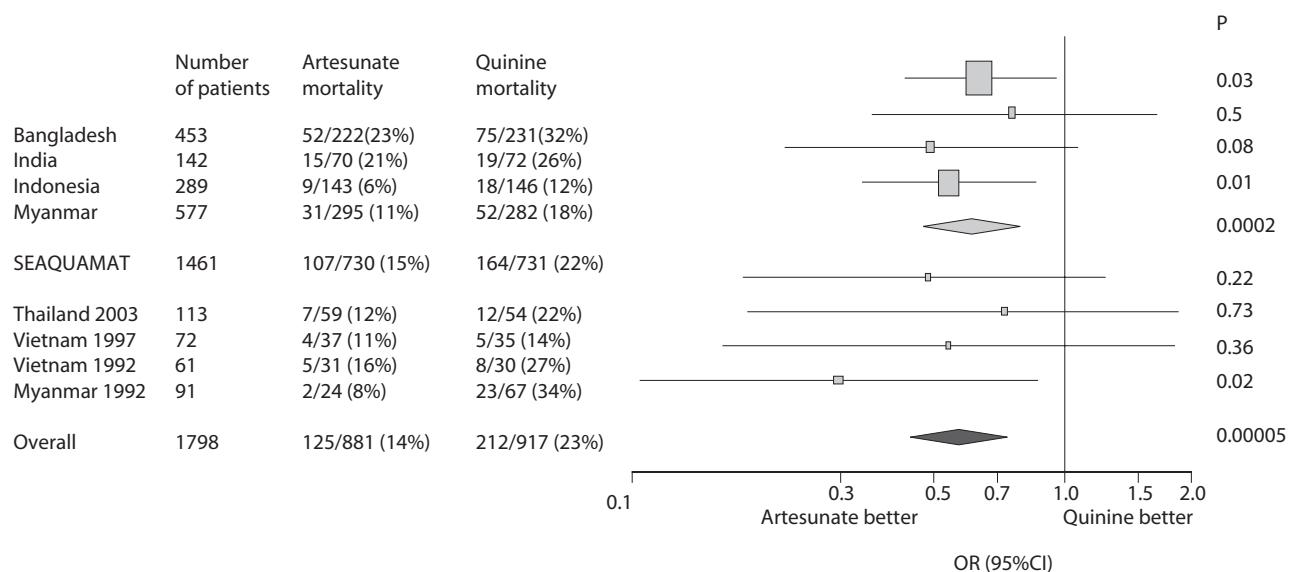

Fig. 62.1 Forest plot of mortalities in randomized comparative trials which compared parenteral quinine and artesunate in severe falciparum malaria. The sizes of the boxes are proportional to the number of events in individual trials. The diamond is the summary stratified odds ratio and 95% confidence interval.

conducted over a decade ago compared artemether and quinine in severe malaria.³⁴ Intramuscular artemether was associated with 14% mortality versus 17% with quinine (odds ratio 0.8, 95% confidence interval 0.62–1.02, $p = 0.08$). In adults, artemether was associated with a significantly lower mortality. Artemether was not associated with any serious adverse effects; notably there was no hypoglycemia and no neurological abnormalities. However, as artemether and the similar compound artemotil (arteether) are oil-based intramuscular injections, and they are absorbed slowly and erratically in severely ill patients,³⁵ the benefits obtained by greater intrinsic activity and broader stage specificity of action are offset partially by their variable absorption.

Artesunate is a water-soluble compound which can be given intravenously and is absorbed rapidly after intramuscular injection.³⁶ The evident pharmacokinetic advantages over artemether and arteether suggested that it would be the best drug for severe falciparum malaria. This has been confirmed in a series of preliminary trials which were followed by the largest ever randomized multicenter trial in severe malaria which enrolled 1461 patients and showed a 35% (95% CI 19–48%) reduction in mortality with parenteral artesunate.³⁷ The number needed to treat to save one life ranged from 11 to 20. Artesunate was also better tolerated and was associated with a lower risk of hypoglycemia.

Artesunate

Artesunate is provided for parenteral use as freeze-dried powder, which is dispensed together with an ampoule of 5% sodium bicarbonate. The two are mixed immediately before injection. The resulting sodium artesunate is hydrolyzed rapidly in vivo to the biologically active metabolite dihydroartemisinin. Artesunate is usually diluted in 5–10 mL of 5%

dextrose or normal (0.9%) saline before intravenous or intramuscular injection. The currently recommended dose is a 2.4 mg/kg given either intravenously or by intramuscular injection at 0, 12, and 24 h, then once daily.

Artemether and artemotil

These two compounds are very similar. They are dissolved in groundnut or sesame oil and given by intramuscular injection to the anterior thigh in an initial dose of 3.2 mg/kg (for artemotil some recommend an initial dose of 4.8 mg/kg), followed by daily injections of 1.6 mg/kg. Oral treatment is substituted as soon as possible.

Rectal formulations

The artemisinin derivatives are absorbed adequately after rectal administration,³⁸ offering the prospect of giving pre-referral treatment in the rural tropics to patients who cannot swallow oral medications reliably or who have severe malaria away from health facilities near home where most fatalities occur. A recent large multicenter trial in Ghana, Tanzania and Bangladesh showed that pre-referral administration of a single 10 mg/kg dose of a rectal artesunate formulation (Rectocap) reduced mortality from falciparum malaria in children under 5 years by 25%.³⁹

Use of artemisinin derivatives has not been associated with any reported toxicity in the treatment of severe malaria. They do not have cardiovascular or metabolic adverse effects, do not need dose adjustment in renal failure or liver dysfunction, and are equally well tolerated by adults and young children. Blackwater (massive hemolysis) seems to occur with the same frequency as with quinine use. In animal models the oil-soluble ethers, artemether and arteether, have both produced

selective toxicity to brainstem nuclei. Similar neurotoxicity also followed administration of dihydroartemisinin, the common metabolite. The water-soluble artesunate and oral administration of any of the drugs is much less neurotoxic. There is no evidence that similar effects occur in humans. Temporary suppression of reticulocyte and neutrophil counts may occur following high doses but the clinical significance of these is uncertain.

QUININE

Parenteral quinine should be given by slow, rate-controlled intravenous infusion. Where this is not possible, intramuscular administration to the anterior thigh is an effective alternative. In order to achieve therapeutic concentrations as early as possible in the course of treatment, which may be life-saving, an initial loading dose should be given. A variety of approaches have been described. The simplest is to give a loading dose of 20 mg quinine dihydrochloride salt/kg by constant rate infusion over 4 h, dissolved in 5% or 10% dextrose, or normal (0.9%) saline.⁴⁰ Alternatively, 7 mg salt/kg may be infused over 30 min, followed immediately by 10 mg/kg over 4 h.⁴¹ After the initial loading dose, maintenance doses of 10 mg salt/kg should be given every 8 h. Maintenance dose intravenous infusions can be given over 2–12 h. Quinine should *never* be given by intravenous injection. Intramuscular bioavailability is good even in severe malaria, although there is still uncertainty as to the optimum dilution. Quinine dihydrochloride should be diluted between 1:2 and 1:5 with sterile water for intramuscular injection and given into the anterior thigh. The initial loading dose should be divided (10 mg/kg to each thigh). Undiluted quinine dihydrochloride (300 mg/mL) is acidic (pH 2) and painful, and may occasionally result in sterile abscesses or tetanus. The therapeutic range for quinine has not been defined, but total plasma concentrations between 8 and 15 mg/L are safe and effective. There is an increased potential risk of toxicity with free (unbound) quinine levels over 2 mg/L (corresponding to total plasma concentrations of approximately 20 mg/L). To prevent accumulation to toxic levels the dose of quinine should be reduced by one-third on the third day of treatment if there is no clinical improvement or the patient is in acute renal failure.

The principal adverse effect of quinine in the treatment of severe malaria is hypoglycemia.⁴² This is a particular problem in children and pregnant women (occurring in 50% of the latter group) and tends to occur after 24 h of treatment in those patients who remain severely ill. Management is difficult as hypoglycemia is often recurrent. A maintenance infusion of 10% glucose should be given after correction with a bolus of 0.3 g/kg (25 g) of glucose given by slow intravenous injection. Cinchonism is common in recovering patients, but does not limit dosage. Adverse cardiovascular or central nervous system effects (particularly retinal blindness or deafness) are very unusual and, in general, parenteral quinine is well toler-

ated in the treatment of severe malaria. Electrocardiographic monitoring is not necessary except in patients with previous heart disease. In the tropics there have been concerns over the use of a loading dose in areas where patients are commonly pretreated before admission to hospital and therefore may already have therapeutic blood concentrations of quinine on admission, but these concerns have not been substantiated in large trials.⁴³ Undertreatment is more dangerous than over-treatment. Our practice is to give a loading dose of quinine unless the patient has definitely received 25 mg/kg of quinine or more in the preceding 48 h. We have not seen any serious complications using these guidelines.

QUINIDINE

In some countries parenteral artemisinin derivatives or quinine are not available.⁴⁴ In this case quinidine (the dextrorotatory diastereoisomer) may be used as an alternative. This is usually available as the gluconate salt. Quinidine is intrinsically more active than quinine as an antimalarial; however, as it also has an approximately four-fold greater effect on the heart, electrocardiographic monitoring is necessary.⁴⁵ The dose has been controversial (as there are few studies on which to base it). An infusion of 10 mg base/kg given by constant rate intravenous infusion over 1 h as a loading dose, followed by 0.02 mg/kg per min (1.2 mg/kg per hour) thereafter until the patient can be safely switched to oral treatment, will achieve therapeutic concentrations. If the QT interval is prolonged by more than 25% of the baseline value, or exceeds an absolute value of 0.6 s, the infusion should be stopped. Hypotension should be treated with intravenous saline. Quinidine has the same propensity as quinine to induce hypoglycemia. As with quinine, the therapeutic range has not been determined precisely, but total plasma concentrations of 5–8 mg/L should be achieved. Plasma concentration monitoring is advisable. If this is not available, then the dose of quinidine should be reduced by one-third on the third day of treatment if there is no clinical improvement, or the patient is in renal failure.

ANTIMALARIAL TREATMENT OF CHILDREN

Apart from early vomiting, children generally tolerate the antimalarial drugs better than adults. For oral treatment, particularly in younger children, care should be taken to cool and calm the patient before oral treatment is given. If the temperature is $>38.5^{\circ}\text{C}$, tepid sponging, and oral or rectal paracetamol (15 mg/kg) should be administered and the antimalarials given after the temperature has been lowered (usually 30–60 min). Tablets should be crushed and mixed with water or a sweet drink or disguised in jam. The suspension may be drawn up into a syringe so that an accurate dose (on a milligram-per-kilogram basis) can be instilled into the mouth.

The pharmacokinetic properties of some antimalarials differ in children. The plasma concentrations of sulfadoxine and pyrimethamine in young children are half those in adults, suggesting that this important age group may have been systematically underdosed.⁴⁶ Piperaquine levels are also lower in the elimination phase. More data are needed for all antimalarials in infancy, and further dose optimization in children is required. Nevertheless, current dose regimens on a milligram-per-kilogram basis are the same as in adults, except that primaquine should not be given to neonates, tetracycline should not be given to children <8 years old, and (in resistant areas) the oral dose of quinine should be increased to 15 mg/kg every 8 h after the fourth day.

Children with severe malaria are more likely than adults to have convulsions, or become severely anemic or hypoglycemic. They are less likely to develop renal failure, pulmonary edema or jaundice. In general, children deteriorate more rapidly than adults, but they also recover more quickly.

ANTIMALARIAL TREATMENT IN PREGNANCY

Pregnant women should be treated in the same way as non-pregnant adults, except that for symptomatic women there should be a much lower threshold for admission to hospital. Tetracyclines (or doxycycline), long-acting sulfonamides at term and primaquine should not be used. Mefloquine has been associated with an increased risk of stillbirth in one study, but not in others, and is still generally regarded as safe.⁴⁷ There are now enough reassuring safety data to recommend artemisinin derivatives for women in the second or third trimesters of pregnancy.⁴⁸ In the first trimesters oral artemisinin derivatives for uncomplicated malaria should be avoided unless there is no effective alternative, as there are insufficient data to support their use. There are little or no data on the use of halofantrine, atovaquone-proguanil or dihydroartemisinin-piperaquine in pregnancy.

Chloroquine, pyrimethamine, proguanil and quinine are all considered safe, although quinine-stimulated hyperinsulinemia is more problematic in late pregnancy. For severe malaria artesunate and artemether are safer and easier to administer than quinine. The risks to the mother in severe malaria dictate that they should be used at any stage of pregnancy if the mother is severely ill.

BREASTFEEDING

Primaquine should be avoided, but the other drugs can be used as the doses received by the suckling infant are very small.

MALARIA PROPHYLAXIS

It is difficult to make generalized recommendations for antimalarial prophylaxis as the risks of acquiring malaria and antimalarial drug sensitivity vary considerably over short geo-

graphical distances. Antimalarial prophylaxis is indicated in two circumstances:

- In non-immune travelers visiting areas where they may acquire malaria
- In pregnant women who live in endemic areas.

Antimalarial prophylaxis is not generally recommended otherwise for the indigenous population in malaria-endemic areas, although there is increasing support for intermittent preventive treatment (intermittent treatment doses given to healthy people) in pregnant women, infants and school children. In practice in endemic areas for prophylaxis in pregnancy the only options are chloroquine for vivax malaria prevention or intermittent sulfadoxine-pyrimethamine (given twice during pregnancy) for falciparum malaria prevention. In areas in which multiresistance is prevalent there are no safe effective prophylactics or preventive treatments for pregnant women.

Drugs are only one component of personal protection against malaria (Table 62.2). The risks of acquiring malaria can be reduced considerably by avoiding contact with malaria vectors, by use of appropriate protective clothing, window netting, insect repellents, and sleeping under insecticide-impregnated bed nets. The key elements of malaria prevention are based on the well-established A, B, C, D system: awareness of the risk (this is particularly important for those visiting friends and relatives, who often assume incorrectly that their tropical origins protect them from malaria); mosquito-bite prevention; effective antimalarial chemoprophylaxis; and diagnosis and treatment without delay if malaria is suspected. Travelers should seek medical advice urgently if they develop a febrile illness. Standby treatment sufficient for one complete antimalarial course may be given to those who will be unable to reach medical services for extended periods. As the geographical distribution of drug resistance changes rapidly, the following general recommendations should be under constant scrutiny.

In those few areas where *P. falciparum* malaria remains chloroquine sensitive (such as Central America north of the Panama Canal), chloroquine alone can be given. In areas where antifol sensitivity is retained and/or *P. vivax* is prevalent, the combination of chloroquine (5 mg base/kg weekly) and proguanil (3 mg/kg per day) is still effective in some areas (e.g. parts of India and central Asia). Chloroquine is generally well tolerated, although pruritus is common in dark-skinned patients, and it may cause occasional skin eruptions or worsening of psoriasis. As chloroquine accumulates in the body and may cause retinal damage, ophthalmological examinations are advisable for people who take continuous chloroquine for 5 years or more (total dose >100 g). Retinal toxicity is more common when chloroquine is taken daily for rheumatic diseases, and is probably very unusual with antimalarial prophylaxis. Proguanil is given in a daily dose of 3 mg/kg (adult 200 mg). It is very safe and well tolerated. The main adverse effects are mouth ulcers and, less commonly, alopecia. In renal failure proguanil and its principal metabolite cycloguanil accumulate, and blood dyscrasias have been reported.

Table 62.2 Drugs used in the prophylaxis of malaria

Drug	Usage	Adult dose	Pediatric dose	Comments
Atovaquone–proguanil	Prophylaxis in all areas	Adult tablets contain 250 mg atovaquone and 100 mg proguanil hydrochloride. 1 adult tablet orally, daily	Pediatric tablets contain 62.5 mg atovaquone and 25 mg proguanil hydrochloride: 5–8 kg: ½ pediatric tablet daily >8–10 kg: ¾ pediatric tablet daily >10–20 kg: 1 pediatric tablet daily >20–30 kg: 2 pediatric tablets daily >30–40 kg: 3 pediatric tablets daily >40 kg: 1 adult tablet daily	Should be started 1–2 days before travel to a malarious area and taken for 7 days after leaving the transmission area. Contraindicated in persons with severe renal impairment (creatinine clearance <30 mL/min). Atovaquone–proguanil should be taken with food or a milky drink to enhance absorption of atovaquone. Not recommended for prophylaxis for children <5 kg, pregnant women, and women breastfeeding infants weighing <5 kg
Chloroquine	Prophylaxis only in areas with definite chloroquine-sensitive malaria	300 mg base (500 mg salt) orally, once/week	5 mg base/kg (8.3 mg/kg salt) orally, once/week, up to maximum adult dose of 300 mg base	Should be started 1–2 weeks before travel to a malarious area and taken for 4 weeks after leaving such areas. May exacerbate psoriasis
Doxycycline	Prophylaxis in all areas	100 mg orally, daily	≥8 years of age: 2 mg/kg up to adult dose of 100 mg/day	Should be started 1–2 days before travel to a malarious area and taken for 4 weeks after leaving the transmission area. Contraindicated in children <8 years of age and pregnant women
Mefloquine	Prophylaxis in all areas except those with mefloquine-resistant malaria	250 mg base orally, once/week	≤9 kg: 4.6 mg base/kg orally, once/week; >9–19 kg: ¼ tablet once/week >19–30 kg: ½ tablet once/week >31–45 kg: ¾ tablet once/week ≥45 kg: 1 tablet once/week	Should be started 1–2 weeks before travel to a malarious area and taken for 4 weeks after leaving the transmission area. Contraindicated if there is a history of allergy to mefloquine and in persons with depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders or seizures. Should be used with caution in persons with psychiatric disturbances or a previous history of depression
Primaquine	Prophylaxis for short-duration travel	30 mg base orally, once daily	0.5 mg base/kg up to adult dose once daily	Should be started 1–2 days before travel to malarious areas, and taken daily with food while in the malarious area and then for 7 days after leaving. Contraindicated in persons with G6PD ^a deficiency. Also contraindicated during pregnancy and lactation unless the infant being breastfed has a documented normal G6PD level.

^aGlucose-6-phosphate dehydrogenase. Primaquine should not be given to people with G6PD deficiency.

For most malaria endemic areas the choice is between four drugs: mefloquine, doxycycline, primaquine or atovaquone–proguanil. They are approximately equally effective. Weekly mefloquine (3.5 mg base/kg equivalent to an adult dose of 250 mg) is often the antimalarial prophylactic of choice. Mefloquine should be started at least 1 week before entering the malarious area so that therapeutic levels are achieved before exposure and any adverse effects have declared themselves. Mefloquine is generally well tolerated, with an incidence of serious adverse (neuropsychiatric) effects similar to that with chloroquine prophylaxis (about 1 in 10 000 recipients). In 70% of cases these arise within the first 3 weeks of prophylaxis. Less serious central nervous system effects such as dizziness, muzziness, feelings of dissociation, difficulty concentrating, sleeplessness and nightmares are much more common, but these are usually not sufficiently troublesome to limit prophylaxis. Because of inadequate data, rather than

evidence of toxicity, mefloquine is considered ‘not indicated’ in the first trimester of pregnancy or in children under 2 years old. Serious neuropsychiatric reactions (seizures, encephalopathy and psychosis) are more common if there is a previous history of seizures or psychiatric abnormalities, if quinine has been taken, and when mefloquine is used for treatment rather than prophylaxis. These reactions usually resolve spontaneously. Mefloquine should be continued for 1 month after leaving the endemic area. A maximum of 12 months continuous use is currently recommended.

Daily doxycycline is an alternative which retains efficacy in those few areas where multiresistant *P.falciparum* is also resistant to mefloquine (on the eastern and western borders of Thailand and adjacent Cambodia and Burma). It can be started 2 days before entering the malarious area but, as with mefloquine, it should be continued for 4 weeks after leaving the transmission area. The main adverse effects are nausea, esophagitis, diarrhea,

photosensitivity and, in women, *Candida* vaginitis. Doxycycline should be taken after meals with copious fluids to avoid esophageal irritation. It should not be given to children under 8 years of age (in the UK a 12-year age limit is recommended as there are very limited data on prophylactic use in older children)⁴⁹ (Table 62.1) to pregnant women or for more than 3 months' duration. Atovaquone–proguanil (250/100 mg/day) has proved effective and very well tolerated everywhere it has been tested.⁵⁰ It is a more expensive, but better tolerated, alternative to mefloquine or doxycycline. Primaquine (30 mg/day) has proved remarkably well tolerated in prophylactic use, provided it is not taken on an empty stomach.⁵¹ It has been effective even against multiresistant falciparum malaria. Side effects include abdominal pain (particularly if taken on an empty stomach) and oxidant hemolysis. Primaquine should not be given to people with G6PD deficiency. Both primaquine and atovaquone–proguanil have pre-erythrocytic activity and can be stopped 1 week after the transmission area is left, making them suitable for short-term visitors.

Chloroquine is certainly safe in all age groups and in pregnancy. Although no adverse effects have been reported

with mefloquine prophylaxis in pregnancy, experience is still limited and this should remain under review. Atovaquone–proguanil is considered safe in children but there are limited data in pregnancy, and evidence that drug levels are reduced in late pregnancy. Primaquine and doxycycline are contraindicated in pregnancy. The artemisinin derivatives should not be used for prophylaxis. Neither the sulfadoxine–pyrimethamine combination nor amodiaquine are now recommended for prophylactic use because of toxicity. However, intermittent sulfadoxine–pyrimethamine (twice during pregnancy, three to four times in HIV-infected mothers) has proved very effective in reducing the impact of falciparum malaria in pregnancy in endemic areas where prevalent parasites remain sensitive.

Travelers should obtain detailed information on the risks of malaria, the value of vector avoidance and personal protection, and the efficacy of antimalarial drugs in the area that they will visit. Most travelers visiting South East Asia do not enter areas of risk and do not need to take antimalarial drugs. For India and South America the risks depend very much on the area to be visited, and for sub-Saharan Africa and Oceania malaria risks are very high and prophylaxis is required (Fig. 62.2).

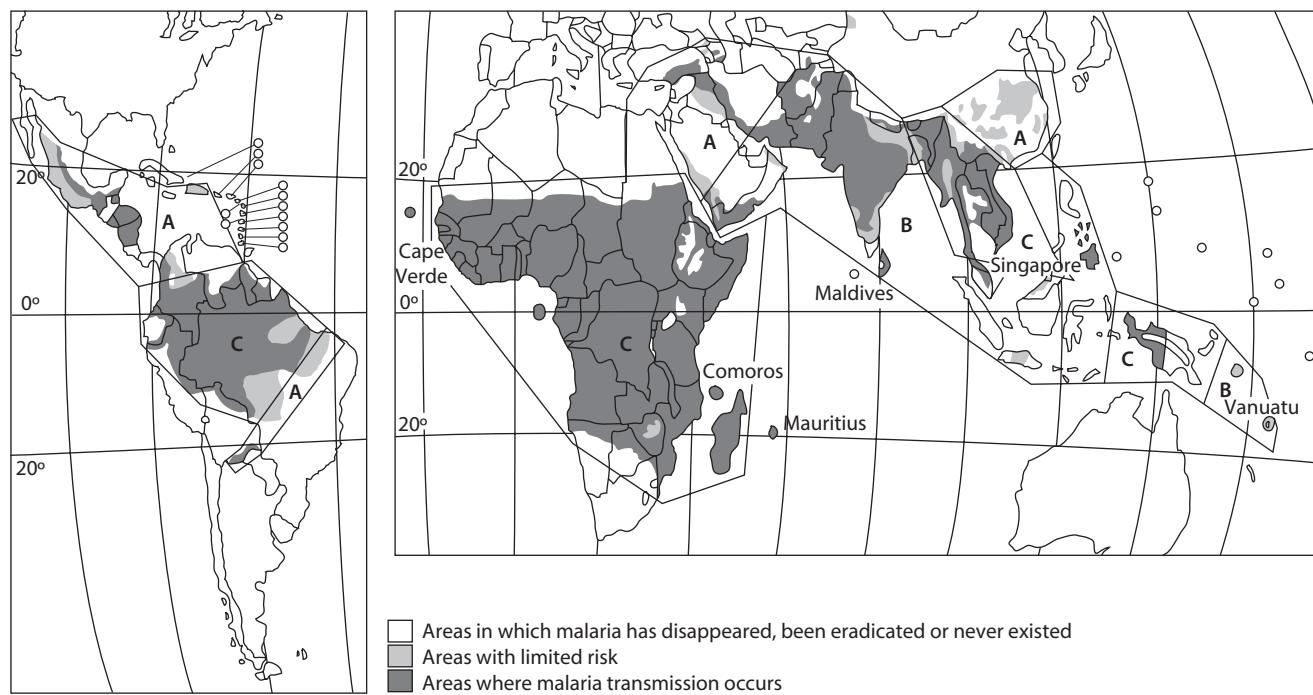

Fig. 62.2 WHO antimalarial prophylaxis recommendations 2000. **A** Risk generally low and seasonal; no risk in many areas (e.g. urban areas). *P. falciparum* absent or sensitive to chloroquine prophylaxis: chloroquine or (in case of very low risk) no prophylaxis. **B** Low risk in most of the areas. Chloroquine alone will protect against *P. vivax*. Chloroquine with proguanil will give some protection against *P. falciparum* and may alleviate the disease if it occurs despite prophylaxis. Prophylaxis: chloroquine + proguanil; second choice mefloquine or (in case of very low risk) no prophylaxis. **C** Risk high in most areas of this zone in Africa, except in some high-altitude areas. Risk low in most areas of this zone in Asia and America, but high in parts of the Amazon basin. Resistance to sulfadoxine–pyrimethamine common in zone C in Asia, variable in zone C in Africa and America. Prophylaxis: first choice mefloquine (except areas Cambodia/Burma/Thailand border); second choice doxycycline; third choice chloroquine + proguanil or (in case of very low risk) no prophylaxis. Note: Protection from mosquito bites should be the rule in all situations, even when prophylaxis is taken.

CHAPTER**63**

Other protozoal infections

Peter L. Chioldini and Carmel M. Curtis

TOXOPLASMOSIS

The regimen of choice is pyrimethamine plus sulfadiazine. The combination is synergistic against toxoplasma tachyzoites. Pyrimethamine is given at a dose of 25–50 mg/day, preceded by a loading dose of 100 mg every 12 h for 1 day. Sulfadiazine is given as 2–8 g/day (in four divided doses). Some authors recommend a loading dose of 75 mg/kg up to 4 g. Alternatives to sulfadiazine are sulfatriad or sulfadimidine.

Therapy with pyrimethamine–sulfadiazine (or an alternative) should be accompanied by folic acid 15 mg/day orally. Duration and dose of combination therapy is influenced by the variant of toxoplasmosis being treated and clinical progress on therapy. Where sulfonamides are contraindicated or cannot be tolerated, clindamycin 2.4–4.8 g/day in four divided doses can be substituted and given in combination with pyrimethamine.

Spiramycin, available in some countries, 2–3 g/day in three or four divided doses is less active than pyrimethamine–sulfadiazine.¹ Its main application lies in the management of toxoplasmosis in pregnancy (Ch. 55).

There is no evidence in the literature for the use of nitazoxanide for toxoplasmosis.

NON-PREGNANT IMMUNOLOGICALLY INTACT INDIVIDUALS

Many infections in the normal population are asymptomatic and thus not recognized. Most symptomatic cases resolve without treatment so do not require drug therapy, but severely ill patients should be treated. The regimen consists of pyrimethamine 25 mg/day plus sulfadiazine 2 g/day plus folinic acid, for 2–4 weeks. Cerebral, pulmonary, hepatic or cardiac involvement also constitute indications for giving antitoxoplasma drugs.²

OCULAR TOXOPLASMOSIS (SEE ALSO CH. 53)

Rothova et al³ examined the action of pyrimethamine 100 mg on the first day followed by 25 mg every 12 h, plus sulfadiazine 1 g every 6 h, plus folinic acid, plus corticosteroids, with the action of clindamycin 300 mg every 6 h plus sulfadiazine (as above) with an untreated control group. Pyrimethamine–sulfadiazine with corticosteroids significantly reduced the size of the retinal lesion in 52% of patients (compared with 25% of controls). Improvement on clindamycin–sulfadiazine with corticosteroids was borderline (retinal lesion reduced in size in 32% of patients). In contrast, Dutton⁴ preferred clindamycin–sulfadiazine to pyrimethamine–sulfadiazine. Soheilian et al conducted a prospective randomized trial of trimethoprim–sulfamethoxazole plus prednisolone versus the classic treatment regimen of pyrimethamine–sulfadiazine plus prednisolone.⁵ They found no significant difference in mean reduction of retinochoroidal lesion size, visual acuity and recurrence rate between the groups and adverse events were similar. In a review of ocular toxoplasmosis, Dodds suggests that trimethoprim–sulfamethoxazole plus prednisolone can be an alternative to classic therapy.⁶

Pearson et al⁷ conducted an open, phase I (safety and efficacy) trial of atovaquone therapy for ocular toxoplasmosis in immunocompetent patients: 17 individuals were treated with atovaquone tablets 750 mg every 6 h for 3 months. Prednisolone 40 mg/day was begun on day 3 and tapered as ocular inflammation resolved. One patient stopped treatment at 6 weeks due to persistent epigastric discomfort. All patients showed improvement on treatment within 1–3 weeks and visual acuity stabilized or improved in all cases, median initial visual acuity being 20/200 and median final visual acuity 20/25. Because recurrent ocular toxoplasmosis is due to reactivation of the bradyzoite (tissue cyst) of *Toxoplasma*, atovaquone's activity against this stage in the parasite's life cycle (an attribute not possessed by conventional antitoxoplasma drugs) may limit the ultimate visual loss caused by this condition.

This hypothesis should be tested by randomized clinical trials. However, Baatz et al reported reactivation of toxoplasma retinchoroiditis in a patient whilst taking atovaquone 750 mg every 8 h which they suggest could have been due to tachyzoite resistance to atovaquone.⁸ Some support for this hypothesis comes from its use in malaria, where resistance of *Plasmodium falciparum* to atovaquone appears rapidly if it is used as monotherapy.⁹

Antitoxoplasma drugs are indicated for ocular toxoplasmosis where there is a threat to vision, either from local posterior pole lesions or from more general inflammation. Systemic corticosteroids are indicated in the presence of posterior pole lesions if there is a possibility of large vessel involvement or if the lesions are in the patient's only eye. Steroid therapy must be accompanied by antitoxoplasma drugs and is reserved for sight-threatening lesions.

Indications for surgical intervention include the development of a cataract, uncontrolled rise in intraocular pressure, vitreous membranes, epiretinal membranes and retinal detachment. Systemic steroid cover is administered if surgery is undertaken for ocular toxoplasmosis. Peripheral retinal lesions that are no threat to vision can be observed and do not usually require specific antitoxoplasma drugs.¹⁰

TOXOPLASMOSIS IN THE IMMUNOCOMPROMISED PATIENT

CARDIAC TRANSPLANTATION

Cardiac transplantation is the organ donation most likely to lead to toxoplasmosis in the recipient. Most instances occur when the donor heart comes from a seropositive patient and the recipient is seronegative. The other possibility is reactivation of latent toxoplasmosis secondary to immunosuppression, in an already seropositive recipient. Luft et al¹¹ reported a series of 50 heart or heart-lung transplant patients: of four patients who were seronegative before receiving a heart from a seropositive donor, three developed life-threatening toxoplasmosis. None of 19 patients who were seropositive before transplantation developed illness attributable to toxoplasmosis, although 10 showed significant increases in toxoplasma antibody titers. Another series studied 21 seronegative recipients of seropositive heart or heart-lung transplants.¹² Four patients (two of whom died) from the first seven suffered clinical toxoplasmosis within 17–32 days of the transplant. The next 14 transplant patients deemed at risk of toxoplasmosis received pyrimethamine prophylaxis 25 mg/day plus folinic acid 15 mg every 8 h for 6 weeks postoperatively; two cases developed.

The most effective prophylaxis for toxoplasmosis is the combination of a dihydrofolate reductase inhibitor and a sulfonamide as they are highly synergistic.¹³ Although Soave¹⁴ recommends prophylaxis with pyrimethamine 25 mg/day, plus folinic acid 15 mg every 8 h, for 6 months after heart transplantation in seronegative recipients of seropositive organs, Derouin and Pelloux¹³ state that pyrimethamine is at

least 10-fold less efficient than when combined with a sulfonamide. Prophylaxis should be continued beyond 6 months in patients with ongoing risk factors for reactivation of toxoplasmosis or with persistent allograft dysfunction.

Trimethoprim-sulfamethoxazole plus folinic acid and pyrimethamine-sulfadoxine plus folinic acid are both effective in preventing toxoplasmosis. Derouin and Pelloux¹³ regard trimethoprim-sulfamethoxazole plus folinic acid as the prophylactic regimen of choice in solid organ transplantation. Treatment of acute toxoplasmosis after heart or heart-lung transplantation is with pyrimethamine-sulfadiazine with folinic acid, continuing until 4–6 weeks after all symptoms and signs have resolved.

RENAL TRANSPLANTATION

The risk of the recipient developing toxoplasmosis after renal transplantation appears to be small,¹⁵ but is recorded as the result of reactivation of latent infection or, more commonly, due to recently infected donor to host transmission.¹⁶ In a review, these authors found 22 cases of disseminated toxoplasmosis following renal transplantation. Ten of 11 recipients whose serology was known were seronegative before transplantation. In the six cases for whom the corresponding donor serology was known, it was positive in five.

HEPATIC TRANSPLANTATION

Toxoplasmosis following liver transplantation appears to be rare^{17–19} and there are few published data on the efficacy of post-transplantation prophylaxis against *Toxoplasma*. However, as trimethoprim-sulfamethoxazole is often used after liver transplantation as prophylaxis against *Pneumocystis jirovecii* based on its efficacy in preventing *Toxoplasma* encephalitis in AIDS, this regimen might be expected to confer protection against *Toxoplasma* in liver transplant patients.^{17,18} Knowledge of the *Toxoplasma* serological status pretransplantation for both donor and recipient will help alert the clinical team to toxoplasmosis as one of the possible diagnoses to be considered in the investigation of fever after liver transplantation.

BONE MARROW TRANSPLANTATION

In contrast to solid organ transplants, toxoplasmosis in bone-marrow-graft recipients appears to be due largely to reactivation of latent infection in the recipient, rather than infection coming from the transplanted organ.²⁰ There are likely to be more problems in countries with a higher toxoplasma seroprevalence rate.²¹ Slavin et al reported 12 cases of toxoplasmosis in 3803 bone marrow allograft patients:²² 2% of seropositive patients developed toxoplasmosis, which

appeared to occur by reactivation within the first 6 months after marrow transplantation, in patients who were *Toxoplasma*-seropositive pre transplant, had received allogeneic marrow and had severe graft-versus-host disease. Recipients seropositive before bone marrow transplantation should receive chemoprophylaxis from months 2 to 6 after grafting.²³ Foot et al studied the efficacy of weekly pyrimethamine–sulfadoxine prophylaxis in bone marrow transplant recipients.²⁴ In 69 evaluable seropositive patients, the combination was given from the time of established engraftment (median day 40; range 13–100 days) and was scheduled to be given until 6 months, or longer in instances of continued immunosuppression (median 10 months, range 72 days to 22 months). No cases of toxoplasmosis occurred in patients receiving prophylaxis over a 21-month period.

HEMATOPOIETIC STEM CELL TRANSPLANTATION (HSCT)

The major risk is from latent infection in seropositive recipients and allogeneic recipients are at very high risk compared to autologous HSCT recipients. The median time to disease onset is approximately 2 months after HSCT. In their comprehensive review, Derouin and Pelloux¹³ point out that there is no consensus regarding initiation and duration of prophylaxis. They state that a delay of 30 days post HSCT before starting prophylaxis is reasonable and that it should be continued for 6 months post HSCT; longer in cases of graft-versus-host disease, prolonged neutropenia and prolonged administration of corticosteroids. Trimethoprim-sulfamethoxazole (co-trimoxazole) is most commonly used, but pyrimethamine–sulfadoxine is deployed in some centers.

CEREBRAL TOXOPLASMOSIS AND HIV CO-INFECTION

Toxoplasma gondii may cause diffuse encephalitis, but this is an extremely rare infection and cerebral toxoplasmosis is normally manifested as solitary or multiple brain abscesses. The condition is typically seen in HIV-positive patients who have $<100 \times 10^6$ CD4 lymphocytes/L and who have positive *Toxoplasma* serology. More rarely transplant patients and other patients with severe deficiencies of cellular immunity may get cerebral toxoplasmosis. Clinically the patients develop symptoms of intracerebral expansion; seizures, headache and confusion are the most common manifestations. The most common differential diagnoses are cryptococcal meningitis, AIDS dementia complex and progressive multifocal leukoencephalopathy. Diagnosis is obtained by CT scan of the brain showing typical ring-enhanced lesions combined with demonstration of *Toxoplasma* antibodies.

If diagnosed reasonably early, treatment of cerebral toxoplasmosis is normally successful. First-line treatment is

sulfadiazine 4–6 g/day combined with pyrimethamine 50–100 mg/day and folinic acid 15 mg/day. In patients who cannot take sulfonamides, clindamycin 600 mg every 6 h has been recommended as a replacement for sulfadiazine. Another alternative to sulfadiazine is clarithromycin 2 g/day or atovaquone 750 mg orally every 6 h, both to be combined with pyrimethamine and folinic acid. In a review, Dedicoat and Livesley considered pyrimethamine plus sulfadiazine and pyrimethamine plus clindamycin to be equivalent for the treatment of acute toxoplasma encephalitis in HIV-infected patients.²⁵ They also stated that trimethoprim–sulfamethoxazole appears to be an effective alternative to pyrimethamine plus sulfadiazine in resource-poor settings.

Both primary and secondary prevention of cerebral toxoplasmosis should be considered in HIV-positive patients. Those who lack antibodies should be advised to avoid raw and undercooked meat, which are the most common modes of transmission of the infection. Antibody tests should be repeated if the CD4 count falls below 100×10^6 /L. At or below that CD4 count primary prophylaxis with a daily dose of trimethoprim 160 mg and sulfamethoxazole 800 mg (which also prevents *Pneumocystis jirovecii* pneumonia) is recommended for antibody-positive patients. Alternatives to trimethoprim–sulfamethoxazole are dapsone plus pyrimethamine or atovaquone with or without pyrimethamine. However, these regimens are incompletely documented. Several studies indicate that primary prophylaxis can be discontinued if the CD4 count rises to above 200×10^6 /L as a result of antiretroviral treatment.

The regimens recommended for primary prophylaxis should also be administered as secondary prophylaxis to patients who have had an episode of cerebral toxoplasmosis. In these patients the evidence does not allow a recommendation to discontinue prophylaxis if the CD4 count increases.

TOXOPLASMOSIS IN PREGNANCY

This is discussed in Chapter 55.

LEISHMANIASIS

CUTANEOUS LEISHMANIASIS

OLD WORLD CUTANEOUS LEISHMANIASIS

Most lesions heal spontaneously. Treatment may produce more rapid healing and less severe scarring and is indicated for multiple sores, those at risk of causing disfigurement or disability, or lesions sited where healing is expected to be slow. Options for local drug treatment are topical paromomycin (aminosidine) ointment²⁶ or infiltration of a pentavalent antimonial drug, sodium stibogluconate, into the edge and base of the sore.²⁷ Systemic treatment may be required for

multiple or potentially disfiguring lesions. The consensus for systemic treatment is less clear than for New World lesions but 20 mg/kg of sodium stibogluconate daily for 10 days is standard, to be extended to 20 days if necessary.²⁸ Oral miltefosine (a phosphocholine analog) has been used with mixed results for New World cutaneous leishmaniasis²⁹ and preliminary results from Afghanistan treating *L. tropica* have been disappointing.³⁰

NEW WORLD CUTANEOUS LEISHMANIASIS

If infection with *Leishmania (Viannia) braziliensis* complex is suspected, the cutaneous lesion should be treated systemically to prevent the development of mucosal leishmaniasis. Systemic therapy of cutaneous leishmaniasis (CL) is undertaken with pentavalent antimonials (sodium stibogluconate or meglumine antimoniate; *see below*). On the basis that a course of pentamidine isethionate is cheaper and shorter than antimonial therapy, some clinicians use pentamidine in the treatment of CL. Nacher et al³¹ examined the efficacy of short-course pentamidine in treating CL due to *Leishmania braziliensis guyanensis* in French Guiana. Two intramuscular injections of pentamidine 4 mg/kg each, separated by 48 h, cured 165 of 189 (87%) evaluable patients. Of the 24 patients who were not cured by one course, 80% were cured by a repeat course of pentamidine. The five individuals in whom active lesions persisted after two courses of pentamidine all responded to antimonial therapy.

DIFFUSE CUTANEOUS LEISHMANIASIS

This condition requires expert assessment and follow-up. In principle, *Leishmania aethiopica* is treated with paromomycin plus sodium stibogluconate daily³² until the parasite is thought to be eliminated, which may take a few months. Weekly pentamidine is an alternative.³³

MUCOSAL LEISHMANIASIS

South American mucosal leishmaniasis, due to *Leishmania (Viannia) braziliensis*, is treated with antimonials at 20 mg antimony/kg daily for 6–8 weeks, provided the patient is previously untreated and does not have laryngeal involvement. For those previously treated, or in whom the larynx is involved, amphotericin B 1 mg/kg is given by intravenous infusion on alternate days for 6–8 weeks.³⁴

Sudanese mucosal leishmaniasis is due mainly to *Leishmania donovani* and is usually a primary mucosal disease, though it may appear during or after an attack of visceral leishmaniasis. Therapy is with sodium stibogluconate 10 mg/kg per day for 30 days.³⁵

ADJUNCTIVE THERAPY

Lessa et al studied 10 Brazilian patients with mucosal leishmaniasis who had failed to respond to at least two courses of conventional pentavalent antimonial therapy.³⁵ Based on observations that suggested a possible role of tumor necrosis factor-alpha (TNF- α) in the pathology of mucosal leishmaniasis, a TNF- α inhibitor (pentoxifylline) was assessed in combination with a pentavalent antimonial drug. Each patient received parenteral pentavalent antimony (20 mg/kg per day) plus oral pentoxifylline (400 mg every 8 h) for 30 days. The criteria for cure were complete re-epithelialization of the mucosal tissue 90 days post treatment and no evidence of relapse after 1 year of follow-up. Complete healing was found by day 60 in eight patients and by day 90 in one person: one patient was not cured, although some improvement in the lesion was reported. Mean TNF- α levels fell from 776 before treatment to 94 within 60 days after the end of treatment ($p < 0.05$). A subsequent small double-blind, placebo-controlled, randomized trial showed that the addition of pentoxifylline significantly reduced healing time and the need for further courses of antimony in the treatment of mucosal leishmaniasis.³⁶

ORAL THERAPY

Amato et al conducted a small open study of the efficacy of itraconazole in the treatment of mucosal leishmaniasis in Brazil.³⁷ Ten patients received 6 weeks' therapy with itraconazole 4 mg/kg per day to a maximum of 400 mg/day in two divided doses with food; 6 of the 10 showed healing of the lesions at 3 months and none of these showed reactivation of disease after follow-up for 12–18 months. One of the six had previously failed to improve on pentavalent antimonial treatment and another had relapsed after initial healing on pentamidine therapy.

VISCERAL LEISHMANIASIS

Until recently, pentavalent antimonials were the first choice for therapy of visceral leishmaniasis (VL). Sodium stibogluconate solution contains 100 mg antimony/mL, while meglumine antimoniate solution contains 85 mg antimony/mL. Antimonial resistance develops easily following inadequate treatment³⁹ and has now become a significant problem, notably in recent epidemics in India and the Sudan. Traditional dosage regimens recommended by the World Health Organization⁴⁰ advocated 20 mg/kg of antimony daily, subject to a maximum daily dose of 850 mg, for a minimum of 20 days, until no parasites are found in consecutive splenic aspirates taken at 14-day intervals, but this would result in suboptimal dosage of patients weighing more than 42 kg.⁴¹ Herwaldt and Berman advocated lifting of the 850 mg ceiling

for antimony dosage, with close monitoring of the patient for drug-related reactions.⁴² Current regimens advocate 28–30 days of treatment.⁴¹ In children, who tolerate pentavalent antimony better than adults, dosage is calculated by body surface area.⁴³

A successful immune response to VL is T-cell dependent, mainly Th1 type,⁴¹ thus, Th1-derived interferon- γ was assessed to see if it would augment the response to antileishmanial chemotherapy. A controlled trial comparing combination therapy of Kenyan VL with alternate-day interferon- γ plus daily sodium stibogluconate and daily sodium stibogluconate alone, suggested that combination therapy accelerated the early clearance of parasites.⁴⁴ Sundar et al⁴⁵ used sodium stibogluconate, 20 mg/kg per day intravenously for 30 days, plus interferon- γ 25 μ g/m² subcutaneously on day 1, 50 μ g/m² on day 2 and 100 μ g/m² daily for 28 days, to treat 15 Indian patients, all of whom had failed an initial course of 30 or more days of antimony treatment at 20 mg/kg per day. Eight of the patients had received two courses and seven had received three or four treatment courses. Combination therapy was discontinued in two patients, both of whom died. After 30 days of therapy, 9 of the 13 surviving patients (69%) were apparently cured. All nine had negative bone marrow smears at 6 months and none relapsed after a mean follow-up of 15.9 (\pm 1.7) months. Combination therapy with antimonials plus interferon- γ may have a role in selected refractory cases, but its cost renders it unsuitable for widespread use in the tropics. Furthermore, it would be unwise to use it in areas where there is significant antimony-resistant VL.

Secondary infection is an important cause of morbidity and mortality in VL. Granulocyte-macrophage colony-stimulating factor (GM-CSF) was compared to placebo as adjunctive therapy in Brazilian patients with VL and leukopenia due to *Leishmania chagasi*. Patients received antimony 10–20 mg/kg per day for 20 days plus GM-CSF 5 μ g/kg daily or placebo, for 10 days. Neutrophil counts were significantly higher in the GM-CSF group at 5 and 10 days. Eosinophil and monocyte counts were significantly higher at 10 days in the patients who received GM-CSF. Significantly fewer secondary infections occurred in the GM-CSF group.⁴⁶

Paromomycin (aminosidine) is active against antimony-resistant strains causing VL.⁴⁷ Scott et al⁴⁸ treated seven patients with Mediterranean VL with daily intravenous infusions of paromomycin 14–16 mg/kg for 21 days or for 1 week after demonstration of parasitological cure, whichever was the longer: four of the seven (treated for between 22 and 54 days) were cured; one relapsed 4 months after an apparent cure, but was successfully re-treated with a second course lasting 63 days; the remaining two showed a partial parasitological response. Jha et al compared paromomycin with sodium stibogluconate for the treatment of VL in Northern Bihar.⁴⁹ While the cure rate for pentavalent antimony was only 63%, paromomycin at 16 mg/kg per day for 30 days gave a cure rate of 93% and a cure rate of 97% at 20 mg/kg per day for 30 days.

Indian and Nepalese VL has become significantly less responsive to pentavalent antimonials. By the early 1990s the regimen for VL treatment in Bihar was sodium stibogluconate 20 mg/kg per day for 40 or more days, a dosage regimen associated with increased toxicity and higher costs of hospital care. A decade later, Sundar et al⁵⁰ reported a long-term cure rate of 35% for VL treated with pentavalent antimonials in Bihar, versus 86% of VL cases in Uttar Pradesh given identical treatment. They concluded that traditional pentavalent antimony therapy should be abandoned in Bihar. Following reports of a study from Kenya, where paromomycin 12 mg/kg per day in combination with sodium stibogluconate 20 mg/kg per day for 20 days appeared more effective than sodium stibogluconate alone, Thakur et al undertook a pilot study of the activity of the combination on VL in Bihar, India.⁵¹ Twenty-four patients were assigned to receive paromomycin 12 mg/kg per day plus sodium stibogluconate for 20 days. Two patients died before completing the course, one from hemorrhage following splenic puncture and one as a result of severe gastroenteritis. Of the 22 patients who completed therapy, 18 (82%) were cured and did not relapse within a 6-month follow-up period. The remaining four patients improved clinically and parasitologically. Seaman et al⁵² confirmed the efficacy of combined paromomycin plus sodium stibogluconate in a study on VL in Southern Sudan. Mishra et al⁵³ compared conventional amphotericin B with sodium stibogluconate in the treatment of Indian visceral leishmaniasis: 80 patients, none of whom had been previously treated with antileishmanial agents, were randomized to receive either sodium stibogluconate 20 mg/kg in two divided doses intramuscularly daily for 40 days or amphotericin B 0.5 mg/kg infused in 5% dextrose on alternate days for 14 doses. All 40 patients who received amphotericin B showed initial cure (no fever and no amastigotes in a bone marrow smear after 6 weeks) and definitive cure (well at the end of 12 months). In the stibogluconate-treated group 28 of 40 (70%) showed initial cure and 25 of 40 (62.5%) showed definitive cure. Patients who failed to respond to stibogluconate, or who relapsed after initial cure, were treated with, and cured by, amphotericin B. Davidson⁵⁹ regards the optimal regimen for amphotericin B deoxycholate as 20 mg/kg given as 0.5 mg/kg per day or 1 mg/kg on alternate days.

The amastigotes of *Leishmania* are found in macrophages, which also clear liposomes from the circulation. Thus, the sites of infection can be targeted by amphotericin B, itself a more active antileishmanial drug than sodium stibogluconate. Davidson et al reported a multicenter trial of liposomal amphotericin B in Mediterranean VL.⁵⁴ Ten immunocompetent patients (six of them children) received 1–1.38 mg/kg per day for 21 days and a further 10 (nine of them children) received 3 mg/kg per day for 10 days. All were clinically cured after a follow-up period of at least 12 months.

Lipid-associated amphotericin B preparations all reach very high levels in liver and spleen and are less toxic than conventional amphotericin B. All three are more expensive. Liposomal amphotericin B (AmBisome) is given as a total dose of 20–30 mg/kg, split into more than five daily doses of

3–4 mg/kg over 10–21 days.⁵⁴ Liposomal amphotericin B was the first drug approved for the treatment of VL by the US Food and Drug Administration, in a regimen of 21 mg/kg given on 7 days over a 21-day period.⁵⁵ As cost is a major issue affecting the use of liposomal amphotericin B, short-course, low-dose regimens have been investigated as a way of reducing treatment costs. Sundar et al⁵⁶ compared single-dose infusions of liposomal amphotericin B at 5 mg/kg with once-daily infusions of 1 mg/kg for 5 days in the therapy of Indian VL. Cure rates at 6 months were 92% (84 of 91 patients) for the whole study, 91% (42 of 46) for the single-dose group and 93% (42 of 45) in the five-dose group, with no significant difference in response rates between the two groups. Further work is required to support the use of the regimens described and to see whether or not their deployment will encourage the development of amphotericin-resistant strains of *Leishmania*.

Amphotericin B cholesterol dispersion (Amphotericin B cholesterol dispersion 2 mg/kg per day intravenously for 10 days, and another 10 patients received a 7-day course.⁵⁷ The authors reported treatment success in all patients. One patient who received the 7-day course had scanty parasites in the bone marrow smear 15 days after treatment, but the remainder (95%) had negative bone marrow smears. All patients were well after 6 months of follow-up. Side effects consisting of fever, chills and respiratory distress were noted in children under 3 years of age.

Amphotericin B lipid complex (Abelcet) at a dosage of 3 mg/kg per day for 5 consecutive days proved effective in the treatment of Indian VL unresponsive to more than 30 days' treatment with pentavalent antimony.⁵⁸

ORAL THERAPY

Effective oral therapy for VL would constitute a major therapeutic advance. Miltefosine (hexadecylphosphocholine), an orally administered agent initially developed as a potential anticancer drug (see Ch. 35), was found to have antileishmanial activity in vitro and in animal models.⁵⁹ Studies in Indian VL showed very encouraging activity and have been summarized by Murray.⁴¹ A total of 249 patients aged 12 years or more were included: 96% (224 of 234) patients treated with 50–200 mg/day for 14–42 days were regarded as long-term cures; 97% (68 of 70) of those who received 100 mg/day (in two divided doses) for 28 days were cured, but only 89% were cured by 100 mg/day for 14 days. Gastrointestinal side effects were frequent on miltefosine (up to two-thirds of cases) but were judged mild to moderate in severity.⁵⁹ Miltefosine is teratogenic in animals and should not be given in pregnancy.⁴¹ The potential impact of miltefosine in the treatment of VL, should its efficacy and safety be confirmed in larger studies, is substantial. It should also be assessed in AIDS-related VL,

both for initial treatment and for maintenance therapy, and in post-kala-azar dermal leishmaniasis.⁴¹

VISCERAL LEISHMANIASIS AND HIV CO-INFECTION

Before the development of highly active antiretroviral therapy (HAART), 20–70% of patients with VL in the Mediterranean area were co-infected with HIV³⁹ but there has been a significant decrease in the incidence of VL in HIV-infected patients since HAART was introduced.⁶⁰ As a general principle, co-infected patients have reduced therapeutic options for treatment of VL. They suffer greater drug toxicity including interactions with other drugs, inaccessibility due to price and lack of efficacy data in this particular patient group. Extrapolating treatment data from European studies to Africa and Asia is fraught with pitfalls due to differing drug susceptibilities and differing infective strains, and optimal treatments for each region have not yet been agreed. Davidson³⁹ reports that clinical remission can be produced at first presentation of VL in approximately 65% of patients co-infected with HIV and *Leishmania* with a regimen of sodium stibogluconate or meglumine antimoniate 20 mg antimony/kg per day or amphotericin B 0.7 mg/kg per day, for 28 days. Berenguer et al report the use of meglumine antimoniate (as above) or liposomal amphotericin B, at doses of 4 mg/kg per day on days 1–5, 10, 17, 24, 31 and 38.⁶¹ As toxicity and increased mortality make antimonial drugs unsuitable for co-infected patients, the Hospital for Tropical Diseases recommends the following treatment for co-infected leishmaniasis and HIV patients:

- *Acute infection (first episode):* Liposomal amphotericin 4 mg/kg for 10 doses (days 1–5, 10, 17, 24, 31 and 38) (prohibitive cost in resource-poor settings)
- *Acute infection (second-line options):* Pentavalent antimonials, e.g. sodium stibogluconate 20 mg/kg per day for 28 days; oral miltefosine 100 mg/day. The role of paromomycin or sitamaquine for this indication is unclear.

Sindermann et al⁶² report on 39 co-infected European patients who received 100 mg oral miltefosine per day on a named patient basis for a mean of 55 days. The majority of patients had received some form of antiretroviral treatment and most of the patients had failed other antileishmanial treatments including amphotericin B. Approximately 64% were cured initially but almost all relapsed; however, many responded with a further course of treatment. They demonstrated that prolonged treatment was safe but made no evaluation of miltefosine prophylaxis. In Ethiopia a study comparing miltefosine with sodium stibogluconate reported that miltefosine was less effective in co-infected patients, with 18% versus 2% failing initial treatment and 25% versus 11% relapsing within 6 months. However, the miltefosine group experienced fewer side effects and reduced mortality.⁶³

The evidence for the efficacy of paromomycin, the cheapest of the antileishmanial drugs, is lacking in co-infected patients. Resistance develops easily in vitro but combination

treatments with sodium stibogluconate have been successful in VL patients in the absence of HIV.⁶⁴

There is no indication for giving primary prophylaxis; however, maintenance therapy (secondary prophylaxis) is now in wide use following the first relapse, although the data supporting this come from non-controlled trials.⁶⁴ This co-infected patient group is at risk of multiple relapses which require careful management if the development of resistance is to be avoided. Berenguer et al described secondary prophylaxis in HIV/*Leishmania* co-infection which was one dose of either meglumine antimoniate or liposomal amphotericin B per month. They studied the relapse rate in 15 patients with HIV and VL established on HAART. Although larger studies are still required, they were able to conclude that secondary prophylaxis against *Leishmania* should not be discontinued in patients who were co-infected with HIV and VL and were unable to achieve and maintain a CD4 cell count above 200/ μ L on HAART; however, it may be safe in patients whose CD4 cell count is above 350/ μ L.⁶¹

The only prospective randomized trial to date which demonstrates the benefits of maintenance therapy used liposomal amphotericin (3 mg/kg every 21 days). The probability of being relapse free at 12 months was 50% in the maintenance group versus 22% in the placebo group.⁶⁵ Marques et al⁶⁶ report a small series of five co-infected patients who were treated with miltefosine for both relapse (50 mg every 12 h) and maintenance (50 mg, three times a week). Prophylaxis was discontinued after the CD4 count reached >250/ μ L on HAART and in the absence of VL relapses for a minimum of 12 months. To date, three patients were disease free for a median period of 20 months after miltefosine discontinuation (one patient died of gastrointestinal hemorrhage due to Kaposi's sarcoma and one patient was lost to follow-up). There is clearly a need for randomized trials and prospective studies to ascertain the optimal maintenance dose. The ultimate goal in these co-infected patients must surely be the use of effective antiretroviral treatment plus an agent such as miltefosine in order to achieve VL control while keeping the patient in the community.

Despite recent advances, there remains significant cause for concern regarding co-infection with HIV and VL. Although most reported cases have been from the Mediterranean region, Rosenthal et al have pointed out the potential for an explosion of co-infection with HIV and *Leishmania* in Eastern Africa and the Indian subcontinent due to the simultaneous spread and geographical overlap of both infections,⁶⁰ migration of refugees and seasonal workers, and periodical epidemics of VL.

TRYPANOSOMIASIS

TRYPANOSOMA BRUCEI GAMBIAE INFECTION

Hemolymphatic disease can be treated with eflornithine or suramin or pentamidine. Eflornithine (α -difluoromethylornithine, DFMO) has been evaluated for the treatment of established

gambiense sleeping sickness (i.e. with central nervous system involvement),^{67–69} but can also be used to treat hemolymphatic disease due to *T. brucei gambiense*.

Suramin is used to attempt radical cure of the hemolymphatic stage of the disease or to clear trypanosomes from the blood and lymph before melarsoprol therapy. All doses are given by slow intravenous infusion of a 10% aqueous solution. A test dose of 200 mg is given first, then 20 mg/kg (maximum dose 1 g) on days 1, 3, 7, 14 and 21.

Pentamidine 4 mg/kg by intramuscular injection daily or on alternate days for 7 doses is an alternative for the hemolymphatic stage for *T. brucei gambiense* only. Doua et al⁷⁰ evaluated pentamidine as an alternative to the expensive eflornithine and the toxic melarsoprol in early–late stage *T. brucei gambiense* trypanosomiasis (patients with cerebrospinal fluid (CSF) white cell count <20/mm³ and/or the presence of trypanosomes by microscopy or culture). Fifty-eight patients received pentamidine 4 mg/kg on alternate days by deep intramuscular injection to a total of 10 injections per patient: three patients relapsed with trypanosomes present in the CSF, one at 15 months and two at 18 months after the end of treatment, giving a 94% cure rate at 24 months.

In the absence of treatment, late-stage infection with meningoencephalitis is uniformly fatal. Until recently the mainstay of therapy was melarsoprol, an arsenical compound with significant toxicity (approximately 6% of patients die of drug-induced encephalopathy). The development of eflornithine has proven to be a major advance.⁶⁷ Pepin et al⁶⁸ treated 26 patients with *T. brucei gambiense* sleeping sickness resistant to arsenicals (melarsoprol or trimelarsan) with eflornithine, 100 mg/kg every 6 h (total daily dose 400 mg/kg) by intravenous infusion over 1 h for 14 days, followed by oral eflornithine 75 mg/kg every 6 h (300 mg/kg per day) for a further 30 or 21 days. Five patients died. Follow-up of the surviving 21 patients for a mean of 16 (range 6–30) months showed no relapses. Trypanosomes disappeared rapidly from the CSF, the CSF lymphocyte count gradually fell and there was improvement in symptoms after the first 2 weeks of treatment, such that most patients were asymptomatic by the time of hospital discharge. Giving 2 weeks intravenous eflornithine before commencing oral treatment appeared to give a lower relapse rate than did oral therapy reported from other studies. The authors felt that reducing the oral phase of therapy from 30 to 21 days reduced the frequency of side effects. Further to this work, Pepin et al⁷¹ conducted a randomized controlled trial of 321 patients, in four different countries, with late-stage Gambian trypanosomiasis, comparing whether 7 days of intravenous eflornithine (100 mg/kg every 6 h) was as effective as the more standard 14-day treatment regimen. They concluded that the 7-day course was adequate treatment for relapsing cases of Gambian trypanosomiasis but was inferior compared to 14 days of treatment for new cases. However, there were variations between countries and the cost of eflornithine remains prohibitive for many.

Milord et al examined the effect of three different eflornithine treatment regimens on a group of 207 patients with

late-stage *T. brucei gambiense* sleeping sickness.⁶⁹ In some cases eflornithine was the first antitrypanosomal drug administered, while other patients had relapsed after melarsoprol or nifurtimox or pentamidine plus suramin. Of 152 patients followed for at least 1 year, only 13 (9%) relapsed. Relapse after eflornithine was more frequent in children under 12 years of age and in previously untreated than in relapsing cases. Patients with a CSF leukocytosis of $\geq 100/\mu\text{L}$ were slightly, though not significantly, more likely to relapse than those with lower CSF white cell counts. Relapse rates in patients with trypanosomes seen in the CSF were not significantly different from those in patients in whom none were seen. Therapy with eflornithine 100 mg/kg intravenously every 6 h for 14 days, followed by 75 mg/kg orally every 6 h for 21 days showed no relapses in 28 patients followed for at least 1 year after treatment. In patients treated by the intravenous route only (200 mg/kg every 12 h for 14 days) the relapse rate was 10 of 108 (9%), compared with 19% (3 of 16) in those treated by the oral route (75 mg/kg every 6 h for 35 days). Eflornithine was found to be safer than melarsoprol in a trial of 251 patients in southern Sudan. Chappuis et al showed that patients treated with eflornithine experienced fewer cutaneous and neurological side effects as well as a reduced risk of death during treatment.⁷²

Where affordable, melarsoprol has been superseded by eflornithine for the therapy of late-stage *T. brucei gambiense* sleeping sickness. Where melarsoprol has to be used, consideration should be given to the use of an accelerated 10-day schedule described from Angola.⁷³ This consisted of 10 daily injections of melarsoprol 2.2 mg/kg. Prednisolone was given at 1 mg/kg per day for days 1–7; 0.75 mg/kg on day 8; 0.5 mg/kg on day 9 and 0.25 mg/kg on day 10. The schedule was compared with the 26-day standard Angolan schedule of three series of four daily injections of melarsoprol, increasing from 1.2 to 3.6 mg/kg within each series, with 7 days between series. A total of 250 patients on each regimen were studied. Adverse events resulting in withdrawal were 40 on standard treatment and 47 on the concise schedule. Fifty patients on the standard regimen, but only two on the new regimen, deviated or withdrew from treatment. All patients were deemed parasitologically cured 24 h after treatment. Six patients in each group died as a result of encephalopathy. Skin reactions were more common on the new regimen.⁷³ This concise regimen for melarsoprol has not been validated for the treatment of *T. brucei rhodesiense*.

This work was further supported by Pepin and Mpia who conducted a randomized controlled trial of 389 patients comparing efficacy and toxicity of three regimens of melarsoprol in the treatment of late-stage *T. brucei gambiense* trypanosomiasis.⁷⁴ Patients were followed with 6-monthly lumbar punctures for 2 years. The trial compared the more traditional regimen 'A' of three series of three injections (3.6 mg/kg) at the full melarsoprol dosage; a new regimen 'B' of 10 consecutive daily intravenous injections (2.16 mg/kg); and three series of three injections but with graded dosing (1.8–3.6 mg/kg), regimen 'C'. The relapse rate was 5.4%, 7.4% and 25% for regimens A, B and C, respectively ($p < 0.001$). The newer

regimen of 10 daily injections was as effective and had no additional toxicity compared to regimens of three series of three injections. It also had the additional benefit of a shorter hospital stay and a reduction in total cost of melarsoprol. Furthermore, the authors felt that the graded dosing regimen should be abandoned in view of its higher relapse rate and associated increased incidence of seizures.

Nifurtimox monotherapy is too toxic to be preferred to eflornithine. Pepin et al treated 30 patients suffering from arseno-resistant *T. brucei gambiense* sleeping sickness with high-dose nifurtimox (30 mg/kg per day for 30 days).⁷⁵ Trypanosomes disappeared from the CSF of the nine patients in whom they were shown before therapy, and the CSF white cell count fell in all but one patient. Nine of 25 (36%) patients relapsed after follow-up, seven with trypanosomes in either CSF or blood. The relapse rate was lower than in the authors' previous study of nifurtimox 15 mg/kg per day for 60 days, when only 31% (6 of 19) were cured. However, high-dose nifurtimox produced serious toxicity; one patient died and another eight developed neurological problems, the most common being a cerebellar syndrome. There have been recent calls for nifurtimox monotherapy to be abandoned.⁷⁶ However, there is now a role for combination treatment with oral nifurtimox plus intravenous eflornithine. Priotto et al found that in a small (interrupted) randomized clinical trial comparing three treatments, nifurtimox and eflornithine combination treatment demonstrated increased cure rate over both melarsoprol–eflornithine and melarsoprol–nifurtimox combinations in second-stage Gambian sleeping sickness.⁷⁷ The trial was stopped prematurely due to the increased mortality in the melarsoprol–nifurtimox group.

Further data came from a case series of 48 patients suffering from stage 2 *T. brucei gambiense* infection treated with nifurtimox–eflornithine combination therapy in Uganda. There were no relapses. Two deaths occurred, neither judged to be due to trypanosomiasis nor to drug treatment.⁷⁸ A phase III clinical trial, enrolling 103 patients in the Republic of Congo, showed that for stage 2 Gambian disease nifurtimox–eflornithine combined treatment (NECT) was as efficacious as eflornithine monotherapy. Patients were randomized to receive either eflornithine alone 400 mg/kg per day intravenously in four divided doses for 14 days or eflornithine 400 mg/kg per day intravenously in two divided doses for 7 days, plus nifurtimox 15 mg/kg per day orally in three divided doses for 10 days; 94.1% of the eflornithine group and 96.2% of the nifurtimox–eflornithine group were cured. Severe drug reactions occurred in 25.5% of the eflornithine group and 9.6% of the nifurtimox–eflornithine group.⁷⁹ NECT has the benefit of a reduction in drug doses and therefore a reduction in toxic side effects, a shortened hospital stay (treatment duration is reduced to 10 days) and reduced drug costs (the number of injections is reduced to 14). The Drugs for Neglected Diseases initiative (DNDi) and the World Health Organization (WHO) Essential Medicines list (http://www.who.int/neglected_diseases/disease_management/drug_combination/en/index.html) have stated that NECT, while not ideal, offers 'an

immediate and practical improvement' for patients as a replacement therapy for melarsoprol.

The DNDi have also released information regarding a rediscovered oral agent, fexinidazole, a nitroimidazole, which can be used in both stages of the disease. This agent entered clinical development in 2009.

TRYPANOSOMA BRUCEI RHODESIENSE INFECTION

Hemolymphatic disease is treated with suramin (see *T. brucei gambiense*). Pentamidine is ineffective against *T. brucei rhodesiense*.

For late-stage disease with CNS involvement, eflornithine is not effective against *T. brucei rhodesiense*, even when used at a dose of 800 mg/kg per day for 14 days⁸⁰ and the treatment of choice for late-stage *T. brucei rhodesiense* infection remains melarsoprol. Several different treatment regimens are currently advocated, though there is no clear evidence that one is superior.⁴⁰ The regimens usually consist of three or four daily injections, separated by 7- to 10-day periods off treatment (Table 63.1).⁴⁰ Despite the evidence to support the abandonment of graded melarsoprol dosing for *T. brucei gambiense*, there is no clinical trial-based evidence to inform such a decision for late-stage *T. brucei rhodesiense*.

Therapy with melarsoprol can be followed by a Jarisch-Herxheimer reaction, which may be very severe. Thus, melarsoprol therapy is usually preceded by suramin treatment in the case of *T. brucei rhodesiense* (Table 63.1). As many as 1–5% of patients die during melarsoprol therapy, so it must be used only where there is clear evidence for CNS involvement in *T. brucei rhodesiense* infection. Especially dangerous is reactive encephalopathy, with headache, tremor, slurred speech, convulsions and coma. The syndrome appears 3–10 days after the first dose of melarsoprol.⁴⁰ Pepin et al examined the effect of prednisolone on the incidence of melarsoprol-induced encephalopathy in *T. brucei gambiense* (rather than *T. brucei rhodesiense*) sleeping sickness;⁸¹ 308 control patients received melarsoprol, preceded by a single dose of suramin to decrease peripheral parasitemia, while 290 patients received the same drugs plus prednisolone 1 mg/kg (maximum 40 mg) daily by mouth. The prednisolone group showed a significant ($p = 0.002$) reduction in the incidence of encephalopathy compared to controls. However, there was no significant difference in case-fatality rate for encephalopathy between the two groups (66.7% in the prednisolone group, 54.3% in the control group). The presence of fever during an episode of encephalopathy was associated with an adverse outcome: none of 10 patients with fever and 20 of 37 without fever survived. Thus, reduction in encephalopathy-associated death was due to a lower incidence of encephalopathy rather than a lower case-fatality rate. Reduction of the encephalopathy rate by prednisolone supports an autoimmune etiology for this complication, since steroids seem unlikely to decrease direct toxicity of arsenicals. In contrast, the incidence of polyneuropathy, thought to be due to a direct toxic effect of

arsenic, was not reduced by prednisolone.⁸¹ The authors rightly advise exclusion of strongyloidiasis and amebiasis before giving prednisolone in view of the propensity of these infections to fulminate in steroid-treated individuals. Although the study was undertaken in *T. brucei gambiense* sleeping sickness, the authors thought that prednisolone should be given to patients with *T. brucei rhodesiense* sleeping sickness receiving melarsoprol.

Pepin et al enlarged upon their work on melarsoprol-induced encephalopathy,⁸² reporting on 1083 patients with *T. brucei gambiense*, which included data from their earlier study of 598 patients.⁸¹ Of these 1083 patients, 64 (5.9%) developed drug-induced encephalopathy; 62 of these died, 43 from reactive encephalopathy and 19 from other causes, including trypanosomiasis. Prednisolone (1 mg/kg up to 40 mg/day) significantly reduced the incidence of encephalopathy and mortality on treatment, especially in patients with trypanosomes seen in the CSF and/or whose CSF white cell count was $\geq 100/\text{mm}^3$. In patients with CSF white cell counts of $\geq 100/\text{mm}^3$, changing the melarsoprol regimen to three series of three injections, instead of three series of four injections, halved the mortality rate.

The addition of dimercaprol to intravenous steroids and anticonvulsants for the treatment of melarsoprol-induced encephalopathy was possibly harmful and the authors gave a clear recommendation not to use dimercaprol in the treatment of this condition. They also recommended that for patients with late-stage Gambian trypanosomiasis with white cell counts of $\geq 100/\text{mm}^3$ in the CSF, the maximum melarsoprol dosage should be three series of three injections of 0.1 mL/kg each (maximum 5.6 mL/day).

Foulkes reported a patient with arsenical-refractory *T. brucei rhodesiense* infection with CNS involvement who responded to combined intravenous suramin and high-dose oral metronidazole.⁸³ The patient's CSF was normal, with no trypanosomes evident, at 1-year follow-up.

TRYPANOSOMA CRUZI INFECTION

There have been few advances in the chemotherapy of this infection for many years. Both of the standard drugs (nifurtimox and benznidazole) are toxic, with adverse reaction rates of 30–55%.⁸⁴ Tanowitz et al,⁸⁵ reviewing Chagas disease, drew attention to studies in which 42% of rabbits receiving benznidazole and 33% of rabbits receiving nifurtimox developed widely invasive lymphomas, yet none of the control animals did so. They also point out that both agents have been widely used in Latin America for several decades, without reports of an increased frequency of lymphomas in treated patients. It should be noted that both agents are contraindicated in pregnancy.

Despite initial optimism,^{84,86} the WHO has stated that allopurinol lacks any demonstrable parasiticidal activity in humans.

Nifurtimox acts against trypomastigotes and amastigotes. Side effects of nifurtimox are common and dose related. It is rapidly absorbed from the gastrointestinal tract and predominantly metabolized in the liver by cytochrome P₄₅₀ reductase. Recognized side effects include gastrointestinal symptoms (30–70% of patients), headache, vertigo, excitability, myalgia, arthralgia, convulsions and peripheral polyneuritis.⁴⁰

Benznidazole is also active against trypomastigotes and amastigotes. Side effects commonly occur, including rashes,

fever, purpura, peripheral polyneuritis, leukopenia and agranulocytosis.^{39,87} Response to therapy is variable; for example, some central Brazilian strains are less sensitive. Andrade et al isolated 11 strains of *T. cruzi* from patients with Chagas disease in central Brazil and characterized them biologically and by isoenzyme analysis.⁸⁸ Patients received benznidazole or benznidazole plus nifurtimox. Mice infected with the corresponding strain were treated with the drug(s) corresponding to the regimen received by the patient. Mice underwent a test of cure 3–6 months after the end of treatment. Patients were tested by xenodiagnosis monthly on at least 25 occasions. Mice infected with type II (zymodeme 2) strains showed 66–100% cure rates, but those infected with type III (zymodeme 1) strains showed 0–9% cure rates. In humans, five of six patients with type II strains but only two of five patients with type III strains were cured. There was correlation between treatment outcome in patients and mice in nine of 11 (81.8%) cases.

Congenital Chagas disease can be treated with nifurtimox or with benznidazole.⁸⁷ Parasitological cure is thought to occur in 90% of congenitally infected infants treated in the first year of life.⁸⁹ Neither drug is available in pediatric formulations but both are well tolerated by infants and young children.

As a result of increasing geographical overlap, reactivation of latent *T. cruzi* infection secondary to HIV-mediated immunosuppression is increasingly recognized. Solari et al⁹⁰ reported a patient with hemophilia and AIDS complicated by multifocal necrotic encephalitis due to *T. cruzi*: 2 weeks' therapy with benznidazole 400 mg/day failed to improve the condition, but itraconazole 200 mg/day, later changed to fluconazole 400 mg/day in an attempt to achieve better CNS penetration, was associated with resolution of fever and stabilization of the neurological symptoms. Further evaluation of triazole antifungal agents against *T. cruzi* infections should be undertaken. Sartori et al describe a small series of patients co-infected with HIV and Chagas disease who responded to a standard 60-day benznidazole regimen which resulted in decreased parasitemia and clinical improvement.⁹¹ DiazGranados et al⁹² regard the recommended treatment for reactivated *T. cruzi* infection in HIV-positive patients as benznidazole 5 mg/kg per day in two divided doses for 60–90 days or nifurtimox 8–10 mg/kg per day in three divided doses for 60–120 days, though there is less clinical experience with the latter. Following treatment they advocate secondary prophylaxis with benznidazole 5 mg/kg three times weekly. Antiretroviral therapy should be commenced to promote immune reconstitution. There are no studies to provide definitive guidance on the necessary duration of secondary prophylaxis or criteria for its possible withdrawal.

While specific treatment of *T. cruzi* was originally limited to the acute phase, recent evidence has suggested that drug therapy may be indicated in chronically infected individuals. Solari et al used the polymerase chain reaction (PCR) to follow-up children treated with nifurtimox in the chronic phase of *T. cruzi* infection.⁹³ 66 children were treated with

nifurtimox 7–10 mg/kg per day for 60 days and followed up by repeated serology, xenodiagnosis and PCR for 36 months after therapy. Although all but two patients remained seropositive, xenodiagnosis rapidly became negative after 3 months. PCR became negative in most cases by 24 months and in all cases by 36 months post treatment. These smaller studies in children, together with growing clinical experience, have now encouraged the early diagnosis and prompt treatment of all infected children.⁸⁶

Estani and Segura advocate the following guidelines for the treatment of *T. cruzi* infection, which have been adopted in Argentina.⁹⁴ They recommend treatment for all patients in the acute phase, for young people in the indeterminate phase, for adult patients in the indeterminate phase or with heart lesions, for laboratory accidents and during surgery, for organ transplant recipients or donors.

In a non-randomized, non-blinded controlled trial of Chagas disease patients with cardiac disease, benznidazole treatment (for 30 days) appeared to slow the progression of cardiomyopathy in adults.⁹⁵ This trial and Argentinian clinical experience⁹⁶ have encouraged some experts to treat these chronic Chagas disease patients. There is currently underway a phase III multicenter, randomized, double-blind, placebo-controlled trial (the BENEFIT trial) which remains ongoing until 2010. It will evaluate benznidazole treatment versus placebo (for 60 days) in the prevention of progression of cardiac disease.⁹⁷

Neto, based in Brazil, advocates the following treatment regimen:⁹⁸

- For prevention of infection by *T. cruzi* following a laboratory accident and possibly after a blood transfusion from a *T. cruzi*-infected donor: benznidazole 7–10 mg/kg for 10 days.
- Benznidazole is given as 5 mg/kg per day for 60 days for adults; 5–10 mg/kg per day for 60 days for children.
- Nifurtimox is given as 8–10 mg/kg per day for 60–90 days for adults; 15 mg/kg per day for 60–90 days for children.

Reviewing the results from a variety of sources, Neto quotes the following percentages of cure (based upon negative xenodiagnosis and serology) for persons treated at various stages of infection:⁹⁸

- Acute phase 70%
- Recent chronic phase 60%
- Long-term chronic phase 20%.

Rassi and Luquetti⁹⁹ state that efficacy of treatment may depend on geographical area. They also point out that extensive use of benznidazole took place after 1980 so they expect the efficacy rate for the late chronic phase to rise as more adults achieve 20-year post-treatment follow-up, the period required to regard the infection as cured. However, not all are convinced that therapy of chronically infected individuals is appropriate. In Brazil, Braga et al used nested PCR to follow-up 17 treated (at least 30 days of anti-trypanosomal nitrofuran or nitroimidazole treatment) and 17 untreated chronic Chagas disease patients.¹⁰⁰ There was no statistically

significant difference in the mean number of *T. cruzi* per mL in untreated (25.83) and treated (6.45) individuals. These authors took the view that treatment of chronic Chagas disease remains controversial and argue that further evaluation of the benefits of treatment with nitro derivatives is required. They reinforced the need for a precise definition of the role of treatment with nitrofuran and nitroimidazole compounds in chronic *T. cruzi* infection.

A further note of caution was sounded by Silveira et al,¹⁰¹ who studied 12 children aged between 7 and 12 years in the indeterminate phase of *T. cruzi* infection, with both positive serology and xenodiagnosis. Two patients had received nifurtimox 7 mg/kg for 60 and 90 days and 10 had received benznidazole 5–7 mg/kg for 60 days. The patients were residents of an area where transmission had been interrupted for more than 10 years. Eight individuals were followed up for 8 years and four for 20 years. Clinical evaluation consisted of physical examination, electrocardiogram and esophageal radiography with contrast. Only one child was negative in all examinations performed; seven (58.4%) remained in the indeterminate stage and four (33.3%) progressed to second-degree cardiopathy and/or megaesophagus. However, the authors' data showed only one of the 12 patients to be PCR and xenodiagnosis positive, the other patients being negative by both tests.

Iatrogenically immunosuppressed individuals in the chronic phase of *T. cruzi* infection are at risk of reactivation of the infection, with increased parasitemia. Rassi et al treated 18 adult patients in the chronic phase of Chagas disease, who were taking corticosteroids for concomitant diseases, with benznidazole (at the start of corticosteroid treatment in 12 patients or 15 days afterwards in six patients).¹⁰² Benznidazole therapy (10 mg/kg per day for 60 days in all but one patient) was reported to prevent the increase, and thus might potentially be useful in immunosuppressed patients with chronic Chagas disease. Reactivation of Chagas disease has been estimated at 9–16% in renal transplants, 50–100% in cardiac transplants and 17–40% in autologous and allogeneic transplants. Altclas et al¹⁰³ argue that there is no evidence to support the use of pre-emptive treatment of transplant patients with Chagas disease. Patients would still need post-transplant monitoring for reactivation. This is especially the case as benznidazole has reported adverse side effects in immunocompromised patients.⁹⁵

The Pan American Health Organization recommends treatment of *T. cruzi* infection as follows:¹⁰⁴

- Treatment is with nifurtimox or benznidazole. For nifurtimox, patients up to 40 kg in weight should receive 10–12 mg/kg per day. Those whose weight exceeds 40 kg should receive 8 mg/kg per day. The total daily dose is split into two or three equal doses per day and given for 30–60 days. For benznidazole, patients weighing up to 40 kg should receive 7.5 mg/kg per day. Those who weigh more than 40 kg should receive 5 mg/kg per day. The drug is administered in two or three doses per day for 30–60 days.

- Congenital infection is treated with nifurtimox 10–15 mg/kg per day or benznidazole 10 mg/kg per day.
- In preterm or low birthweight infants, treatment should be started with half the dose. If there is no evidence of leukopenia or thrombocytopenia at 72 h, it is possible to give the definitive dose for the next 60 days.
- It should be noted that whereas acute-phase or congenital *T. cruzi* infection can be treated with either nifurtimox or benznidazole, in the case of recent chronic infection evidence of successful treatment exists only for benznidazole.
- For late chronic infection, the objectives of treatment are to eradicate the parasite, prevent the appearance or progression of visceral lesions, and interrupt the cycle of transmission. There is no age limit to eligibility for treatment. Specific therapy is *not* recommended during pregnancy or breastfeeding, in hepatic or renal insufficiency, when there are serious coexisting lesions. Nifurtimox is given at a dose of 8–10 mg/kg per day (split into 8-hourly doses, preferably after food) for 60–90 days. Benznidazole is given at a dose of 5 mg/kg per day (split into 8- or 12-hourly doses, preferably after food) for 60 days.
- Long-term follow-up with clinical assessment, electrocardiography, serology and PCR is required.

As Neto points out,⁹⁸ the decision on treatment requires consideration of each case individually, balancing the chance of a cure and the stage of the disease against the known side effects of the drugs.

For the future, new triazole derivatives (e.g. SCH56592; Schering-Plough) and bisphosphonates (e.g. pamidronate) have shown encouraging activity against *T. cruzi* in murine models.¹⁰⁵

Interestingly, there is further accumulating evidence that some patients infected with *T. cruzi* spontaneously cure the parasite with no further sequelae. Dias et al report one such case in Brazil of a 5-year-old girl first reported in 1944 with smear-positive acute trypanosomiasis; she had no treatment and continued to have both clinical and laboratory follow-up until 2007.¹⁰⁶ She has no evidence of chronic disease and remains completely well.

In summary, who should be treated for *T. cruzi* infection and with what agent? The WHO⁸⁶ recommendations are as follows.

ACUTE PHASE

- For uncomplicated cases, benznidazole 7.5 mg/kg per day for weight up to 40 kg, 5 mg/kg per day for over 40 kg body weight.
- Acute meningoencephalitis, up to 25 mg/kg per day.
- For congenital cases, full-term neonates should receive benznidazole 10 mg/kg per day. Dosing starts at 5 mg/kg per day and is increased to 10 mg/kg per day after 3 days provided there is no leukopenia or thrombocytopenia.

- The total daily dose is given as two or three divided doses. Duration of treatment in all cases is 60 days.
- For organ transplantation, the WHO states that infected donors should be treated for 2 weeks before donation and recipients for 2 weeks afterwards.
- For laboratory accidents, a 10-day course of benznidazole 7–10 mg/kg per day is recommended.

CHRONIC PHASE

- The WHO states that every patient can benefit from antiparasitic treatment and that the treating physician should determine the age limits and clinical suitability of therapy. A 60-day course of either benznidazole 5 mg/kg per day split to two or three divided doses or nifurtimox 8 to 10 mg/kg per day split to three divided doses is recommended.
- For prevention of reactivation in *T. cruzi* and HIV co-infection, benznidazole 5 mg/kg per day three times weekly. Prophylaxis is not justified in those receiving HAART.

Writing from the United States and thus dealing predominantly with the chronic phase, Bern et al⁸⁹ recommend antitrypanosomal treatment for:

- all cases of acute and congenital Chagas disease
- reactivated infection
- chronic *T. cruzi* infection in individuals 18 years or younger and state that it should generally be offered to those aged 19–50 years without advanced heart disease. They regard it as optional for those over 50.

Treatment should be strongly considered for previously untreated individuals with *T. cruzi* and HIV co-infection and for patients awaiting organ transplantation.

ENTAMOEBA HISTOLYTICA

Choice of treatment regimen depends upon the particular clinical presentation of amebic infection.

AMEBIC DYSENTERY

The treatment of choice is metronidazole followed by diloxanide furoate. Metronidazole 800 mg every 8 h for 5 days produced a cure rate in excess of 90%.¹⁰⁷ Other nitroimidazoles such as tinidazole (adult dose 2 g/day for 3–5 days) or a single dose of the long-acting nitroimidazole secnidazole 2 g are alternative agents. The use of a single dose of secnidazole showed microscopic clearance in 81% at day 21.¹⁰⁸

With the above regimens, neither nitroimidazole achieves adequate clearance of amebic cysts from the intestinal lumen; thus, a luminal amebicide is required to complete therapy. Diloxanide furoate 500 mg orally every 8 h for 10 days is first choice, alternatives being paromomycin (aminosidine) 500 mg orally every 8 h for 10 days, or iodoquinol (diiodohydroxyquin)

650 mg every 8 h for 20 days.¹⁰⁹ However, diiodohydroxyquin therapy, albeit in longer courses, has been associated with the development of blindness,¹¹⁰ and since there are good alternate agents available, the use of this drug is not recommended. Nitazoxanide, a nitrothiazolyl-salicylamide derivative, at a dose of 500 mg every 12 h for 3 days showed cyst passage clearance rates of 81% in treated patients within 7–10 days of therapy compared with 40% in the placebo group.^{111,112} This compares well with similar clearance rates after the longer treatment regimen of diloxanide furoate.

AMEBIC LIVER ABSCESS

The dose of metronidazole required in amebic liver abscess is lower than in amebic dysentery. Amebic liver abscess is treated with metronidazole 400 mg orally every 8 h for 5 days,¹⁰⁷ followed by diloxanide furoate (as above). Tinidazole is an alternative to metronidazole. Initial work used a dosage regimen of 800 mg every 8 h for 5 days,¹¹³ but 2 g/day orally for 3–5 days is currently used. Scragg and Proctor achieved a 92% cure rate in children with amebic liver abscess with tinidazole in a mean dose of 55 mg/kg per day for 3–5 days, in combination with therapeutic aspiration.¹¹⁴ Secnidazole 500 mg every 8 h for 5 days is another nitroimidazole that can be used in the treatment of amebic liver abscesses.¹¹⁵

Rarely, when nitroimidazoles do not seem to be effective despite therapeutic aspiration of the abscess (*see below*), dehydroemetine or emetine can be considered. However, both have serious side effects, notably cardiotoxicity. Where it is essential to use one of them, dehydroemetine is preferred as it is less toxic than emetine. The dosage regimen is dehydroemetine 1.25 mg/kg (maximum daily dose 90 mg) intramuscularly or deep subcutaneously for 10 days. Emetine dosage is 1 mg/kg (maximum daily dose 60 mg) intramuscularly or deep subcutaneously for 10 days.^{116,117}

Chloroquine is another alternative where nitroimidazoles fail or cannot be used. However, it is only moderately effective in amebic liver abscess and ineffective in amebic dysentery.¹⁰⁷ The regimen is chloroquine 150 mg base every 6 h for 2 days, then 150 mg base every 12 h for 19 days.¹¹⁷

Aspiration of an amebic liver abscess is occasionally necessary. Reed gives the following indications:¹⁰⁹

1. To rule out a pyogenic abscess, particularly with multiple lesions. Aspiration for diagnostic purposes should only rarely be required, provided good-quality amebic serology is available and if appropriate antibacterial and antiamebic therapy can be given from the outset pending the outcome of blood cultures and amebic serology. Scragg thought there was no place for diagnostic aspiration and that aspiration should be considered as part of treatment.¹¹⁸
2. As an adjunct to medical treatment, if a patient does not respond to therapy within 3–5 days and if rupture is believed to be imminent.
3. To decrease the risk of rupture of an abscess of the left lobe of the liver into the pericardium.

ASYMPTOMATIC CYST PASSAGE

The decision whether or not to treat asymptomatic cyst passage depends on several factors. If the patient is ordinarily resident in an area highly endemic for *Entamoeba histolytica* and thus likely to become reinfected fairly quickly, the benefit of eradicating cyst carriage has to be weighed against the cost of treatment and likely benefit to the individual, bearing in mind the fact that most strains of '*E. histolytica*' are non-pathogenic. *Entamoeba histolytica* has now been split into *E. histolytica*, which is always regarded as pathogenic, and *Entamoeba dispar* (formerly non-pathogenic *E. histolytica*), which had originally been proposed by Brumpt in 1925 and was confirmed by Sargeaunt.¹¹⁹ However, where asymptomatic cyst passage persists following therapy of amebic dysentery or amebic liver abscess, further treatment with a luminal amebicide is mandatory, otherwise relapse is frequent.¹¹⁶

In areas where indigenous amoebiasis is very uncommon, most *E. histolytica/E. dispar* infections are imported, and good luminal amebicides are readily available, so the decision is more in favor of treatment. Ideally, treatment strategy should be based on the results of PCR to separate *E. histolytica* from *E. dispar* (since they are morphologically identical), but the technique is available in only a few centers. Some population groups appear to harbor only non-pathogenic strains. For example, Allason-Jones et al studied '*E. histolytica*' cysts from men who have sex with men (MSM) in London and all strains had a non-pathogenic zymodeme pattern.¹²⁰ They concluded that asymptomatic '*E. histolytica*' cyst passage in MSM did not require treatment.

GIARDIASIS

The treatment of choice is tinidazole 2 g as a single dose, a regimen effective in approximately 90% of cases. Metronidazole 2 g/day for 3 days gives a similar cure rate. Low dose, longer duration metronidazole regimens (200 mg every 8 h for 7–10 days) give cure rates of 60–87%.¹²¹ Failure of therapy with nitroimidazole therapy may be due to a variety of possible factors: reinfection, underlying immunodeficiency or drug resistance. Where nitroimidazole resistance is thought to be the explanation, there are few alternative agents.

Mepacrine (quinacrine, atebrin) is active against *Giardia*¹²² and is given as 100 mg every 8 h for 5–7 days, with reported cure rates of 90–95%.^{123,124} It should be used with caution in view of its known side effects: Wolfe reported toxic psychosis in 1.5% of adult patients treated with this agent¹²⁵ and other side effects include CNS stimulation and (on prolonged therapy) yellow discoloration of the skin.

Furazolidone provides another option¹²⁶ and is given at 100 mg every 6 h for 7 days, with reported cure rates of 75–90%.¹²³ Side effects, though usually mild, occur in approximately 20% of patients¹²⁷ and patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency may develop hemolysis on furazolidone.

Hall and Nahar compared the efficacy of albendazole with that of metronidazole against *Giardia* infection of children in Bangladesh.¹²⁷ Albendazole, 400 mg/day for 5 days, produced a 94.8% cure rate, not statistically different from the 97.4% cure rate produced in children receiving metronidazole 375 mg/day for 5 days.

Paromomycin (aminosidine) (25–30 mg/kg per day in three divided doses for 5–10 days) is effective in 60–70% of cases.¹²⁴ As it is excreted nearly 100% unchanged in the feces, it is used by some practitioners when nitroimidazoles cannot be used in pregnancy.

Nitazoxanide 500 mg every 12 h as a 3-day course showed *Giardia* cyst clearance in 91% of patients, compared with 36% clearance in the placebo group at days 7–10.¹¹¹ This clearance rate compared well with similar rates achieved with metronidazole.

TRICHOMONAS VAGINALIS

Metronidazole 2 g as a single oral dose has produced cure rates as high as 97% and lends itself better to compliance.¹²⁸ An alternative regimen is 400 mg every 12 h for 7 days; this regimen has the advantage of protecting against reinfection during the 7-day treatment period. Tidwell et al compared a single 2 g oral dose of metronidazole with a single 2 g intravaginal dose:¹²⁹ 88% of the oral group but only 50% of the intravaginal group were microbiologically cured ($p = 0.0037$). Given the level of asymptomatic carriage, treatment of both partners simultaneously is recommended.

Tinidazole 2 g as a single dose, repeated if the first dose fails to produce clinical benefit, is an alternative to metronidazole.

Secnidazole, another nitroimidazole, is also effective against *Trichomonas* when given as a single 2 g dose.¹³⁰

The most common causes of treatment failure are reinfection or non-compliance with therapy, but metronidazole-resistant strains of *T. vaginalis* are well documented:¹³¹ approximately 5% of all *T. vaginalis* isolates from patients had some level of resistance to metronidazole.¹³² Treatment of resistant isolates requires higher doses (usually double the recommended treatment dose for an extended period of time) and, in high-level resistance, intravenous metronidazole. There is likely to be cross-resistance to other nitroimidazoles and therapy with another drug class might be necessary.¹³³ Refractory cases occur after two standard courses of treatment and are very problematical as higher and higher doses often lead to drug toxicity and intolerable side effects. Nitazoxanide has demonstrated good in-vivo activity against other protozoa and good in-vitro activity against metronidazole-resistant *T. vaginalis*, making it a potential agent for the future.¹³⁴ Alternative topical agents include clotrimazole, nonoxynol-9 and povidone-iodine, none of which has given consistently effective cure in women and all of which are ineffective in men,¹³⁵ highlighting the need for new anti-trichomonal drugs.

For *T. vaginalis* infections during the first trimester of pregnancy, treatment with nitroimidazole derivatives is contraindicated; 100 mg clotrimazole suppositories intravaginally at bedtime for 14 days have been tried, with a cure rate of 50% with some associated symptomatic relief.¹⁰⁵ The cure rates in a multicenter study for a single oral 2 g metronidazole dose were 80% compared with 11.1% for vaginal clotrimazole (two 100 mg tablets per day) and 18.6% for vaginal suppositories (containing 1.05 g sulfanilamide, 14 mg aminacrine hydrochloride and 140 mg allantoin) intravaginally every 12 h for 7 days.¹³⁶ Treatment should be reserved for those with severe symptoms. Nitroimidazoles can be used during the second trimester of pregnancy.

Breastfeeding mothers can be treated with a single dose of 2 g secnidazole or metronidazole with a 24 h interruption of breastfeeding after therapy.

Neonatal trichomoniasis is dependent on maternal estrogen levels, which begin to wane in the neonate after 3–6 weeks of life; therapy for symptomatic neonates can only be considered at 2 months of age.¹³² In neonates beyond 8 weeks of age where the infection persists or there are symptoms, the infant may be treated with metronidazole as a single 50 mg/kg dose or 10–30 mg/kg per day for 5–7 days.¹³³

In general, drugs delivered intravaginally are of significantly lower efficacy than systemically administered nitroimidazoles, which still remain the drugs of choice.

Cryptosporidium

Diarrhea due to this organism is usually self-limiting in those with normal immunity, but can be devastating in immunocompromised people, notably in patients with AIDS. Highly effective treatment remains elusive, but several drugs have been found to be effective in some studies. Paromomycin has been reported effective in a double-blind, placebo-controlled trial.¹³⁷ Vargas et al reported successful use of azithromycin in two cases in immunocompromised children.¹³⁸ A case report in a pediatric renal transplant patient with profuse cryptosporidial diarrhea used a combination of nitazoxanide, azithromycin and paromomycin to achieve clearance.¹³⁹ In a randomized, double-blind, placebo-controlled study, nitazoxanide 500 mg every 12 h for 3 days (100 mg every 12 h for 1–3 year olds, 200 mg every 12 h for 4–11 year olds) showed an 80% clinical resolution and 67% oocyst clearance at day 7 (values were 41% and 22%, respectively, in the control group).^{111,112}

Therapy of the immunocompromised patient with cryptosporidiosis is difficult and the mainstay of treatment is modulation of the immune defect. HIV-infected patients on HAART showed persistent parasitological clearance after 1 month of paromomycin 2 g every 6 h. Groups on triple and double therapy showed no relapses, except for two patients who stopped HAART. The groups on no antiretroviral therapy or monotherapy showed only 20% resolution after paromomycin.¹⁴⁰

A double-blind, placebo-controlled, randomized trial of 66 patients with HIV compared 14 days of nitazoxanide with placebo and saw a 80–92% resolution of diarrhea with nitazoxanide compared to 50% in the placebo group.¹⁴¹ A further compassionate use program of nitazoxanide in 365 patients with AIDS saw 209 patients achieve a sustained clinical response.¹⁴²

Hyperimmune bovine colostrum has also been used for the treatment of cryptosporidiosis in HIV-positive patients.^{143,144}

ISOSPORA BELLI

The treatment of choice is trimethoprim-sulfamethoxazole.¹⁴⁵ A combination of pyrimethamine and sulfadiazine given for 8 weeks was successful in an HIV-positive patient in whom trimethoprim-sulfamethoxazole daily for 2 weeks had failed. Diiodohydroxyquin, paromomycin and spiramycin have also been unsuccessful.¹⁴⁶

For two AIDS patients with hypersensitivity to trimethoprim-sulfamethoxazole, a combination of albendazole and ornidazole showed parasitological clearance in one patient.¹⁴⁷

Furazolidone is an alternative agent for the treatment of isosporiasis.

CYCLOSPORA CAYETANENSIS

Cyclospora infection may be self-limiting, so antimicrobial therapy is not required in every case. Where specific treatment is deemed necessary, the agent of choice is trimethoprim-sulfamethoxazole 960 mg every 12 h for 7 days.¹⁴⁸ In a cohort study of Haitian HIV-positive patients the relapse rate after initial therapy with 960 mg trimethoprim-sulfamethoxazole every 6 h for 10 days was 43% and secondary prophylaxis of single dose 960 mg trimethoprim-sulfamethoxazole three times a week was required. No patient had received antiretroviral therapy.¹⁴⁹ For patients with hypersensitivity to sulfa drugs, monotherapy with trimethoprim showed no effect,¹⁵⁰ but ciprofloxacin 500 mg every 12 h for 7 days showed a 70% parasitological clearance on day 7 (clearance was 95% in the trimethoprim-sulfamethoxazole group).¹⁵¹ Ciprofloxacin could be used in patients with hypersensitivity to sulfonamides.

MICROSPORIDIOSIS

Intestinal microsporidiosis in AIDS patients is caused by *Enterocytozoon bieneusi* or *Encephalitozoon (Septata) intestinalis*. Albendazole 400 mg every 12 h for 3 weeks showed excellent efficacy for the treatment and prophylaxis of *E. intestinalis* infection in patients with AIDS.¹⁵² Albendazole lacks efficacy against *E. bieneusi*, but 20 mg fumagillin every 8 h has shown

some promise but the number of cases is small and neutropenia is a recognized adverse effect.¹⁵³ Thalidomide 100 mg at night for 1 month showed 38% complete remission and 17% partial remission.¹⁵⁴ Nitazoxanide 1 g every 12 h for 60 days achieved parasitological clearance in an AIDS patient who had not been on antiretroviral therapy at the time nitazoxanide was administered.¹⁵⁵ Immune modulation of HIV-infected patients achieved with HAART remains an important therapeutic intervention in the treatment of microsporidial infections.^{141,156}

BABESIOSIS

BABESIA BOVIS AND BABESIA DIVERGENS

These infections are usually encountered in splenectomized humans, leading to fulminant illness and death. There are no controlled trials of treatment. Diminazene (Berenil) is active against animal babesiosis and has been used in a case of human infection with *B. divergens*, but the patient did not survive.¹⁵⁷ The same authors reported successful treatment of a splenectomized patient infected with this parasite using pentamidine plus trimethoprim-sulfamethoxazole. Successful treatment of three cases with massive exchange blood transfusion (2–3 blood volumes) followed by intravenous clindamycin and oral quinine was reported by Brasseur and Gorenflo.^{158,159}

Atovaquone is effective against *B. divergens* in vitro.¹⁶⁰ In the absence of data from randomized controlled trials, treatment for human infection with *B. divergens* should consist of exchange blood transfusion plus intravenous clindamycin and intravenous or oral quinine, depending upon the patient's condition.

BABESIA MICROTI

In most cases patients suffer a mild illness and recover spontaneously. Where illness is severe enough to merit treatment, quinine plus clindamycin is the treatment of choice.¹⁶⁰ Whole blood or red cell exchange transfusion has produced a rapid and substantial fall in parasitemia.¹⁶¹ Krause et al compared atovaquone 750 mg every 12 h plus azithromycin 500 mg on day 1 and 250 mg/day thereafter for 7 days with clindamycin 600 mg every 8 h and quinine 650 mg every 8 h for 7 days, all drugs being given orally.¹⁶² Atovaquone plus azithromycin proved to be as effective as clindamycin plus quinine and had fewer adverse reactions. The authors recommended the use of atovaquone plus azithromycin for the treatment of non-life-threatening babesiosis in immunocompetent adult patients and in others who cannot tolerate clindamycin and quinine. Ranque has suggested that a trial of atovaquone plus clindamycin should be performed.¹⁶³

CHAPTER

64 Helminthic infections

Tim O'Dempsey

Helminths are complex, multicellular, parasitic worms occupying a wide variety of geographical, ecological and anatomical niches. They are classified into three groups: nematodes (roundworms), platyhelminths (flatworms, including trematodes and cestodes) and annelids (segmented worms, including leeches) (Table 64.1). Their life cycles vary in complexity. Some, for example *Enterobius vermicularis*, are principally dependent upon their human host, while others, such as the hepatic and intestinal flukes, require two intermediate hosts to complete their life cycle. Pathological effects in humans may be caused by the adult worms, egg deposition in tissues, or migration and death of larvae or microfilariae. Most infections are asymptomatic. Clinical disease is more likely in those who are immunologically naive following substantial initial exposure, in heavy infections and in people who are immunosuppressed or malnourished.

Helminthic infections are a major cause of morbidity and mortality worldwide and are prominent among the so-called neglected tropical diseases (NTDs).¹ The NTDs include schistosomiasis and the 'soil transmitted helminths' (STH), a group of parasites whose life cycle usually depends on a period of development outside the human host, typically in moist, warm soil. The most important STH are *Ascaris lumbricoides*, *Trichuris trichiura* and the hookworms (*Necator americanus* and *Ancylostoma duodenale*). Unprecedented efforts are now being made to control or eradicate these infections by means of health education, improved hygiene and sanitation, provision of safe water, vector control, and selective and mass chemotherapy using a limited repertoire of safe and effective anthelmintic agents (Table 64.2).

Recently, nitazoxanide, a thiazolidine compound, has been shown to be well tolerated and effective in the treatment of a wide range of helminthic and other gastrointestinal infections, including *Ascaris lumbricoides*, *Strongyloides stercoralis*, *Trichuris trichiura*, *Enterobius vermicularis*, *Taenia saginata*, *Hymenolepis nana* and *Fasciola hepatica*.²

INTESTINAL HELMINTHS

INTESTINAL NEMATODE INFECTIONS

ASCARIASIS

Ascaris lumbricoides, the most common roundworm infection in humans, affects over 1 billion people worldwide. The peak prevalence and intensity of infection are among children aged 3–8 years. Infection follows ingestion of eggs contaminating vegetables, soil or dust. Larvae, liberated as the eggs pass through the stomach and small intestine, penetrate the intestinal mucosa and enter blood and lymphatic vessels. A proportion reaches the lungs 4–16 days after infection. After penetrating the alveoli and molting, they migrate via the respiratory tract to the esophagus and are carried to the small intestine. Here they develop into adults, mate and start producing eggs 6–8 weeks after infection. Adults grow to a length of 15–35 cm and may survive for 1–2 years. Females are capable of producing 200 000 eggs per day. The eggs are excreted in feces and their ova mature into infective embryos within 1–4 weeks. Eggs may remain viable in soil for years.

Migration of larvae through the lungs may cause fever, cough, dyspnea, wheeze and urticaria. Chest pain and cyanosis occur in more severe cases and sputum may be slightly blood-stained. Chest radiographic abnormalities range from discrete densities to diffuse interstitial, or more confluent, infiltrates. *Ascaris* pneumonitis, when accompanied by eosinophilia, is known as Löffler's syndrome. The episode usually subsides spontaneously within 10 days.

Adult intestinal worms are rarely noticed unless passed in the stool. In heavy infections the worms may intertwine to form a bolus, causing intestinal obstruction, volvulus or

Table 64.1 Clinically important helminths and their principal modes of infection

Helminth (common name)	Principal mode of infection
Intestinal helminthes	
Nematodes:	
<i>Ascaris lumbricoides</i> (roundworm)	Ingestion of egg
<i>Enterobius vermicularis</i> (pinworm/threadworm)	Ingestion of egg
<i>Trichuris trichiura</i> (whipworm)	Ingestion of egg
<i>Ancylostoma duodenale</i> (hookworm)	Larval penetration of skin
<i>Necator americanus</i> (hookworm)	Larval penetration of skin
<i>Strongyloides</i> spp.	Larval penetration of skin
Cestodes:	
<i>Taenia saginata</i> , <i>Taenia solium</i> (beef/pork tapeworm)	Ingestion of cyst
<i>Diphyllobothrium latum</i> (fish tapeworm)	Ingestion of plerocercoid larva
Larval helminths	
Nematodes:	
<i>Trichinella</i> spp. (trichinosis)	Ingestion of cyst
<i>Toxocara</i> spp. (toxocariasis)	Ingestion of egg
Cestodes:	
<i>Taenia solium</i> (cysticercosis)	Ingestion of egg
<i>Echinococcus granulosus</i> (hydatid cyst)	Ingestion of egg
<i>Echinococcus multilocularis</i> (alveolar hydatid)	Ingestion of egg
Trematodes (flukes)	
<i>Schistosoma</i> spp. (bilharzia)	Cercarial penetration of skin
<i>Paragonimus</i> spp. (lung fluke)	Ingestion of metacercariae
<i>Fasciolopsis buski</i> (intestinal fluke)	Ingestion of metacercariae
<i>Fasciola hepatica</i> , <i>Fasciola gigantica</i> (liver flukes)	Ingestion of metacercariae
<i>Opisthorchis sinensis</i> , <i>O. viverrini</i> (oriental liver flukes)	Ingestion of metacercariae
Filarial nematodes	
<i>Onchocerca volvulus</i> (river blindness)	Infective larvae from:
<i>Loa loa</i> (loiasis, eye worm)	Bite of <i>Simulium</i> (black fly)
<i>Dracunculus medinensis</i> (Guinea worm)	Bite of <i>Chrysops</i> (red fly)
<i>Wuchereria bancrofti</i> , <i>Brugia malayi</i> , <i>Brugia timori</i> (lymphatic filariasis)	Ingestion of L3 larva within <i>Cyclops</i>
	Bite of various mosquitoes

Table 64.2 Side effects of selected anthelmintic agents

Anthelmintic agent	Frequent side effects	Occasional side effects	Rare side effects
Albendazole		Abdominal pain, reversible alopecia, increased transaminases, headache	Leukopenia, rash, renal toxicity, fever
Diethylcarbamazine citrate	Mazzotti reaction with onchocerciasis	Gastrointestinal disturbances, hypersensitivity reactions	Encephalopathy, renal failure (especially in patients with loiasis and high microfilaria counts)
Ivermectin		Gastrointestinal disturbances	Mazzotti reaction in onchocerciasis, encephalopathy in loiasis, transient postural hypotension
Levamisole	Nausea, diarrhea, altered taste	Dermatitis, alopecia, arthralgia, blood dyscrasias, myalgia, bone pain, depression, dizziness, headache, stomatitis, vomiting	Ataxia, visual disturbance, hepatitis, paresthesia, convulsions, tardive dyskinesia, tremors
Mebendazole		Gastrointestinal disturbances, headache	Hypersensitivity reactions, hypospermia, leukopenia, agranulocytosis
Niclosamide	Gastrointestinal disturbances, dizziness, pruritus		
Nitazoxanide		Abdominal pain, diarrhea, vomiting, headache	Hypotension, tachyarrhythmias, hepatitis, anemia, menorrhagia, myalgia, urinary symptoms and discoloration
Oxamniquine		Headache, fever, dizziness, nausea, vomiting, hepatitis, insomnia, hallucinations, orange discolouration of urine	Convulsions
Piperazine		Gastrointestinal disturbances, hypersensitivity reactions	Stevens–Johnson syndrome, angioedema, ataxia ('worm wobble'), drowsiness, confusion, convulsions in patients with neurological/renal abnormalities
Praziquantel		Gastrointestinal disturbances, headache, dizziness, sedation, fever	Pruritus, rash, edema, hiccups
Pyrantel pamoate		Gastrointestinal disturbances, dizziness, rash, fever	
Thiabendazole	Gastrointestinal disturbances, vertigo, headache, drowsiness, pruritus	Leukopenia, crystalluria, rash, neuropsychiatric disturbances, erythema multiforme	Shock, tinnitus, intrahepatic cholestasis, convulsions, angioneurotic edema, Stevens–Johnson syndrome

perforation. Migrating worms may obstruct ducts or diverticuli causing biliary colic, cholangitis, liver abscess, pancreatitis or appendicitis. A well-known hazard of anesthesia is endotracheal tube obstruction by a wandering ascaris. Cases of pneumothorax and pericarditis have also been reported.³

Diagnosis and treatment

Ascaris pneumonitis is diagnosed on clinical grounds; the presence or absence of eggs in the stools is irrelevant. Larvae may be found in the sputum. Stool examination for eggs is the standard method for diagnosing established infection, although stools may be negative if infection is entirely due to male worms. Worms may also be identified on barium studies, ultrasonography and endoscopy.

Albendazole 400 mg in a single oral dose eliminates most infections. In heavy infections this may need to be repeated for 2–3 days. The recommended dose in children aged 1–2 years is 200 mg. Mebendazole 100 mg orally every 12 h for 3 days is also effective, although use in children under 2 years is not recommended by the manufacturer. There are also reports of ectopic migration of *Ascaris* following the use of mebendazole.

Piperazine 75 mg/kg (to a maximum of 3.5 g for adults and children over 12 years and a maximum of 2.5 g for children aged 2–12 years) is also effective. As side effects are relatively common and may be serious, piperazine should be used only if safer alternatives are unavailable. Pyrantel pamoate (11 mg/kg up to a maximum of 1 g) can be given as a single dose. Pyrantel and piperazine have antagonistic effects and should never be prescribed concurrently.

Levamisole 2.5–3 mg/kg (max. 150 mg) for children 1 month to 18 years, 120–150 mg for adults, as a single dose is also highly effective. Nitazoxanide given orally every 12 h for 3 days is also effective in the following doses: adults and children >12 years, 500 mg; children aged 4–11 years, 200 mg; children aged 1–3 years, 100 mg.

Intestinal ascariasis should be treated with an anthelmintic agent. Intestinal obstruction may respond to conservative management with nasogastric aspiration, intravenous fluids and antispasmodics, followed by an anthelmintic when the obstruction has subsided. Laparotomy is required if this fails or if the patient is seriously ill. Manipulation of the worms through the ileocecal valve may be possible without having to open the bowel. Surgical or endoscopic removal of single worms blocking ducts should be reserved for patients who fail to respond to anthelmintic treatment and those with persisting pain or raised serum amylase.⁴ *Ascaris* pneumonitis is generally managed symptomatically using bronchodilators and steroids if indicated. The use of anthelmintics is questionable as symptoms of pneumonitis may be exacerbated by larval death.

TRICHURIASIS

Trichuris trichiura, the whipworm, infects about 900 million people worldwide. Following ingestion of eggs in contaminated soil, food or fomites, larvae emerge in the cecum,

penetrate the crypts of Lieberkün and migrate within the mucosal epithelium. The adult matures and remains partly embedded in the mucosa of the cecum and ascending colon, or throughout the colon in heavy infections.

Most infections go unnoticed; however, heavy infections may cause severe gastrointestinal symptoms. The friable mucosa bleeds easily, resulting in iron deficiency anemia in children on marginal diets. Chronic trichuris colitis is associated with growth retardation. Severe trichuris dysentery syndrome frequently leads to rectal prolapse.

Diagnosis and treatment

Diagnosis may be obvious on identifying adult worms attached to the mucosa of prolapsed bowel. In less dramatic circumstances, the characteristic eggs may be identified in the stool, by concentration techniques if necessary for light infections. Trichuriasis may cause a significant eosinophilia.

A single oral dose of mebendazole 500 mg appears to be more effective than albendazole 400 mg.⁵ Severe infections require either mebendazole 100 mg every 12 h for 3 days or albendazole 400 mg/day for 3 days. Single-dose combination treatment using albendazole 400 mg plus ivermectin 200 µg/kg is also highly effective.⁶

HOOKWORM

Ancyl. duodenale and *Necator americanus* are the principal hookworms infecting humans, affecting 900 million people worldwide. Both species are widely distributed in tropical Africa and Asia. *N. americanus* is the most common species in the Americas; *Ancyl. duodenale* also occurs in the Middle East, North Africa, southern Europe, the Caribbean, and Central and South America.

Hookworm eggs passed in the feces hatch in soil in warm, moist conditions, liberating rhabditiform larvae. These subsequently develop into filariform larvae, which inhabit the surface layer of soil. When these larvae come into contact with the skin of the human host, they penetrate via fissures or hair follicles and are carried in the venous circulation to the lungs. Here they penetrate the alveoli and migrate to the pharynx. They are then carried into the small intestine where they mature into adults. Rarely, infection with *Ancyl. duodenale* may occur following ingestion of larvae on contaminated vegetables. Infantile hookworm disease has been described in China and attributed to transmammary transmission, laying infants on contaminated soil, or using nappies made of cloth bags stuffed with infected soil.

Adult hookworms attach themselves to the upper half of the small intestine and feed on blood. An adult *Ancyl. duodenale* may consume between 0.15 and 0.26 mL/day; *N. americanus* consumes a relatively modest 0.03 mL/day. Blood loss also occurs at the site of attachment. Loss of plasma proteins may result in hypoproteinemia. In Africa and Asia, 30–54% of moderate and severe anemia in pregnancy is due to hookworm infection.

Initial infection is usually asymptomatic. Ground itch at the site of larval penetration when severe may be associated with the development of vesicles or pustules. Cutaneous larva migrans is sometimes seen. Larval migration through the lungs may give rise to a pneumonitis similar to that in ascariasis. Nausea, vomiting, pharyngeal irritation, cough, dyspnea and hoarseness (Wakana syndrome) may follow oral ingestion of *Ancyl. duodenale* larvae.

Occasionally, 4–6 weeks after infection, abdominal symptoms occur, including discomfort, flatulence, anorexia, nausea, vomiting and diarrhea, which may contain blood and mucus in heavy infections. Rarely, life-threatening gastrointestinal hemorrhage occurs in young children with severe primary infections.

Most chronic infections are asymptomatic. Problems arise when iron intake is low or demands are high. A gradually worsening iron deficiency anemia develops, often associated with hypoalbuminemia and edema, and eventually progresses to cardiac failure.

Diagnosis and treatment

Diagnosis is made by identification of the characteristic eggs in the stool. Concentration techniques may be necessary for lighter infections. Culture techniques similar to those used for strongyloides may also be helpful. If stool samples are left for a few days before examination, eggs may hatch liberating larvae that may be mistaken for strongyloides, although they are morphologically distinct. Mixed infections may also occur.

Albendazole 400 mg as a single dose is more effective than mebendazole 100 mg every 12 h for 3 days.⁷ Pyrantel pamoate 11 mg/kg (maximum 1 g) as a single dose is also effective. Treatment for iron-deficiency anemia may be indicated. Transfusion is rarely essential.

OTHER HOOKWORM INFECTIONS

Cutaneous larva migrans

Humans are accidental hosts in this infection caused by the larvae of the dog or cat hookworm, most commonly *Ancyl. braziliense*. Larvae penetrate the skin and migrate in the dermis, their progress mapped by an itchy, erythematous, serpiginous rash. Blistering sometimes occurs. Unable to complete their life cycle, they wander about in the dermis for several weeks or months until they eventually die. Rarely, infection may trigger hypereosinophilia and pneumonitis.

Topical thiabendazole may suffice for infections involving a limited area. A paste made by grinding one 0.5 g thiabendazole tablet in 5 g of petroleum jelly is applied every 8–12 h over the track, extending 1–2 cm beyond the leading edge. An occlusive dressing containing thiabendazole paste enhances the effect. Oral thiabendazole was previously recommended for more severe infections; however, this has been superseded by albendazole 400 mg/day for 3 days. More recently, ivermectin 200 µg/kg as a single dose has been shown to be more effective and less toxic than albendazole. Repeated doses are sometimes required.⁸

Eosinophilic enteritis

This has been described in Australia following infection with the immature adult dog hookworm, *Ancyl. caninum*, which provokes an allergic reaction resulting in edema of the gut wall, ascites and regional lymphadenopathy. Ulceration may occur at the site of the hookworm bite. Enterobiasis and anisakiasis may also cause eosinophilic enteritis.

STRONGYLOIDIASIS

Strongyloidiasis affects 50–100 million people worldwide, occurring in warm, wet, tropical and subtropical regions and in suitable niches in temperate regions, where conditions are moist and sanitation poor. *Strongyloides stercoralis* is the predominant species affecting humans, although *Strongyloides fullebomi*, principally a parasite of primates, has also been found in humans in Africa and Papua New Guinea. Human infection follows cutaneous penetration by filariform larvae contaminating soil, in a similar manner to hookworm. Indeed, both parasites may be present in the same habitat. Filariform larvae are carried in the venous circulation to the lungs where they penetrate the alveoli, migrate to the pharynx and then travel to the small intestine. There they develop into adults that penetrate the duodenal and jejunal mucosa. Fertilized females produce embryonated eggs resembling those of hookworm, but these are rarely seen as they hatch in the intestinal mucosa, releasing the first-stage rhabditiform larvae characteristically found in the stool. In favorable soil conditions, the excreted rhabditiform larvae transform into infectious filariform larvae within 24–48 h, remaining viable in soil for a few weeks.

Autoinfection may occur if rhabditiform larvae rapidly transform into infectious dwarf filariform larvae in the lumen of the bowel. These penetrate the gut mucosa (internal autoinfection) or the perianal skin (external autoinfection). Infection may thus persist for decades without further external exposure. Person-to-person transmission has also been described.⁹

Larval penetration of the skin may result in ground itch, and an urticarial, serpiginous rash is sometimes observed.

Pneumonitis may be associated with larval migration. Initial invasion of the small bowel mucosa by adult worms may cause abdominal pain and, in heavy infections, vomiting, malabsorption and paralytic ileus. Chronic infection may be asymptomatic or cause intermittent episodes of abdominal discomfort, sometimes associated with diarrhea and urticaria. Some patients develop malabsorption. Larva currens ('creeping eruption') may appear transiently as an intensely itchy serpiginous wheal, usually on the trunk or buttocks. *Strongyloides* may also cause episodes of pneumonitis and, rarely, a reactive arthritis.

Strongyloides hyperinfection syndrome occurs as a result of massive autoinfection. Risk factors include immunosuppression associated with organ transplants, cytotoxic drug therapy, corticosteroid therapy,¹⁰ ribavirin therapy for

hepatitis C,¹¹ malignancies (particularly leukemia and lymphoma), severe malnutrition and severe infections. HIV infection does not appear to predispose to strongyloides hyperinfection syndrome, although hyperinfection may occur in debilitated patients with advanced AIDS. Human T-cell leukemia virus type 1 (HTLV-1) infection does, however, appear to be a significant risk factor for strongyloides hyperinfection syndrome.¹² Rarely, hyperinfection syndrome occurs in an immunocompetent individual. A severe protein-losing enteropathy may develop in debilitated patients. More commonly, in patients who are abruptly immunosuppressed, hyperinfection syndrome presents with severe diarrhea, often with blood. Bowel inflammation may be associated with microperforations and give rise to paralytic ileus accompanied by Gram-negative septicemia caused by enteric organisms. The condition is usually fatal if effective chemotherapy is delayed. Complications include meningitis, often caused by *Escherichia coli* and/or larvae of *S. stercoralis*; both organisms are often detected in cerebrospinal fluid (CSF). Larvae may be widely disseminated in the central nervous system (CNS) and elsewhere, causing microinfarcts. Additional complications include peritonitis, endocarditis and pneumonitis. All patients with a history of possible exposure should be screened for strongyloides before immunosuppression. Patients at high risk should be treated empirically even if investigations are negative.¹³

Diagnosis and treatment

Rhabditiform larvae may be difficult to identify in feces. Various concentration techniques have been advocated and fecal culture on damp charcoal or Harada–Mori culture on vertical strips of damp filter paper may be helpful, although culture on nutrient agar plates is now emerging as the preferred technique.¹⁴ Larvae may be identified in duodenal aspirates or using the string capsule technique (Enterotest).

Serological tests (indirect fluorescent antibody test or enzyme-linked immunosorbent assay (ELISA)) are useful for patients who are not normally resident in an endemic area; however, cross-reactions with filarial antigens remain a problem. Strongyloidiasis in immunocompetent individuals is usually accompanied by an eosinophilia. Diagnosis in patients who are immunocompromised is more difficult. Eosinophilia is less likely and its absence is associated with a poorer prognosis. Serological tests are likely to be negative. It is essential to search carefully for larvae in feces or bowel aspirates. Larvae may also be found in sputum, CSF and urine.

Ivermectin is the drug of choice for strongyloidiasis. An oral dose of 200 µg/kg per day for 2 days gives excellent cure rates with few side effects.¹⁵ Thiabendazole 25 mg/kg (maximum 1.5 g) orally every 12 h for 3 days is also effective, although it is advisable to repeat this after 1 week because of the difficulty in confirming eradication of infection. Side effects are common and may be serious. Albendazole has fewer side effects than thiabendazole. A course of 400 mg every 12 h for 7 days has been used with encouraging results.

Hyperinfection syndrome poses therapeutic difficulties. In patients who are able to absorb oral treatment, ivermectin given in a multidose schedule offers the greatest promise of success. Patients who are unable to absorb oral therapy present a difficult challenge as no parenteral preparations of thiabendazole, albendazole or ivermectin are licensed for use in humans. However, parenteral ivermectin, available as a veterinary preparation, has been administered subcutaneously in the successful treatment of two patients with strongyloides hyperinfection.¹⁶ Patients with hyperinfection syndrome may also require treatment for Gram-negative septicemia.

ENTEROBIASIS

Enterobius vermicularis, the pinworm or threadworm, occurs worldwide and is the most common helminthic infection in Western Europe and the USA, although, strictly speaking, it is not a soil transmitted helminth. Infection follows ingestion of the egg on contaminated food or fomites. Autoinfection occurs when perianal irritation caused by migration of gravid female worms results in scratching and transmission of eggs from anus to mouth on fingertips. Secondary bacterial infection may occur at the site of excoriation. Vulvovaginitis, enuresis, urinary tract infection and appendicitis may also be associated with *E. vermicularis*. Infection may be accompanied by mild eosinophilia.

Diagnosis and treatment

Diagnosis is usually made by collecting eggs from the perianal region using adhesive tape or a moist cotton swab. Eggs may appear in urine samples from girls.

Mebendazole, albendazole and piperazine all achieve cure rates above 90%. Mebendazole 100 mg is given as a single oral dose, repeated 2–4 weeks later. Albendazole 400 mg as a single oral dose is repeated after 7 days for adults and children over 2 years. A dose of 100 mg should be used in children aged less than 2 years. Piperazine is effective but must be given daily for 7 days and repeated after 2–4 weeks. It has been superseded by mebendazole and albendazole. Pyrantel pamoate 11 mg base/kg (maximum dose 1 g) orally as a single dose repeated after 2 weeks is also effective.

Family members and other close contacts are likely to be infected and it is usual to recommend their treatment simultaneously, except for pregnant women during the first trimester.

INTESTINAL CESTODE INFECTIONS (TAPEWORMS)

Tapeworms are flattened, segmented, hermaphroditic worms ranging in length from 10 mm to 20 m. The head (scolex) attaches to the intestinal mucosa by means of suckers or hooklets. All, with the exception of *Hymenolepis nana*, require a

secondary intermediate host in which the larvae develop into cysts, usually in muscle. Human infection follows consumption of undercooked meat or fish. Larval cestode infections may also occur in humans following the ingestion of the egg, the most important being cysticercosis.

TAENIASIS

Taenia saginata, the beef tapeworm, and *Taenia solium*, the pork tapeworm, are the most common tapeworms affecting humans. Infection follows consumption of undercooked beef or pork containing cysts. *T. saginata* cysts may occur in other domestic bovines and a closely related Asian species has been shown to infect pigs, ungulates and monkeys. *T. solium* cysts also occur in dogs and cats. A third species of human *Taenia*, *T. asiatica*, which is also transmitted in pigs, has recently been described in Asia where prevalence rates of up to 20% have been documented among Indonesian villagers.

Most infections are asymptomatic, the host only becoming aware when a proglottid segment is noticed in feces or felt as it passes through the anus. Gastrointestinal symptoms may include loss of appetite, nausea or vague abdominal pain. A patient who is vomiting profusely, for whatever reason, may be further distressed when several meters of tapeworm appear in the vomit. Rarely, complications arise following migration of proglottids to unusual sites, such as the appendix or pancreatic and bile ducts.

DIPYLOBOOTHRIASIS

The most common of the 13 or more species of fish tapeworm affecting humans is *Diphyllobothrium latum*. Human infection follows ingestion of undercooked or raw fish or roe. Most infections involve a single worm and are asymptomatic or associated with vague, non-specific abdominal symptoms. Megaloblastic anemia may occur, resembling pernicious anemia in severe cases.

HYMENOLEPIASIS AND DIPYLIDIASIS

Hymenolepis nana, the dwarf tapeworm, occurs worldwide, principally among children. Most infections are asymptomatic, but heavy infections may cause abdominal pain, nausea, vomiting, pruritus ani and diarrhea, sometimes containing blood. Headache, dizziness, sleep and behavior disturbances are frequent. Convulsions have also been reported. Autoinfection is common.

Hymenolepis diminuta, the rat tapeworm, may affect humans who ingest the intermediate host, usually a weevil, flea or cockroach. Most infections are asymptomatic and of short duration.

Dipylidium caninum infection may occur in humans, usually young infants, following accidental ingestion of a flea, the intermediate host of this cestode whose usual host is a dog or other carnivore. Most infections are asymptomatic. Some children experience abdominal pain, diarrhea, pruritus ani and urticaria.

Diagnosis and treatment

Diagnosis is usually made by identification of characteristic eggs or proglottids in feces. There may be a variable eosinophilia, minimal in cases of *T. saginata* and often reaching 5–10% in hymenolepiasis.

Praziquantel is the drug of choice for all of the above intestinal cestode infections. A single oral dose of 10 mg/kg is usually effective. *H. nana* requires 25 mg/kg as a single dose. Praziquantel should be used with caution in populations in which cysticercosis is common, as there is a possibility of precipitating or aggravating symptoms. Niclosamide, given as a single oral dose of 2 g for adults, is also effective. Doses for children are 500 mg if <10 kg, 1 g if 11–34 kg and 1.5 g if >34 kg. Tablets should be chewed well and swallowed with water. There is no clinical evidence to justify the routine use of purgatives and antiemetics in patients with *T. solium* before cestocidal treatment, in order to prevent retrograde peristalsis of eggs and possible risk of cysticercosis.

LARVAL HELMINTHIC INFECTIONS

CYSTICERCOSIS

Neurocysticercosis is the most common parasitic infection of the CNS and the main cause of adult-onset epilepsy worldwide. Cysticercosis occurs following ingestion of eggs of *T. solium* and can occur in strict vegetarians or those who avoid eating pork for religious reasons. The oncosphere is liberated in the upper intestinal tract, penetrates the mucosa and enters the mesenteric vessels and lymphatics. Dissemination then occurs throughout the body and cysts develop in the tissues.

Living cysts usually provoke little or no immunological reaction. Clinical symptoms are more likely to arise as a result of the inflammatory response to dying cysticerci. Calcification eventually occurs at the site of dead cysticerci. Two forms of cysticerci – parenchymal and racemose – are found in the CNS. Racemose cysticerci are uncommon in children and are associated with a poorer prognosis.

Most infections are asymptomatic. The most common clinical presentations occur with neurocysticercosis and include epilepsy, symptoms of raised intracranial pressure, psychiatric disturbances, dementia, encephalitis, chronic meningitis, cranial nerve palsies and symptoms due to spinal cord lesions. Learning difficulties, behavior changes and psychomotor involution may be additional presenting symptoms in children.¹⁷ Cysticerci may develop in the eye, most commonly in the retina, but sometimes are free floating in the anterior

or posterior chamber. Subcutaneous cysticerci are present in about 50% of cases of neurocysticercosis. Cysticerci in muscles may result in increased muscle bulk and weakness. Cardiac involvement may also occur.

Diagnosis and treatment

Serological diagnosis is possible using an enzyme-linked immunoelectrotransfer blot (EITB) or ELISA.^{18,19} CSF may be normal or white cells (lymphocytes or eosinophils) raised to a variable extent. Glucose may be reduced. Total protein and IgG may be elevated and the EITB may be positive. Single ring-enhancing intracranial lesions are often negative using currently available immunodiagnostic techniques. Subcutaneous nodules can be biopsied. Ophthalmoscopy may reveal ocular cysts. Calcified cysts may be evident on X-ray films in muscle and other tissue. MRI is superior to CT in diagnosing neurocysticercosis if cysts are still viable. CT is better for demonstration of calcified cysts.

Praziquantel (50–100 mg/kg per day in three divided doses for 15 days) and albendazole (400 mg every 12 h for adults or 15 mg/kg every 12 h for children for 8–30 days) may be used alone or in combination in the treatment of viable cysts. The inflammatory response to dying cysticerci may precipitate or exacerbate symptoms. Simultaneous administration of steroids is usually advised to mitigate the inflammatory response.²⁰ The bioavailability of albendazole and praziquantel are increased with cimetidine.^{21,22}

A recent meta-analysis showed that treatment with cysticidal drugs results in better resolution of enhancing lesions and cysts, lower risk of recurrence of seizures in patients with enhancing lesions, and a reduction in the rate of generalized seizures in patients with viable cysts.²³ Therefore, a full course anthelmintic therapy is now recommended for patients with active parenchymal neurocysticercosis. Single-dose praziquantel treatment may be adequate for patients who have single brain-enhancing lesions and positive serology.²⁴ Patients with inactive parenchymal disease do not require anthelmintic treatment. In either circumstance, anticonvulsants may be indicated and, in some cases, neurosurgical intervention may be required. Extraparenchymal cysts may require treatment with combinations of antiparasitic drugs, steroids and, possibly, surgery, depending on the number, size, location and complications.

Ophthalmic cysticercosis is usually treated surgically. Muscular and subcutaneous cysticercosis infections generally do not require treatment. However, if anticysticercal drugs are used, steroids or non-steroidal anti-inflammatory drugs may also be required.

HYDATIDOSIS

The larval stage of the canine tapeworm, *Echinococcus granulosus*, causes cystic hydatid disease in humans. The disease is prevalent in sheep-rearing areas throughout the world. Dogs

and other carnivores are the definitive host for the adult tapeworm. Sheep and other domestic livestock become infected after ingesting ova shed in dog feces, following which hydatid cysts develop in the viscera of the infected animal. The cycle is completed when dogs ingest cysts in offal and other infected tissues. Human infection follows the accidental ingestion of eggs in dog feces. The ingested egg releases an oncosphere which penetrates the intestinal wall and is carried in the circulation to a variety of tissues, most commonly the liver and lungs.

Symptoms are usually either due to a mass effect produced by the growing cyst or occur as a result of leakage of fluid from a cyst. Hepatic cysts are more frequent in the right lobe and are usually asymptomatic until they become large. A non-tender mass may be evident on examination. Secondary bacterial infection of a cyst may mimic a liver abscess. Rupture may be spontaneous, traumatic or occur during surgery, precipitating a hypersensitivity reaction ranging from urticaria, pruritus and fever to fatal anaphylaxis. Rupture into the peritoneal cavity may lead to seeding and the development of secondary cysts. Rupture into the biliary tree may cause colic, urticaria and obstructive jaundice, sometimes complicated by secondary bacterial infection.

Most lung cysts are asymptomatic, often being found incidentally on a chest radiograph. Patients may experience fever, dyspnea, chest pain and cough, sometimes with hemoptysis or productive of clear salty-tasting liquid. Collapsed cysts have a characteristic 'water lily' appearance on chest radiographs. Patients may cough up the soft, white outer membrane of the cyst. Rupture into the lung may cause a hypersensitivity reaction, or result in pneumothorax and empyema. A lung abscess may develop at the site of a cyst. Seeding of pulmonary cysts is uncommon.

Hydatid cysts occur at a variety of other sites including spleen, bone (causing pain and pathological fracture), brain (causing convulsions or a mass effect) and eye (causing proptosis and chemosis).

Diagnosis and treatment

Abdominal ultrasound is useful for detecting abdominal cysts; radiography, CT or MRI may be useful for detecting cysts elsewhere. Of the serological tests available, the specific IgG ELISA AgB (antigen-B-rich fraction) is the most sensitive.²⁵ Others include an EITB assay and the double diffusion test for arc 5 (DD5). All lack sensitivity for extrahepatic cysts and DD5 may give false-positive results in patients with cysticercosis. Urine antigen detection tests are promising.²⁶ Eosinophilia may follow leakage or rupture of a cyst.

Until recently, surgical removal was the preferred method of managing accessible cysts and remains the recommended treatment for cysts >10 cm diameter, for infected cysts and for cysts in the brain, lung or kidney.²⁷ Surgical removal of hydatid cysts requires great care to avoid spillage. Before removal, large cysts are carefully aspirated and the aspirate replaced with an equivalent volume of hypertonic saline, a scolicide. Puncture, aspiration, injection and reaspiration (PAIR) of cysts under

ultrasound control is now used increasingly as an alternative to surgery.²⁸ Following initial aspiration, hypertonic saline is injected into the cyst and reaspirated after 20 min. PAIR plus chemotherapy is associated with lower morbidity, mortality and disease recurrence rates, and shorter hospital stays.²⁹

Small cysts can be surgically removed intact. Laparoscopic treatment of hydatid cysts of the liver and spleen is also effective.³⁰

Albendazole, either alone or in combination with praziquantel, should be given for 1–3 months prior to surgery or PAIR. Patients undergoing surgery or percutaneous aspiration should receive concomitant albendazole, either alone or in combination with praziquantel. PAIR should be followed by an 8-week course of albendazole. Anthelmintic treatment may reduce the need for surgery in patients with uncomplicated pulmonary cysts.³¹

Albendazole is useful for patients with inoperable, widespread or numerous cysts and in patients who are unfit for surgery. The recommended regimen is a now 400 mg every 12 h for adults, or 5–7.5 mg/kg every 12 h for children, for 3–12 months depending on response. Monthly treatment interruptions are no longer recommended.³² Absorption of albendazole is enhanced when taken with fatty meals. A combination of albendazole and praziquantel has been shown to have greater protoscolicidal activity in animal studies and *in vitro* than either drug alone.^{33,34} Combination therapy has been used with success in treating inoperable spinal, pelvic, abdominal, thoracic and hepatic hydatidosis.³⁵

ALVEOLAR HYDATID DISEASE

Echinococcus multilocularis is a tapeworm of foxes, wild canines, dogs and cats. Rodents are the usual intermediate hosts. The disease is endemic in North America, Europe, Siberia and China. Human infection follows ingestion of the egg in a similar manner to infection with *E. granulosus*. Unlike cystic hydatid disease, lesions caused by *E. multilocularis* are ill defined and more solid than cystic, developing in the manner of a slowly growing, invasive malignant tumor: it may be 30 years before a patient becomes symptomatic. The primary site of tissue invasion is usually the liver, although metastatic lesions may occur in other tissues.

Clinical presentation is usually with right upper quadrant pain, hepatomegaly and a palpable mass. Complications as a result of local invasion or due to metastatic lesions involving brain, lung or mediastinum occur in around 2% of patients. Untreated, 90% of patients die within 10 years of presentation; however, a 90% 10-year survival rate is possible with early diagnosis and appropriate treatment.

Diagnosis and treatment

Ultrasonography, CT and serology are useful in establishing the diagnosis. Histology provides confirmation. Surgical excision is the treatment of choice for the primary lesion. Pre- and

postoperative treatment with albendazole is recommended. Treatment with albendazole 10–15 mg/kg is recommended postoperatively and for inoperable patients. In practice, a dose of 400 mg every 12 h is usual for adults. The optimal duration of treatment remains uncertain; patients often remain on treatment for more than 12 months. Albendazole at these doses has been used for up to 20 years; higher doses of 20 mg/kg per day have been used for up to 4.5 years.³² Mebendazole, 40–50 mg/kg per day, has also been used extensively, sometimes for up to 10 years. Serology may remain positive for several years following successful treatment.

TRICHINOSIS

Several species of *Trichinella* cause disease in humans, affecting about 50 million worldwide. The best known, *Trichinella spiralis*, occurs widely; most of the others are limited to particular geographical niches. Human infection follows consumption of larval cysts in raw or undercooked meat, especially pork. Larvae liberated in the stomach pass into the duodenum, where they burrow into the mucosa and develop into adults. Female worms produce larvae which seed throughout the body, particularly in skeletal and cardiac muscle, and form cysts invoking an inflammatory response. Cysts begin to calcify within 6–12 months, resulting in death of the encysted larvae.

Clinical symptoms may occur at the time of initial larval invasion and development in the intestinal mucosa. Early symptoms are more likely with heavy infection and include abdominal pain, anorexia, nausea, vomiting and diarrhea, sometimes accompanied by fever, headache and malaise. Systemic symptoms tend to occur a week or more after infection, when seeding of larvae in the tissues is associated with fever, headache, myalgia and malaise. Urticaria, conjunctivitis, periorbital and facial edema may be evident. Muscles become swollen and tender. Patients may experience cough, hoarseness, dyspnea and dysphagia. Splinter hemorrhages may be present. Myocarditis may develop 4–8 weeks after infection. Pericardial effusions are the most common manifestation of cardiac involvement.³⁶ Congestive cardiac failure and arrhythmias also occur. Larvae migrating through the CNS may cause a wide range of focal or generalized neurological symptoms including meningoencephalitis and psychosis. Convalescence may be prolonged with persisting myalgia, fatigue and headaches.

Diagnosis and treatment

There is usually a marked eosinophilia and raised creatinine phosphokinase, lactic dehydrogenase, aldolase and aminotransferase levels, reflecting muscle damage. Myocarditis should not be assumed on the basis of elevated creatinine phosphokinase isoenzyme-MB as this has been found in patients without clinical or other evidence of cardiac involvement. The most useful serological test for clinical purposes is the ELISA-IgG. Tissue diagnosis can be made from skeletal muscle biopsy using compression and histological techniques.

Either mebendazole 100 mg every 12 h for 5 days or albendazole 400 mg/day for 3 days is effective in the early intestinal stage of infection. Patients with severe symptoms associated with larval seeding should be treated with prednisolone 40–60 mg/day plus either albendazole 400 mg every 12 h for 8–14 days or mebendazole 200–400 mg every 8 h for 3 days, then 400–500 mg every 8 h for 10 days.

TOXOCARIASIS

Toxocara canis and *Toxocara cati* are parasitic roundworms of dogs and cats. Infection in humans is most common in young children, who ingest eggs in sand or soil contaminated by dog or cat feces. Clinical disease is relatively uncommon and depends on the intensity of infection and the organs involved.

Visceral larva migrans is caused by migrating larvae and includes symptoms of pneumonitis, fever, abdominal pain, myalgia, sleep and behavior disturbances, and focal or generalized convulsions. Lymphadenopathy and hepatosplenomegaly may be evident. Eosinophilia, anemia, hypergammaglobulinemia and elevated titers of blood group isohemagglutinins are common. Serological diagnosis may be established by ELISA. The drug of choice is albendazole 5–10 mg/kg or, for adults, 400 mg, every 12 h for 5 days. Alternatively, mebendazole 100–200 mg every 12 h for 5 days may be used but is inferior to albendazole. Symptomatic treatment with bronchodilators, steroids or antihistamines may also be indicated.

Ocular larva migrans is more likely to occur in light infections. A single larva invades the eye, provoking a granulomatous reaction, usually in the retina. This may result in visual disturbance or blindness in the affected eye, which may go unnoticed or present as strabismus. The diagnosis is sometimes made by chance on routine ophthalmoscopy. The usual appearance is of chorioretinitis with a mass lesion, sometimes mistaken for a retinoblastoma. Serology is usually positive. Antibody detection in vitreous fluid is more sensitive and specific. Management of acute ocular larva migrans is directed at suppressing the inflammatory response with topical or systemic steroids. Anthelmintics are often used concurrently, although there is no consistent evidence of additional benefit. Destruction of the larva is possible using laser photocoagulation. Steroids may be useful in exacerbations of chronic ocular larva migrans. Surgery is often required for adhesions.

MISCELLANEOUS TISSUE HELMINTHS

GNATHOSTOMIASIS

Gnathostoma spinigerum and related species occur principally in South East Asia. Human infection follows ingestion of larvae in raw or undercooked flesh from certain fish, frogs, snails, snakes, chicken and pigs. Infection can also be acquired from contaminated water. Acute gnathostomiasis is associated with

fever, abdominal pain, tender hepatomegaly, pneumonitis, rashes (including a serpiginous rash resembling cutaneous larva migrans) and painless or pruritic subcutaneous swellings caused by migrating immature adult worms. Eosinophilia is usually marked. Invasion of the eye may result in subconjunctival hemorrhage and edema. Eosinophilic myeloencephalitis is an important and characteristic complication arising when the worm migrates along a large nerve trunk and invades the CNS, causing a radiculomyelitis, radiculomyeloencephalitis or subarachnoid hemorrhage. Migratory CNS lesions can be detected using MRI.³⁷ CSF may be bloody or xanthochromic with a raised white cell count, of which >20% are usually eosinophils. Highly sensitive and specific immunodiagnostic tests are available for use with serum or CSF, including ELISA and Western blot. Definitive diagnosis requires identification of the worm.

Albendazole 400 mg every 12 h for 21 days may be useful. Anti-inflammatory analgesics are helpful for symptomatic relief. Steroids may be required for patients with neurological complications. Cerebral gnathostomiasis is associated with a high case-fatality rate.

ANGIOSTRONGYLIASIS

ANGIOSTRONGYLUS MENINGITIS

Infection with *Angiostrongylus cantonensis* occurs most commonly in South East Asia following consumption of larvae in salads contaminated with slug or snail slime, or in undercooked snails, crabs or prawns. Clinical disease is usually mild and self-limiting. However, the parasite is an important cause of eosinophilic meningitis, cranial nerve palsies and cerebral abscesses. CSF abnormalities include raised protein, normal or low glucose and a white cell count of 100–5000 cells, up to 90% of which may be eosinophils. Specific antibodies in serum or CSF may be detected by ELISA. In the past, treatment of *Angiostrongylus* meningitis with anthelmintics was not recommended because of concern that death of the parasites may lead to worsening of symptoms. Therefore, management was mainly based on the use of analgesics, corticosteroids and repeat lumbar punctures. However, a recent trial in Thailand has shown that albendazole 15 mg/kg per day is safe and is effective in reducing the duration of headache.³⁸ A combination of mebendazole 15 mg/kg every 12 h and prednisolone 60 mg/day for 2 weeks has also been shown to be safe and effective.³⁹

ABDOMINAL ANGIOSTRONGYLIASIS

Infection with *Angiostrongylus costaricensis* follows consumption of food contaminated with slug slime. Cases have been reported in the Americas, the Caribbean and Central Africa.

Children commonly present with an eosinophilic enteritis resembling acute appendicitis or with an ileocecal mass in chronic cases. Testicular infection may mimic torsion. Eggs and larvae are absent from the stool. An ELISA is available for serological diagnosis. Thiabendazole and diethylcarbamazine have been used in treatment; however, the role of anthelmintics remains uncertain. Surgery is sometimes required.

TREMATODES

Trematodes include the intestinal, liver and lung flukes and the schistosomes (blood flukes). About 750 million people are at risk worldwide. Common to all of their life cycles is the involvement of various species of fresh-water snail, which act as intermediate, amplifying hosts liberating millions of cercaria. Schistosomiasis occurs as a result of cercarial penetration, usually via the skin. The other flukes require a second intermediate host (animal or vegetable) for the development of the metacercarial stage infectious to humans. The adult parasites develop in their human host, mate and produce eggs, which are shed in feces, urine or sputum. On contact with water, the egg releases the miracidium, which infects the preferred snail, thus completing the cycle.

Most infections could be prevented by public health measures promoting sanitation and safe preparation of food. Praziquantel is the anthelmintic of choice for all fluke infections, with the exception of *Fasciola hepatica* and *Fasciola gigantica*, where the drug of choice is now triclabendazole.

SCHISTOSOMIASIS

The three most common species of schistosome affecting humans are *Schistosoma haematobium* (endemic in most of Africa and parts of the Middle East), *Schistosoma mansoni* (endemic in most of Africa, part of the Middle East, and in some areas of the Caribbean and South America) and *Schistosoma japonicum* (endemic in East and South Asia and parts of Indonesia and the Philippines). *Schistosoma mekongi* and *Schistosoma intercalatum* are of lesser importance and are confined to parts of South East Asia and Africa, respectively.

In endemic regions, most of the population becomes infected at some time, peak prevalence usually occurring in older children and teenagers. Most infections are mild or asymptomatic. As immunity develops, egg production diminishes and eventually ceases in most of those infected. Susceptibility to long-term complications may be genetically mediated.

Cercarial dermatitis ('swimmer's itch') occurs within 24 h at the site of cercarial penetration, more commonly in individuals who are newly exposed. The papular, pruritic rash usually resolves spontaneously within a few days. Cercarial dermatitis may also occur following exposure to avian schistosomes. Cercariae develop into schistosomula, which migrate via the heart and lungs. Heavy initial infections may be associated with a transient pneumonitis at this stage.

The schistosomula pass through the liver, where they mature into adults without causing pathology. They then migrate to the vesical venous plexus in the case of *S. haematobium*, or to the mesenteric plexus in the case of *S. mansoni* and *S. japonicum*. Adult worms do not provoke any reaction and may survive for up to 7 years. Egg production and deposition in the tissues does, however, result in an immunopathological response, giving rise to the major clinical consequences of schistosomiasis.

Acute schistosomiasis, or Katayama fever, may occur 4–8 weeks following exposure. It is more likely in non-immunes following heavy infection and is more common with *S. japonicum* and *S. mansoni*, coinciding with the onset of egg deposition in the tissues. Symptoms include fever, cough, wheeze, urticaria, headache and malaise. Generalized lymphadenopathy and hepatosplenomegaly may be present. Investigations usually reveal an eosinophilia; however, parasitological diagnosis may be difficult as eggs are unlikely to be found in stool or urine unless sought by special techniques and serology is usually negative during the initial stages.

The intestine and liver are the principal sites of pathology in all types of human schistosomiasis apart from *S. haematobium*. Egg deposition in the intestinal mucosa may lead to abdominal pain, diarrhea, dysentery and malaise. Colonoscopy may reveal hyperemia, erosions, ulceration or polyps, evident on barium studies as filling defects. Egg deposition in the liver occurs in the perisinusoidal radicles of the portal vein, provoking a granulomatous reaction and, eventually, periportal fibrosis and portal hypertension. Hepatomegaly is followed by splenomegaly and hypersplenism as portal hypertension increases. Bleeding may occur from esophageal varices and ascites is common in advanced disease. Increase in portal pressure may open collaterals into the pulmonary circulation with egg deposition, granuloma formation and periarteritis leading to pulmonary hypertension and cor pulmonale. Rarely, pulmonary hypertension may also occur with *S. haematobium*. Liver function tests are usually normal until fibrosis is advanced. Abnormal liver function tests should raise the possibility of co-infection with hepatitis B or C, in which case the prognosis is likely to be worse.

Chronic *S. haematobium* infection principally affects the urogenital system. The most common symptoms are dysuria, frequency, terminal hematuria and hematospermia. Bladder outlet and vesicoureteric obstruction may lead to hydronephrosis. Secondary bacterial infections may occur, including pyelonephritis. In due course, chronic renal failure may develop. Cystoscopy may reveal 'sandy patches' on the mucosal surface, mucosal hypertrophy or polyps. Squamous carcinoma of the bladder is a well-documented long-term complication. Involvement of the female genital tract may cause cervicitis, salpingitis and infertility. These may also occur with *S. japonicum* and *S. intercalatum*. Rarely, patients with *S. haematobium* complain of rectal passage of blood and mucus.

Neurological complications occur if schistosome eggs lodge in the brain or spine, leading to symptoms such as focal or generalized convulsions and transverse myelitis. Subcutaneous

egg deposition, often in the perineal region, may result in the development of painful papules.

A number of clinical conditions have been described arising from co-infection of schistosomes and salmonellae, including recurrent *Salmonella* bacteraemia, nephrotic syndrome associated with co-infection with *S. mansoni* and *Salmonella typhi*, and chronic urinary carriage of *Salmonella typhi* associated with *S. haematobium* infection. HIV and HTLV-1 infection are both associated with increased susceptibility to schistosomiasis.¹²

Diagnosis and treatment

Characteristic eggs may be identified in urine, semen or feces, by use of concentration techniques if necessary. Eggs of all species may be identified on rectal biopsy. Serological diagnosis is problematic as it takes 6–12 weeks for titers to become positive, positive titers persist for years following cure, and false-positive results may be caused by exposure to other helminths. Serology may be useful in returning travelers but not for residents in endemic areas. *S. mansoni* antibody detection in oral fluids appears to be as sensitive as serology.⁴⁰ Antigen from viable eggs can now be detected in serum and urine, offering new possibilities for diagnosis and monitoring of response to treatment.^{41–43} Ultrasonography is useful for assessing patients with hepatic and urinary tract disease.

Praziquantel is the drug of choice for all species: 40 mg/kg as a single dose is usually sufficient for *S. haematobium*, *S. mansoni* and *S. intercalatum*. *S. japonicum* and *S. mekongi* require a larger dose: either 50 mg/kg as a single dose or three doses of 20 mg/kg 8 h apart. Side effects are uncommon. Praziquantel is regarded as safe for treatment of schistosomiasis in pregnant and lactating women.⁴⁴ Although resistance to praziquantel has been observed,⁴⁵ this is not a significant clinical problem at present. Apparent *S. mansoni* resistance may be partly attributable to a higher worm burden and intense transmission.⁴⁶ Oxamniquine 15–30 mg/kg for 1–2 days may be used as an alternative for the treatment of *S. mansoni*; however, side effects are more common and serious compared to praziquantel. Concomitant use of steroids is recommended in the management of patients with neurological disease to reduce inflammation around granulomata.

Katayama fever is managed with non-steroidal anti-inflammatory drugs or steroids depending on the severity, together with praziquantel.

No prophylactic drug is currently recommended for schistosomiasis. Artesunate and artemether are potential prophylactic agents, but a major concern is the risk of promoting resistance in *Plasmodium falciparum*.^{47,48}

INTESTINAL FLUKES

The most important intestinal fluke in humans is *Fasciolopsis buski*, which is widely distributed from India to South East Asia, particularly among pig-rearing communities. Human infection follows ingestion of metacercariae attached to an

edible water plant, such as the water caltrop. The metacercariae excyst and attach to the mucosa of the duodenum and jejunum, where they develop into adults, causing inflammation and ulceration. Most infections are asymptomatic. Heavy infections result in epigastric pain and diarrhea, initially alternating with constipation, but later becoming persistent. Wasting and ascites may develop in severe cases.

Echinostome species, principally found in Asia, may also infect humans, causing symptoms similar to *F. buski*.

Heterophyes, the smallest of the intestinal flukes affecting humans, cause milder gastrointestinal symptoms than *F. buski*. However, ectopic eggs may be carried to other organs, particularly the CNS, causing a mass effect, and to the heart resulting in myocarditis or valve damage.

Diagnosis and treatment

Characteristic eggs, and sometimes adult flukes, can be identified in feces. Adult flukes may also appear in vomit. Intestinal flukes respond to treatment with praziquantel 15–40 mg/kg as a single or divided dose.

LIVER FLUKES

Fasciola hepatica and *Fasciola gigantica* are widely distributed, occurring in sheep- and cattle-rearing areas throughout the world. Human infection follows ingestion of metacercariae on water vegetables, for example watercress. Acute clinical symptoms may develop after 6–12 weeks, including abdominal pain, intermittent fever, weight loss, malaise, urticaria and respiratory symptoms. The liver may be enlarged and tender and liver enzymes are sometimes mildly elevated. Ectopic flukes may lead to granuloma or abscess formation in various organs. Migrating erythematous cutaneous nodules, another form of cutaneous larva migrans, may also occur. Mature flukes tend to migrate to the bile ducts, initially causing fever, anorexia and abdominal pain. This usually subsides spontaneously. A minority of patients develop chronic symptoms associated with recurrent cholangitis or intermittent biliary obstruction.

Diagnosis and treatment

Eosinophilia is common and pleural effusions, if present, may contain eosinophils. Ultrasound is usually normal, although CT scans of the liver may reveal numerous hypodense lesions. Peripheral, branched hypodense hepatic lesions, best seen on CT with use of contrast, are relatively specific for fascioliasis.

Serological tests are helpful in diagnosing *F. hepatica* infections towards the end of the acute phase when eggs are unlikely to be present in feces. Serology is less reliable for *F. gigantica*. In chronic disease, eggs may be present in feces or in bile aspirate. Concentration techniques may be helpful. *Fasciola* excretory-secretory (FES) antigen detection in feces is useful both in pre-patent and patent infections with *F. hepatica*.

Praziquantel is unreliable in the treatment of fascioliasis. Bithionol 30–50 mg/kg per day in three divided doses on alternate days for 10–15 days has been recommended in the past. Side effects include mild gastrointestinal upset and pruritus. A benzimidazole, triclabendazole, is simpler to use, has few side effects and has now become the drug of choice. A single dose of 10 mg/kg taken with food is usually effective. Severe infections require a second dose after 12 h.⁴⁹ The expulsion of dead or dying parasites after 3–5 days may result in biliary colic requiring treatment with an antispasmodic. Unfortunately, triclabendazole resistance has been reported in Ireland, the UK and Australia.⁵⁰ Nitazoxanide 500 mg every 12 h for 6–7 days has been used successfully in treating *F. hepatica* with cure rates of 49–87%.⁵¹ Artesunate has been shown to compare favorably with triclabendazole in the treatment of *F. hepatica*, although the outcome at 3 months was less favorable.⁵²

ORIENTAL LIVER FLUKES

Clonorchis sinensis (also known as *Opisthorchis sinensis*) and *Opisthorchis viverrini* affect about 20 million people in China and South East Asia. A related species, *Opisthorchis felineus*, occurs in Eastern Europe and Russia. Human infection follows consumption of metacercariae in raw or undercooked freshwater fish. Metacercariae excyst in the small bowel and migrate along the common bile duct to colonize the biliary tree. Most infections are asymptomatic. Patients with heavy initial infections may present with an illness similar to Katayama fever. In established infections patients may present with vague right upper quadrant abdominal pain and hepatomegaly. Recurrent episodes of ascending cholangitis, jaundice and pancreatitis may occur. Chronic infection may lead to biliary cirrhosis and, rarely, cholangiocarcinoma.

Diagnosis and treatment

Ultrasound may reveal abnormalities of the biliary tree and gallstones. Other imaging techniques, such as endoscopic retrograde cholangiopancreatography, are useful. Diagnosis is established by identifying characteristic eggs in feces with the aid of concentration techniques, or in biliary aspirate. A fecal antigen test is now available for *O. viverrini*.⁵³ Serological tests are not widely available and generally lack specificity.

Treatment is with praziquantel 40 mg/kg as a single dose or 25 mg/kg every 8 h after meals. A 3-day course is advisable for heavy infections.

LUNG FLUKES

Eight species of *Paragonimus* cause disease in humans, the most important being *Paragonimus westermani*. Paragonimiasis is widespread in Asia and also occurs in regions of Africa, Central and South America. Human infection follows ingestion

of metacercariae attached to undercooked or raw crab, crayfish and shrimp, or, rarely, following consumption of larvae in undercooked wild boar. Most infections are initially asymptomatic. An acute illness may occur as the parasite excysts, penetrates the gut wall and migrates through the diaphragm into the pleural cavity and then to the lungs. Symptoms of abdominal pain and diarrhea 2–15 days after infection may be followed by cough, dyspnea, fatigue, fever and urticaria a few days later. This episode sometimes lasts several weeks. Pleuritic chest pain may occur, sometimes associated with an effusion. Adult flukes form cysts in the lung tissue and produce eggs, provoking an inflammatory response. Cavitatory or nodular, sometimes calcified, lesions develop which may be noticed incidentally on a chest radiograph as the first indication of infection in asymptomatic patients. Early symptoms of pulmonary paragonimiasis include cough, initially non-productive, later productive of gelatinous, rusty or bloodstained sputum. Pulmonary paragonimiasis may be mistaken for tuberculosis and both infections may coincide.

Cerebral paragonimiasis is the most important form of extrapulmonary paragonimiasis. Most patients are children. About one-third present with a clinical picture resembling acute meningoencephalitis, but more commonly presentation is insidious with a wide variety of neurological symptoms and signs depending on the area of the brain or spinal cord affected.

Wandering flukes may cause painless, migratory subcutaneous swellings, subcutaneous nodules or a variety of other symptoms depending on the site involved.

Diagnosis and treatment

Diagnosis can be confirmed by identifying characteristic eggs in sputum, feces or, rarely, pleural effusion. Eosinophilia is usual and should alert one to the possibility of paragonimiasis in patients presenting with a clinical picture mimicking tuberculosis. Serological tests are available, including ELISA and a complement fixation test. *Paragonimus*-specific IgM is useful for diagnosing patients with extrapulmonary disease and pleurisy.⁵⁴

Praziquantel 25 mg/kg every 8 h for 2–3 days is highly effective. A higher dose may be required for treatment of cerebral paragonimiasis and steroid cover is advisable. Two doses of triclabendazole 10 mg/kg administered on the same day is also highly effective in treating pulmonary paragonimiasis.⁵⁵

FILARIAL INFECTIONS

Insect vectors play a role in the transmission of all of the medically important parasitic filarial nematodes, with the exception of *Dracunculus medinensis*. Both the parasite and the insect vector depend on favorable climatic and environmental conditions that occur naturally in certain regions of the tropics. Human infections occur when the insect vector feeds, introducing infective larvae. These mature into adult

worms, which produce microfilariae, which in turn infect the insect vector. Clinical disease is caused by the adult worms, the microfilariae, or both.

Recently, significant progress has been made in the community control of onchocerciasis and lymphatic filariasis. However, one of the obstacles facing these programs is the longevity of the adult worms and their relative lack of response to antihelminthic agents. It is now evident that the development, motility and fertility of the adult worms depend on intracellular, endosymbiotic bacteria of the genus *Wolbachia*. These organisms also play an important role in the pathogenesis of these diseases and are susceptible to tetracyclines and several other antibiotics, offering fascinating new possibilities in the management and control of filarial infections.^{56–58}

LYMPHATIC FILARIASIS

Wuchereria bancrofti, *Brugia malayi* and *Brugia timori* are transmitted by various species of mosquito. *W. bancrofti* is distributed widely in the tropics, whereas *B. malayi* and *B. timori* are endemic in South East Asia and Indonesia. The adult worms develop in the lymphatics and range in length from 20 to 100 mm. Their microfilariae enter the general circulation via the thoracic duct. Recent developments, particularly with regard to the role of *Wolbachia*, have led to significant changes in our understanding of the pathogenesis of lymphatic filariasis. Inflammatory episodes are likely to be multifactorial involving responses to different stages of the parasite, secondary bacterial infection and inflammatory mediators associated with *Wolbachia*.⁵⁹

Lymphatic filariasis affects about 120 million people. Most infections are asymptomatic. Acute symptoms typically occur 8–16 months following infection and often recur several times a year. A first episode of acute filarial fever has been reported more than 15 years following exposure. Several clinical presentations are recognized. Acute filarial fever without lymphadenitis is non-specific and must be distinguished from malaria and other causes of fever in the tropics. Acute filarial lymphangitis is characterized by a circumscribed inflammatory nodule or cord with centrifugal lymphangitis that occurs following the death of the adult worm (whether spontaneous or following treatment). Acute dermatolymphangioadenitis, severe local inflammation resembling cellulitis or erysipelas, is frequently associated with secondary bacterial infection and impaired lymphatic flow, ascending lymphangitis and limb edema. This may eventually progress to elephantiasis.

Chronic lymphatic filariasis may develop months or years after the acute symptoms, or without a history of acute disease. Lymphatic obstruction leads to lymphedema of the affected extremity and, eventually, to elephantiasis. The sites most commonly affected are the legs, scrotum, arms and breast. Recurrent secondary bacterial skin infections, often streptococcal, may cause acute episodes of pain and fever and lead to glomerulonephritis.

Other presentations of chronic lymphatic filariasis include hydrocele, lymph scrotum, acute epididymitis and funiculitis. Chyluria, chylous diarrhea and chylous ascites may also occur with considerable loss of fat-soluble vitamins and protein, resulting in malnutrition and vitamin deficiencies.

Diagnosis and treatment

Eosinophilia is common during the acute stages. Parasitological diagnosis may be made by examination of a Giemsa-stained thick blood film taken at the peak of microfilarial periodicity according to the species (usually 22.00 h–02.00 h for *W. bancrofti*). However, this is relatively insensitive other than for high microfilaremias (>100 microfilariae/mL). Concentration techniques greatly improve sensitivity. Tests for circulating *W. bancrofti* antigen are now available, including an ELISA and a rapid immunochromatographic card test, and these may replace microscopy.⁶⁰ Polymerase chain reaction (PCR) assays have also been developed for *W. bancrofti* and *B. malayi*.^{61,62} Scrotal ultrasound demonstrating live adult worms in the ‘filarial dance sign’ may be useful either for diagnostic purposes or for follow-up of response to treatment.⁶³

Treatment of individual patients with lymphatic filariasis is possible using a combination of anthelmintic agents and antibiotics. If co-infection with onchocerciasis is present or possible, a combination of doxycycline 200 mg/day for 6 weeks plus a dose of ivermectin 150 µg/kg on completion of the course of doxycycline, is recommended unless contraindicated (age <9 years, pregnancy, breastfeeding). In the absence of co-infection with onchocerciasis, a combination of doxycycline 200 mg/day for 6 weeks plus a dose of diethylcarbamazine (DEC) 6 mg/kg on completion of the course of doxycycline is recommended unless contraindicated.⁶⁴

In either of the above situations, if co-infection with *Loa loa* is present, particularly if associated with a high *Loa loa* microfilaremia, it is essential to reduce the microfilaremia using albendazole prior to treatment with DEC or ivermectin as either of the latter may provoke a fatal encephalopathy. This is discussed in more detail in the section on *Loa loa*.

Management of lymphoedema involves elevation, massage, exercise and bandaging of affected limbs. Careful hygiene, use of disinfectant soap and water, and general skin care (including early and effective treatment of any wounds or abrasions) are also important. Antibiotic prophylaxis with penicillin is useful for recurrent streptococcal infections. Hydrocele requires surgical management. Chyluria requires bed rest, nutrition and, in some cases, surgery.

Community control of lymphatic filariasis is based on vector control plus mass treatment annually with a two-drug regimen tailored to the region. Within Africa, because of the risk of onchocerciasis and/or *Loa loa*, a single dose of ivermectin, usually 150 µg/kg, is given with a single dose of albendazole 400 mg. Annual treatment should continue for at least 30 years. Caution is advised in regions where *Loa loa* is endemic and high risk foci of *Loa loa* are currently excluded from ivermectin programs. Outside Africa, DEC

in single dose of 6 mg/kg is given annually, together with a single dose of albendazole 400 mg. Annual treatment should continue for at least 20 years.^{64,65}

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia occurs in areas endemic for lymphatic filariasis, particularly Sri Lanka and Southern India. Microfilarial death triggers a high eosinophilia associated with gradually worsening, non-productive cough and wheeze, and sometimes fever and malaise. Symptoms are worse at night. Chest radiography shows diffuse infiltrates. Pulmonary function tests may reveal restrictive, obstructive or mixed defects. IgE is elevated and filarial serology positive. The diagnosis is supported by a prompt response to treatment with DEC.

LOIASIS

Loa loa is transmitted by flies of the genus *Chrysops* that breed in tropical forests of Africa. Larval parasites migrate in the subcutaneous tissues, where they mature into adults over the course of a year. Clinical symptoms include urticaria, pruritus, arthralgia and malaise. Transient, migratory angiedema (Calabar swelling) occurs most commonly on the extremities where trauma to a migrating adult worm provokes a localized inflammatory reaction. Subconjunctival migration causes pain and inflammation. If instruments are readily to hand, the worm can be removed from the eye after applying local anaesthetic. Other complications include proteinuria in up to 30% of patients, hematuria and, less commonly, neurological complications (particularly meningoencephalitis). Rare presentations include pulmonary infiltrates, pleural effusions, arthritis, lymphangitis and hydrocele. Hypereosinophilia is common and *Loa loa* has been implicated in the etiology of endomyocardial fibrosis, although this condition is well described in association with numerous other causes of hypereosinophilia.

Diagnosis and treatment

Diagnosis of loiasis is often indicated by the history, particularly if an 'eye worm' has made an appearance. Dead, calcified worms are sometimes seen on radiography.

Microfilaremia peaks between 10.00 h and 15.00 h. Parasites can be identified in thick blood films with Giemsa or Wright stains, or by concentration techniques. Assessing the microfilarial load is useful in determining the likelihood of an adverse reaction to treatment. Serological tests are available and may be helpful for diagnosis in travelers from endemic areas, but other filarial parasites cross-react. A specific recombinant antigen test has recently been developed that may be useful in the diagnosis of patients with low microfilaremia.⁶⁶

DEC 2 mg/kg orally every 8 h for 7–10 days is commonly used in the treatment of loiasis, although some prefer 12 days. The course is repeated at intervals of 2 or 3 months if the

patient remains symptomatic. Ivermectin 150 µg/kg as a single dose before treatment with DEC will reduce the likelihood of a Mazzotti reaction in patients who also have onchocerciasis. Caution is needed in managing patients with loiasis who have high microfilarial loads (>2500 microfilariae/mL) as treatment with DEC or ivermectin may precipitate meningoencephalitis or renal failure due to massive release of antigens from dying microfilariae.⁶⁷ Plasmapheresis has been used successfully to reduce microfilarial load in heavy infections before treatment with DEC under steroid cover; however, albendazole 200 mg every 12 h for 3 weeks causes a gradual reduction in microfilaremia, usually without serious adverse effects.⁶⁸ The currently recommended strategy for managing patients with high microfilaremia is administration of albendazole 200 mg every 12 h for 3 weeks, followed by a course of DEC or ivermectin.⁶⁹ Prednisolone, 20 mg/day, given for 3 days before and for 3 days following the start of antihelmintic treatment, may reduce the risk of encephalopathy. This may well become the preferred strategy for managing patients with high microfilaremia.

ONCHOCERCIASIS

Onchocerciasis is one of the most important causes of blindness in the tropics. The disease is endemic in tropical Africa, the Arabian peninsula and parts of Latin America. Over 37 million people are infected, of whom almost 1 million are blind or visually impaired. The parasite is transmitted by blackflies of the genus *Simulium* that breed along fast flowing rivers: hence the common name 'river blindness'. Humans are the only definitive host for *Onchocerca volvulus*. Larvae injected when an infected blackfly feeds migrate in the subcutaneous tissues and mature into adults. Adult worms, measuring up to 80 cm in length, intertwine and become encapsulated in the subcutaneous tissues, forming painless nodules measuring up to 3 cm in diameter. These may be palpable over bony prominences but otherwise cause few clinical symptoms. Microfilariae produced by the adult worms are responsible for the most serious clinical effects of onchocerciasis, principally affecting the skin and eye.

Onchodermatitis initially presents as an intensely itchy papular rash. A chronic papular dermatitis ensues with gradual loss of elasticity in the skin and subcutaneous tissues, resulting in a prematurely aged appearance. Depigmentation, sparing sweat glands and hair follicles, leads to the 'leopard skin' appearance, most commonly seen on the shins. Enlarged inguinal and femoral lymph nodes may hang in apron-like folds of inelastic skin, the so-called 'hanging groin' appearance. Rarely, elephantiasis may occur. 'Sowda', a lichenified dermatitis, presents as intensely pruritic, hyperpigmented papules and plaques, usually affecting one limb and accompanied by edema and enlargement of the regional nodes.

Ocular onchocerciasis results from microfilarial invasion of the eye. Live microfilariae may be visible in the anterior chamber or aqueous humor on slit-lamp examination. They provoke a reversible inflammatory reaction, resulting in punctate

keratitis or ‘snowflake’ corneal opacities. Microfilarial death in longstanding cases results in more severe and irreversible damage, including sclerosing keratitis, iridocyclitis, uveitis, chorioretinitis and optic atrophy. Glaucoma and cataract may also occur. Eye complications are more likely to occur in patients who have onchocercal nodules on the head or upper body.

Onchocerciasis may increase the risk of seroconversion in HIV-1 infections and treatment of onchocerciasis appears to be associated with reduced HIV-1 viral replication. Onchodermatitis also appears to be more severe in HIV-positive patients.⁷⁰

Diagnosis and treatment

The most common method for diagnosis is examination for the emergence of microfilariae from a skin snip placed in a drop of saline. Nodules may be excised and examined for adult worms. In the past, for diagnosis of patients with negative skin snips, DEC was used in a dose of 25–50 mg to provoke a Mazzotti reaction with considerable worsening of the rash and pruritus in the ensuing 24 h. Application of topical DEC under an occlusive dressing produces a similar, localized effect and is less distressing and safer for the patient. As a severe Mazzotti reaction may be precipitated by either the DEC provocative test or the DEC patch test, the use of these diagnostic approaches is seldom indicated.

Skin-snip microscopy is less sensitive than newer diagnostic methods, including skin-snip PCR, ELISAs, enzyme immunoassays and antigen detection. Recent advances include the development of a serum antibody test card using recombinant antigen to detect *O. volvulus*-specific IgG4 in finger-prick whole-blood specimens, a triple-antigen indirect ELISA rapid-format card test, and a highly sensitive and specific urine antigen dipstick test.^{71–75} Antibody detection may be useful for screening populations, whereas PCR and antigen detection in serum and urine are potentially more useful for diagnosing active infection in individuals and for monitoring the success of therapy.

Both the treatment and the community control of onchocerciasis have been greatly improved following the introduction of ivermectin. A single oral dose of 150 µg/kg clears microfilariae for several months and suppresses microfilaria production, but does not kill adult worms.⁷⁶ Mass administration of ivermectin annually in Africa, or on alternate years elsewhere, is the basis of community control of onchocerciasis, with the exclusion of pregnant women. Assuming a minimum of 65% coverage and ongoing efficacy of treatment, the time scale required for elimination of onchocerciasis in affected communities is a daunting 25–30 years.⁷⁷

Ivermectin should be used with caution in *Loa loa*-endemic areas as it may precipitate meningoencephalitis in patients with high *Loa loa* microfilarial loads. In these circumstances, it is advisable to prescribe a course of albendazole before treatment with ivermectin. In the past, nodulectomy was advised for head nodules, possibly reducing the likelihood of eye infection, but is not required for nodules elsewhere.

Treatment of individual patients has been revolutionized in recent years following research on the role of *Wolbachia* in the pathogenesis and persistence of infection. The current recommendation, unless contraindicated (age <9 years, pregnancy, breastfeeding), is doxycycline 100–200 mg/day for 4–6 weeks, the duration depending on whether interruption of embryogenesis or a macrofilaricidal effect is intended, plus a single dose of ivermectin 150 µg/kg after 4–6 months.⁶⁴

GUINEA WORM

Dracunculus medinensis is acquired by swallowing a tiny copepod, *Cyclops*, harboring the larval stage of the parasite. Following digestion of *Cyclops*, the liberated larva penetrates the intestinal mucosa, migrates to loose connective tissue and develops into an adult worm. After mating, the female worm continues to mature with an enlarging gravid uterus and migrates in search of a site suitable for discharge of her larvae. Clinical symptoms occur as the worm prepares to emerge. Patients often complain of prodromal symptoms including rashes, gastrointestinal symptoms, weakness and fever. The emergence of the worm is heralded by the development of a large, indurated erythematous papule with a vesicular center. Over the next few days this develops into a painful, pruritic blister, which the patient seeks to immerse in water for relief. The larvae are thus discharged and, in suitable conditions, complete the cycle by infecting another *Cyclops*. The site of the blister tends to ulcerate and secondary bacterial infection may occur, including tetanus.

Migrating adult worms may penetrate and perish in other tissues, including the spinal cord, peritoneal cavity, pancreas, pericardium and lung, causing symptoms due to focal inflammation.

Management of guinea worm infection has changed little since ancient times. Emerging worms are encouraged to discharge their uterine contents by immersion of the affected part in water. At this stage, the tip of the worm begins to emerge and can be gently and gradually wound onto a matchstick, a few centimeters each day, until the entire worm has been removed. The process can take several days as female worms may exceed 1 m in length. Administration of oral metronidazole or mebendazole may facilitate extraction. Surgical intervention is often required in the management of disease caused by ectopic worms. A highly successful program for the global eradication of guinea worm, based on the provision of safe drinking water or the use of fine filters to trap *Cyclops*, has resulted in a dramatic fall in the incidence of infection in recent years.

CONCLUSION

Helmint infections affect approximately one billion of the world’s poorest people, mainly in tropical developing countries. These diseases are now receiving unprecedented

attention as evidence accumulates that highly cost-effective community interventions can control and, possibly, eliminate many of these infections, and stimulate long-term economic growth and development.¹

The integration of onchocerciasis, filariasis, schistosomiasis and soil transmitted helminth control programs offers a cost-effective strategy for controlling these infections.^{78,79} Regular anthelmintic treatment of schoolchildren in developing countries is being promoted by the World Health Organization as a means of improving anemia, nutritional status and cognitive development in anticipation of long-term benefits to health and economic development.^{80–82} The control of onchocerciasis has progressed rapidly in the past 30 years, largely due to successful international public-private partnerships fostered through the Onchocerciasis Control Programme (1974–2002), the African Programme for Onchocerciasis Control (1995–present) and the Onchocerciasis Elimination Program for the Americas (1991–present).^{1,77,83} Similarly, the Global Alliance for the Elimination of Lymphatic Filariasis, created in 2000, is an international public-private partnership that aims to eliminate lymphatic filariasis as a public health problem.⁵⁹ The Global Network for Neglected Tropical Diseases, established in 2006, is a major international initiative promoting an integrated NTD control strategy. The Network is comprised of international non-profit organizations, the World Health Organization, pharmaceutical companies and ministries of health in disease-endemic countries. The Network is promoting the introduction of a ‘rapid impact package’ to treat seven of the most common NTDs (ascariasis, trichuriasis, hookworm, schistosomiasis, lymphatic filariasis, onchocerciasis and trachoma) using a combination of four drugs (albendazole–mebendazole, DEC–ivermectin, praziquantel, azithromycin) for just 50 cents per person per year, including drugs, delivery, equipment, training, health promotion, monitoring and evaluation.⁸⁴ Mass treatment for helminthic infections is proving to be a highly effective public health intervention, with wider benefits in strengthening health systems and affording opportunities for synergy with other initiatives, such as malaria and tuberculosis control. However, as mass treatment carries with it the risk of emergence of drug resistance, careful monitoring is essential, as is a greater investment in the development of anthelmintic drugs.

In order to achieve the goal of community control and, ultimately, the elimination of helminthic infections, investment is required for research and development of new diagnostic agents, drugs, insecticides and vaccines.¹ However, between 1975 and 2004, of the 1556 new pharmaceuticals that were marketed, only four were anthelmintics.⁸⁵ Many of the most useful anthelmintic agents available to us today were originally developed for veterinary use. Although some of these drugs have been generously donated for use in developing countries, economic imperatives dictate that there is greater profit in developing anthelmintic drugs for the treatment of animals than there is in addressing the needs of impoverished human beings. ‘The poor must be grateful for a mouthful of crumbs, fallen from the table where the rich feed their dogs.’

 clinical uses
 bacterial meningitis 638
 neutropenia 508
 interactions 76t
 resistance 39, 40f
Carbenicillin 201t, 223–224
Carboxypenicillins 220
 antimicrobial activity 220, 220t
 clinical uses 220–221
 pharmacokinetics 220
 resistance 220
Carbuncles 622, 623t
Cardiobacterium hominis see HACEK bacteria
Cardiovascular surgery
 heart transplantation 530
 implanted devices 490–491
 prophylaxis 490
 vasculature 491
Carrión's disease 802
Carumonam 238
 preparations and dosage 238b
Caspofungin 8, 375–376
 antimicrobial activity 376
 clinical uses 376
 aspergillosis 780–781, 781t
 candidal infections 511
 endocarditis 592
 fungal infections 511
 peritoneal dialysis catheter-related infection 550
 interactions 72t, 80t, 376
 mode of action 19
 pharmacokinetics 376, 376t
 distribution 376
 metabolism and excretion 376
 pregnancy/breastfeeding 705
 preparations and dosage 376b
 renal failure 62t
 resistance 376
 toxicity/side effects 376
Cat bite 623t
Cat-scratch disease 623t, 628
 complicated 803
 uncomplicated 803
Cataract surgery 682–683
Catheters
 antimicrobial 546
 peritoneal dialysis, infection of 549–550
 urinary tract, infection of 548–549
 see also Cannula-associated infections

Cathomycin see Novobiocin
Cecropins 360
Cefacetrile (cephacetrile) 171t, 175
Cefaclor 171t, 176–177
 antimicrobial activity 176, 177t
 clinical uses 177
 impetigo 622t
 hemodialysis 63t
 pharmacokinetics 177, 177t
 absorption 177
 distribution 177
 metabolism and excretion 177
 preparations and dosage 177b
 toxicity/side effects 177
Cefadroxil (*p*-hydroxycefalexin) 171t, 178
 antimicrobial activity 177t
 clinical uses, impetigo 622t
 hemodialysis 63t
Cefalexin (cephalexin) 171t, 178–179
 antimicrobial activity 177t, 178
 clinical uses 179
 impetigo 622t
 hemodialysis 63t
 mode of action 13
 pharmacokinetics 178–179, 178t
 absorption and distribution 178
 metabolism and excretion 179
 preparations and dosage 179b
 toxicity/side effects 179
Cefaloridine 7
Cefaloridine (cephaloridine) 171t, 175
Cefalothin see Cefalotin
Cefalotin (cefalothin, cephalothin) 171t, 173–174
 antimicrobial activity 173, 173t
 clinical uses 173–174, 173t
 distribution 173–174
 pharmacokinetics, metabolism and excretion 174
 preparations and dosage 174b
 toxicity/side effects 174
Cefamandole (cephamandole) 171t, 175–176
 antimicrobial activity 173t
 clinical uses, impetigo 622t
 hemodialysis 63t
Cefapirin (cephapirin) 171t, 176
 hemodialysis 63t
Cefatrizine 171t, 180
 antimicrobial activity 177t
Cefazolin (cephazolin) 171t, 174–175
 antimicrobial activity 173t, 174
 clinical uses 175
 cellulitis 623t
 gas gangrene 623t
 hepatectomy 493
 impetigo 622t
 hemodialysis 63t
 pharmacokinetics 174–175, 174t
 distribution 174
 metabolism and excretion 174–175
